WALTER KJELLMAN,[26] ESQ.—The consolidation of a fine-grained soil subjected to a load can be accelerated by vertical drains inserted in the soil. In the United States such drains consist of circular sand-filled wells, having normally about a 20-in. diameter and a spacing of from 10 ft to 15 ft. In Sweden, band shaped cardboard wicks of ⅛-in. by 4-in. cross section (Fig. 11) are used. These are furnished with inner longitudinal channels and spaced about 4 ft apart. It may perhaps interest readers to learn how the problems, so clearly dealt with in this paper, are looked upon in Sweden.

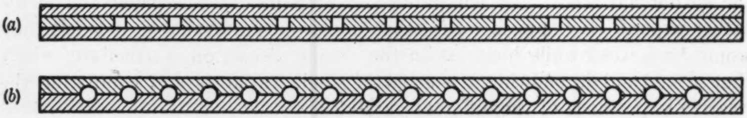

FIG. 11.—CROSS SECTION OF BAND SHAPED CARDBOARD DRAIN
(a) Present Type
(b) Prospective Type

Swedish investigations concerning "deep drainage" of soils were started in 1936. Owing to arching of ground and overburden in all practical cases, the momentary strains were deemed to be nearly equal everywhere in the ground. Therefore, all Swedish calculations refer to this very simple case of equal strain. In the United States, on the contrary, all calculations of this kind prior to Mr. Barron's paper seem to refer to the very complicated case of free strain. Fig. 8 shows that both cases give nearly the same result. Consequently, there is no reason for anyone to become further involved with free strain.

When determining the spacing of the drains in the United States, great reliance is placed on the horizontal draining effectuated by coarse-grained layers.

---

[25] "Sand Wells Speed Marsh Crossing," by Philip Keene, *Better Roads*, September, 1947.

[26] Head, Statens Geotekniska Institut (The Royal Swedish Geotechnical Institute), Narvavägen 25 Stockholm, Sweden.

In Sweden such layers exist in the lower part of the glacial clay deposits, but they are of little use since the spacing must be determined with regard to the upper part of the deposits (the upper part of the glacial clay and, on top of it, the postglacial clay), which as a rule contains no coarse-grained layers. Furthermore, the fine-grained soils in Sweden seem on the whole to be considerably less pervious than those in America. For these reasons, and because the equivalent radius of the wicks used in Sweden is much smaller than the radius of the American wells, the spacing is considerably smaller in Sweden.

By laboratory tests it has been found that the permeability of a clay without coarse-grained layers is not appreciably reduced by remolding. The unfavorable effect of peripheral smear, discussed by the author, must therefore refer to coarse-grained layers only. No reliance is placed on such layers in Sweden, so that peripheral smear need not be considered.

In Sweden the spacing of the drains is rather small. Thus, the vertical water flow is unimportant when compared to the radial flow and is disregarded. This approximation, which simplifies the calculation and leads to safe results, is justified by the uncertainty of the calculation.

In principle the triangular drain pattern is the most economical one, as stated by Mr. Barron. However, certain considerations have shown that in this respect the difference between the triangular and square patterns is quite unimportant. Therefore, in order to attain certain small advantages when driving the wicks, no fixed pattern is used, other than to make the spacing of the wicks in each row equal to the distance between rows.

The longitudinal channels in the cardboard wick easily can be made numerous enough and wide enough to let through (without appreciable resistance) any water flow that the one drain may be called on to carry. Furthermore, the permeability of the cardboard is very great when compared to that of the fine-grained soils in question. Therefore, there is no need to complicate the calculations by taking into account the flow resistance in the drain. Because the cardboard serves as a perfect filter, there is, of course, no risk of the channels becoming clogged as may occur in sand-filled wells. Laboratory tests have shown that the channels do not collapse even under a very high clay pressure on the wick. This is probably due to arching in the clay, causing the pressure to be much lower on the covers of the channels than between them.

The question has been raised as to whether a well (like a pile) attracts a great part of the load, and whether it can be damaged when the soil settles. A cardboard wick cannot, of course, affect the load distribution. Tests have shown that it may crease, if the vertical compression is great, but that it is not damaged.

In Swedish practice (as follows from the foregoing statements), the time-settlement curve of a deep-drained soil is calculated in the simplest possible manner—assuming equal strain, no coarse-grained layers, radial flow only, no peripheral smear, and no drain resistance. The calculation, made in 1937 but never published, is contained in principle in Mr. Barron's paper. As a result of the calculation the following procedure is used for determining the spacing of the drains (square pattern):

(*a*) Having assumed a time, t_h, in months, in which a certain percentage of the final settlement is to occur, Fig. 12 is used to find the value of g, which is a quantity of calculation with no physical meaning.

(*b*) Knowing the value of g, and also the coefficient of consolidation of the soil, c_h (in square centimeters per second), the value of m, which is a quantity of calculation with no physical meaning, is computed from

$$m = g\,c_h \qquad (92)$$

(*c*) Knowing the value of m, Fig. 13 is used to find a convenient combination of drain radius r_w and spacing S.

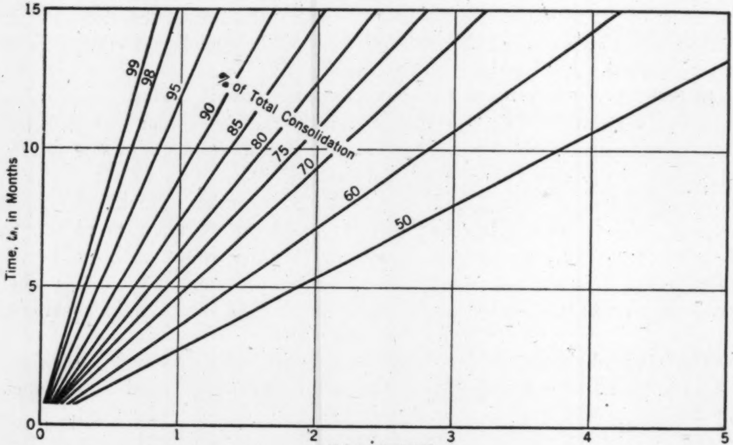

FIG. 12.—DIAGRAM FOR FINDING VALUES OF g

This procedure may be used in cases not too divergent from Swedish conditions.

Obviously, the draining effect of a drain depends to a great extent upon the circumference of its cross section, but very little upon its cross-sectional area. Therefore, the circular cross section has been abandoned in Sweden in favor of the band shaped drain. Certain considerations show that the cardboard wick is as effective as a circular drain with a 1-in. radius. (The circumference of the latter is slightly greater than that of the former.) Thus, the curve in Fig. 13 for a 1-in. radius can be used for the wicks. The curve for a 10-in. radius is valid for the sand wells with a 10-in. radius frequently used in the United States. Comparing these two curves, it appears that wells with 10-ft spacing are equivalent to wicks spaced 6.2 ft apart. Thus, in this case, one well is equivalent to 2.5 wicks.

The wick has several advantages over the well. First, very little material is consumed in its manufacture, and, second, as both its weight and its volume per unit of length are small and as it can be rolled on a drum, it is easy to handle. This means that production can be concentrated in a factory, whence the wicks can be transported inexpensively to the different sites and driven into the ground by a machine working at high speed in about the same manner as a sewing machine.

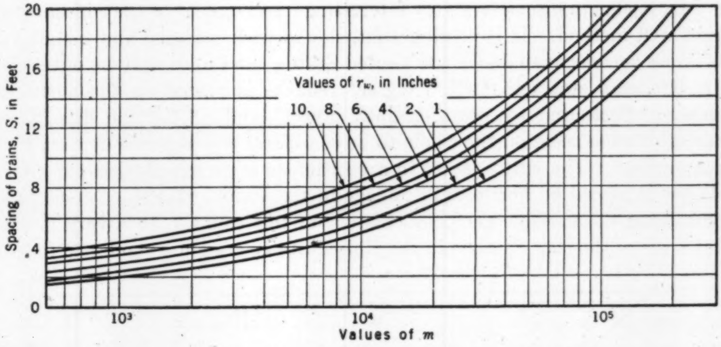

FIG. 13.—DIAGRAM FOR FINDING THE SPACING OF DRAINS

At the Halmsjön Airport outside Stockholm (Sweden) some 3,000,000 ft of cardboard wicks are to be driven in 1947–1949. The cost is between 10¢ per ft and 15¢ per ft. Further information about the wick method will appear in the *Proceedings* of the Second International Conference on Soil Mechanics to be held in Rotterdam, Holland, in 1948.

REGINALD A. BARRON,[27] ASSOC. M. ASCE.—The benefits of drain wells have been brought out by Mr. Lane's discussion. Although, probably, they are not quantitatively correct, Eqs. 89, 90, and 91 are of great use qualitatively. The writer believes that Mr. Lane is correct in his statement that column action by the well backfill would redistribute the soil stresses and would result in a slower rate of consolidation. However, Fig. 8 indicates that the difference in consolidation rates is very minor and of no practical importance. In fact, such column action may be much less than the possible compressive effect of the horizontal seepage gradient. This possibility was not considered by the writer but its effect would be to compress the soil radially in a horizontal plane adjacent to the well where the seepage gradients are high. Because of this radial compression, the soil farther out will probably cause vertical settlement as it deforms radially in extension.

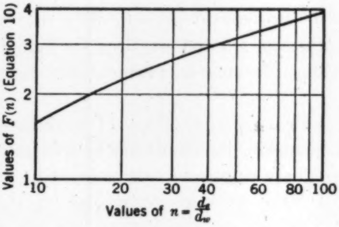

FIG. 14.—CURVE FOR THE DETERMINATION OF $F(n)$

Mr. Keene has discussed the use of consolidation drain wells on a highway project. The use of drain wells to accelerate the consolidation of foundations for highway fills is valuable, especially considering the effect of foundation consolidation on the finished quality of the pavement. On the other hand, such measures are not always necessary for earth dams, and it may be more economical to obtain stability by using flatter embankment slopes.

---

[27] Head, Special Studies Section, Embankment and Foundation Branch, Soils Div., U. S. Waterways Experiment Station, Vicksburg, Miss.

Mr. Kjellman discusses a very interesting development of the consolidation drain well method. It is possible that, should wick material and installation machines become available in the United States, sand wells may be outmoded. Mr. Kjellman states that "* * * great reliance is placed on the horizontal draining effectuated by coarse-grained layers" and "* * * the fine-grained soils in Sweden seem on the whole to be considerably less pervious than those in America." The writer is not in a position to state exactly what degree of reliance is placed on horizontal drainage in the United States. Furthermore, considering the variable geological history of this country, it is very possible that some of the clay deposits in the United States are quite similar to those of Sweden. The writer considered the effect of horizontal permeability in the theoretical developments because such conditions existed at sites for which the studies were made. For other cases this difference in permeability may not be so marked.

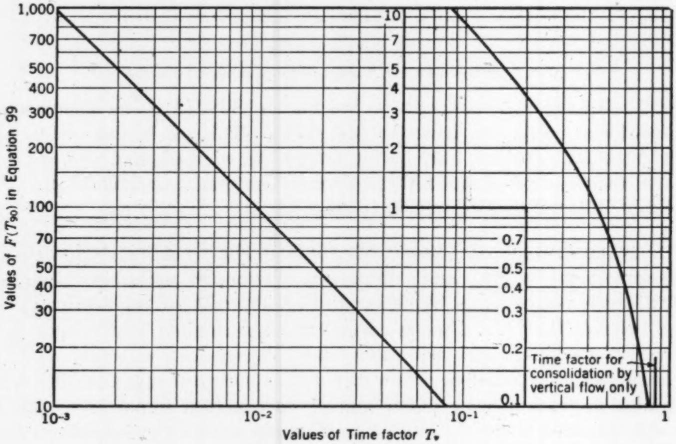

FIG. 15.—CURVE FOR THE DETERMINATION OF TIME FACTOR OF 90% CONSOLIDATION DUE TO COMBINED RADIAL AND VERTICAL FLOW

Mr. Lane requests additional curves indicating the effect of variables. Fig. 14 shows the variation of $F(n)$ as defined in Eq. 10 versus n which is used in the following development for instantaneously applied loads using Eq. 21 in which $\bar{u}_r$ is obtained from Eq. 8. For 90% average consolidation the average hydrostatic excess pressure is 10%. Thus:

$$\bar{u}_{r,z} = \bar{u}_z \, \epsilon^{\lambda} = 0.1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

Expressions for the time factors are

$$T_h = \frac{k_h \, (1 + e) \, t}{\gamma_o \, a_v \, d^2_e} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (94)$$

and

$$T_v = \frac{k_v\,(1 + e)\,t}{\gamma_o\,a_v\,H^2} \qquad (95)$$

and, therefore,

$$T_h = T_v\,\frac{H^2}{d^2_e}\,\frac{k_h}{k_v} \qquad (96)$$

and

$$\lambda = \frac{-\,8\,T_h}{F(n)} = \frac{-\,8\,T_v\,H^2\,k_n}{k_v\,d^2_e\,F(n)} \qquad (97)$$

Consequently,

$$2.3026\,(1 + \log_{10}\bar{u}_z) = \frac{8\,T_v\,H^2\,k_n}{k_v\,d^2_e\,F(n)} \qquad (98)$$

or

$$\frac{(1 + \log_{10}\bar{u}_z)}{T_v} = \frac{8\,k_h\,H^2}{2.3026\,k_v\,d^2_e\,F(n)} = F(T_{90}) \qquad (99)$$

A curve of $F(T_{90})$ versus T_v is given in Fig. 15.

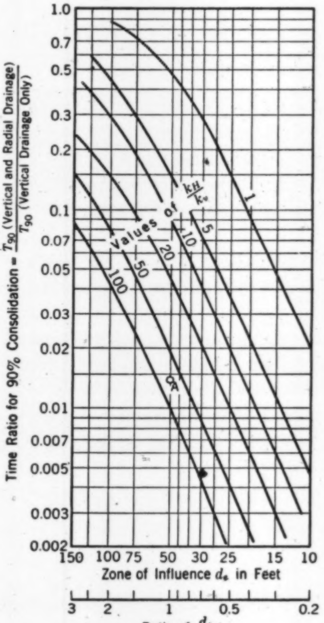

FIG. 16.—EFFECT OF WELL SPACING AND PERMEABILITY RATIO ON TIME REQUIRED FOR 90% CONSOLIDATION

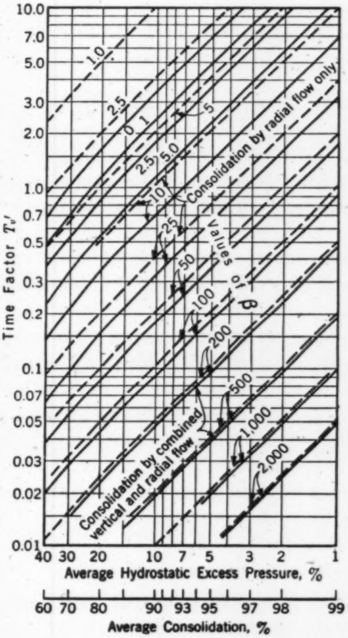

FIG. 17.—AVERAGE PERCENTAGE OF HYDROSTATIC EXCESS PRESSURE AND CONSOLIDATION AT END OF UNIFORM RATE OF LOADING PERIOD

Using the curve in Fig. 15, the curves in Fig. 16 for various permeability ratios were determined for the conditions $d_w = 1$ ft and $H = 50$ ft, with no smear or well resistance. The influence of permeability ratio k_h/k_v and well spacing is evident.

Point A in Fig. 16 was determined for the case of no smear but with well resistance for the condition that $k_w/k_v = 2{,}000{,}000$ and $k_h/k_v = 100$. Well resistance thus requires about 40% more time to reach 90% consolidation; for small ratios of k_h/k_v the effect would be less.

The curves in Fig. 17 for several values of

$$\beta = \frac{8\, k_h\, H^2}{k_v\, d_e^2\, F(n)} \qquad (100)$$

indicate the effects of k_h, k_v, H, d_e, and n on the average percentage of consolidation and average hydrostatic excess pore water pressure at the end of uniform rate of load application.

INFLUENCE LINES FOR CONTINUOUS STRUCTURES BY GEOMETRICAL COMPUTATION

BY DEAN F. PETERSON, JR.,[1] ASSOC. M. ASCE

WITH DISCUSSION BY MESSRS. RALPH E. SPAULDING, RALPH W. STEWART, YI-MAI YAO, OTTO GOTTSCHALK, AND DEAN F. PETERSON, JR.

SYNOPSIS

As the practical span length of continuous girder bridges and rigid frame bridges becomes progressively greater, the use of influence lines or coefficients, for the purpose of investigating the effect of more numerous possible combinations of loading, and for placing loads for maximum effect, becomes correspondingly important. Although such influence lines may be constructed in the usual manner by loading the structure at a number of different points and computing the resulting stress or moment, this is an arduous task and amounts to finding the desired load points by trial and error. The equality of the elastic curve of a structure loaded with a unit deformation at the point for which the stresses are desired, and the influence line for stress at that point, has long been used for determining the influence line for trussed structures. The principle was applied mechanically to all types of indeterminate structures by the late George Beggs,[2] M. ASCE, Otto Gottschalk,[3] and others. This relationship may easily be extended to the analytical computation of influence lines for continuous structures subjected principally to flexure, accomplishing analytically what the use of models accomplishes mechanically. Examples of influence lines for several types of continuous structures have been computed by this procedure using various types of statical analysis. Formulas have also been developed for locating the position and value of the maximum influence ordinate and for the area under the influence line for members of constant cross section.

NOTE.—Published in September, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

BASIC RELATIONSHIP

The basic relationship involved in the development of this paper—the Müller-Breslau relation— is well known. Its validity follows from a consideration of Maxwell's principle of reciprocal deflections, and the principle of superposition which is valid as long as the structures are built of materials that act elastically.

FUNDAMENTAL EQUATIONS OF FLEXURAL GEOMETRY

This paper is concerned with flexural equations both as a means of (1) producing a statical solution and (2) computing elastic curve ordinates. The fundamental differential equation of flexural geometry, $\frac{d^2y}{dx^2} = \frac{M}{E\,I}$ (neglecting the distortions due to shear and direct stresses), is a special case of the general equations of elasticity and has the following first and second integrals:

$$\left.\frac{dy}{dx}\right|_x = \int_0^x \frac{M_\xi}{E_\xi\, I_\xi}\, d\xi + C_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

and

$$y\,\Big|_x = \int_0^x \frac{M_\xi}{E_\xi\, I_\xi}\,(x - \xi)\, d\xi + C_1\, x + C_2 \ldots\ldots\ldots\ldots (1b)$$

in which, in addition to the variable coordinates x and y, M_ξ is the bending moment at ξ; E_ξ is the modulus of elasticity at ξ; I_ξ is the moment of inertia at ξ; C_1 is a constant of integration; and C_2 is a constant of integration. Eqs. 1 may sometimes be solved by integral calculus, but are usually solved by finite integration. However, in the field of indeterminate structures, the imposition of more than the required boundary conditions makes necessary the solution of a set of simultaneous equations, or its mathematical equivalent. The many short cuts which the modern structural engineer uses in his analysis are simply means of setting up and solving Eqs. 1.

PROCEDURE FOR SOLUTION

Influence lines for moments, shears, thrusts, and reactions are obtained by determining the elastic curve of the structure when it is loaded with the corresponding unit axial rotation, transverse axial displacement, longitudinal axial displacement, or deflection in the direction of reaction. It is necessary first to make a statical analysis of the structure bearing only the required displacement loading using any method—moment distribution, slope deflection, elastic curve traverse, etc.—that the designer desires. In general, since all the members are unloaded (in the sense that they do not bear any gravity, wind, hydrostatic, or other usual load), the analysis is simpler than when conventional loads are involved.

After statical solution of the structure has been completed, the end rotations and deflections for each of the members are computed. Using some methods of analysis, such as slope deflection or elastic curve traverse, these will be known directly from the process of solution. Other methods of solution will require the use of the flexural-geometry equations, or some derivative of them (such as the moment-area principle), to arrive at the required rotations and deflections. The elastic curve can be computed by solving Eq. 2, or by various modifications of Eq. 2.

INDIRECT METHOD

The statical solution for the structure loaded with the unit deflection or rotation may also be made using the method, developed in connection with moment distribution,[4] of (*a*) considering separately an unbalanced moment at each joint, (*b*) solving for the required moments in each case, and then (*c*) combining the result of the several fixed-end moments due to the loading in proportion to the original distributions. Instead of choosing fixed-end moments resulting from conventional loads, fixed-end moments compatible with the imposed displacement are proportioned and combined. This method is illustrated, subsequently, by Example 9 using moment distribution and may also be applied using the elastic curve traverse method.[5]

CALCULATING ELASTIC CURVES OF MEMBERS

Throughout the mathematical analysis the following sign convention will be adopted: Ordinate and abscissa as usual. Counterclockwise rotation in the direction of $+x$ will be plus and will produce a positive deflection from the tangent in the direction of $+x$. Moment causing concave bending upward will be considered positive. Positive moment will always give positive rotations and positive deflections in the direction of positive x-values. For a member whose axis can be considered straight, if y_A is the deflection from the original axis of point A and θ_A is the slope of the tangent to the elastic curve at point A, then, for any point, x_n:

$$y_n = y_A + \theta_A\, x_n + \sum_{\xi=1}^{\xi=n} (x_n - x_\xi)\, \frac{M_\xi}{E_\xi\, I_\xi} \Delta\xi \ldots\ldots\ldots\ldots (2)$$

Generally, however, it is simpler to compute the slope and deflection point by point; thus:

$$y_n = y_{n-1} + \theta_{n-1} \frac{\Delta x_{n-1} + \Delta x_n}{2} \ldots\ldots\ldots\ldots (3a)$$

in which

$$\theta_n = \theta_{n-1} + \frac{M_n}{E\, I_n} (\Delta x_n) \ldots\ldots\ldots\ldots (3b)$$

Analytical Solution.—Referring to the haunched beam in Fig. 1, suppose that:

$$\theta_A = -\frac{1{,}000}{E\, I_d}\,; \quad \theta_B = \frac{300}{E\, I_d} \ldots\ldots\ldots\ldots (4)$$

$$y_A = \frac{20{,}000}{E\, I_d}\,; \quad y_B = 0 \ldots\ldots\ldots\ldots (5)$$

[5] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, ASCE, Vol. 104, 1939, p. 521.

in which I_d equals the moment of inertia, in feet^4, at the center section of depth d; and E is the modulus of elasticity in kips per square foot.

The end moments may be obtained by any desired method. For purposes of generalization the basic formulas (Eqs. 1) will be applied; thus, after simplifying and substituting finite summation for the integrals:

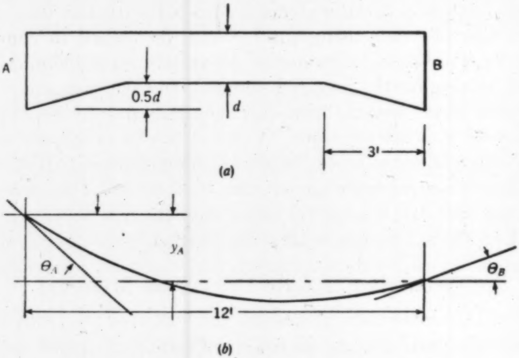

FIG. 1.—EXAMPLE OF A HAUNCHED BEAM

$$1{,}300 = M_A \sum_1^n K_n \left(1 - \frac{x_n}{12}\right) \Delta x_n + M_B \sum_1^n K_n \frac{x_n}{12} \Delta x_n \ldots\ldots (6a)$$

and

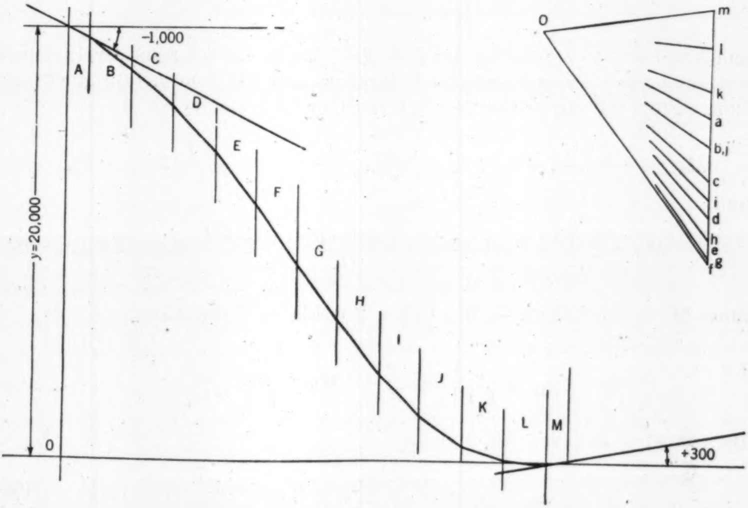

FIG. 2.—CONSTRUCTION OF DEFLECTION CURVE FOR THE BEAM IN FIG. 1

the equations thus solved yield: $M_A = -1{,}061$ ft-kips; and $M_B = 1{,}341$ ft-kips. Using Eqs. 3 the elastic curve is calculated by means of Table 2.

Graphical Solution.—Instead of using Table 2, Eq. 3*a* may be solved graphically by the use of the funicular polygon in Fig. 2. The chords passing through the end points of the beam must have a slope equal to the known slope of the end tangents.

Prismatic Members.—Although beams of constant section may be handled by either the analytical or graphical method of finite integration, it is possible to pass to the integral in the summation of Eq. 2 and derive general equations for the elastic curves when the end rotations and deflections are known. Consider a length AB of a straight, unloaded member (Fig. 3). Let the rotation at end A be equal to θ_A; and, at end B, to θ_B. Let y_A and y_B, respectively, represent the perpendicular displacement of points A and B from their original position. From the slope-deflection equations, or by geometry:

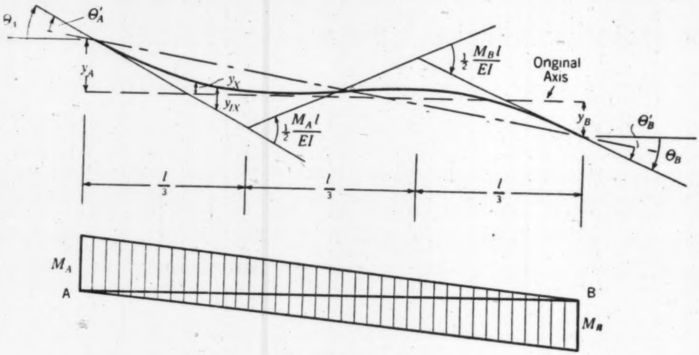

FIG. 3.—EXAMPLE OF A PRISMATIC MEMBER

$$M_A = -\frac{2\,E\,I}{l}\left(2\,\theta_A + \theta_B - 3\,\frac{y_B - y_A}{l}\right) = \frac{-2\,E\,I}{l}\,(2\,\theta'_A + \theta'_B)\,..\,(8a)$$

and

$$M_B = \frac{2\,E\,I}{l}\left(\theta_A + 2\,\theta_B - 3\,\frac{y_B - y_A}{l}\right) = \frac{2\,E\,I}{l}\,(\theta'_A + 2\,\theta'_B)\,....\,(8b)$$

Since $M_\xi = M_A + (M_B - M_A)\,\frac{\xi}{l}$, Eq. 2 yields, by integration,

$$y_{1x} = \frac{1}{E\,I}\left[\,M_A\,\frac{x^2}{2} + (M_B - M_A)\,\frac{x^3}{6\,l}\right]\,..............\,(9a)$$

By geometry, however, Eq. 2 yields,

$$y_x = y_A + \frac{y_B - y_A}{l}\,x + \theta'_A\,x + y_{1x}\,..............\,(9b)$$

Substituting Eq. 9*a* in Eq. 9*b* as well as the values of M_A and M_B from Eqs. 8, simplifying and collecting terms:[6]

$$y_x = y_A + (y_B - y_A)(k_1)(1 - k^2_1 + k_1\,k_2) + l\,(\theta_A\,k_1\,k^2_2 - \theta_B\,k^2_1\,k_2)\,..\,(10)$$

---

[6] *Transactions*, ASCE, Vol. 104, 1939, p. 555, Eq. 23.

in which $k_1 = \frac{x}{l}$, and $k_2 = 1 - \frac{x}{l}$.

Location of Maximum Load Point

When concentrated loads are being considered, it is important to know where the load should be placed to produce the maximum effect on the section being investigated. Eq. 10 may be rewritten since $k_2 = 1 - k_1$; thus:

$$\begin{aligned} y_x = y_A &+ [l\,\theta_A + l\,\theta_B - 2\,(y_B - y_A)]\,k_1^3 \\ &+ [3\,(y_B - y_A) - 2\,l\,\theta_A - l\,\theta_B]\,k_1^2 + l\,\theta_A\,k_1 \ldots\ldots\ldots\ldots (11) \end{aligned}$$

Differentiating with respect to k_1 and equating the result to zero a quadratic equation results, which may be solved to yield:

$$\begin{aligned} k_{1m} = &\frac{1}{3\,[l\,(\theta_A + \theta_B) - 2\,(y_B - y_A)]}\,[l\,(2\,\theta_A + \theta_B) - 3(y_A - y_B) \\ &\pm \sqrt{9\,(y_B - y_A)^2 - 6\,l\,(y_B - y_A)(\theta_A + \theta_B) + (\theta_A^2 + \theta_A\,\theta_B + \theta_B^2)\,l^2}\,] \ldots (12a) \end{aligned}$$

If $y_B - y_A = 0$, then:

$$k_{1m} = \frac{1}{3\,(\theta_A + \theta_B)}\,[(2\,\theta_A + \theta_B) \pm \sqrt{\theta_A^2 + \theta_B^2 + \theta_A\,\theta_B}\,] \ldots\ldots (12b)$$

Value of Maximum Influence Ordinate

It is possible to derive an expression for the value of the maximum influence ordinate for a member of constant section when $y_B - y_A = 0$. Substituting the value of k_{1m} from Eq. 12b for k_1 in Eq. 11 and solving:

$$\begin{aligned} y_m = &\frac{l}{27\,(\theta_A + \theta_B)^2}\,[(\theta_A^2 + 4\,\theta_A\,\theta_B + \theta_B^2) \mp (\theta_A - \theta_B)\,\sqrt{\theta_A^2 + \theta_B^2 + \theta_A\,\theta_B}\,] \\ &\times [(\theta_A - \theta_B) \mp \sqrt{\theta_A^2 + \theta_B^2 + \theta_A\,\theta_B}\,] \ldots\ldots\ldots\ldots (13) \end{aligned}$$

Area Under the Influence Line

An equation for the area under the influence line for a prismatic member may be obtained by integrating Eq. 11 between the limits $k_1 = 0$ and $k_1 = 1$. This operation yields:

$$Q = \frac{l}{2}\,(y_A + y_B) + \frac{1}{12}\,l^2\,(\theta_A - \theta_B) \ldots\ldots\ldots\ldots (14)$$

in which Q is the area under the influence line. Eq. 14 is of value when the entire span carries a uniformly distributed load. It cannot be used directly when the deflection curve is discontinuous or contains a slope discontinuity within the span. For members with varying cross section the area under the influence line may be determined by a summation of the influence line ordinates (see Col. 9, Table 2).

Examples

A fairly large number of examples have been included. This was done in order to furnish an illustration for each of several different methods of statical analysis of the structure bearing the deformation load. Although fairly simple structures have been used in the examples, the principles can be extended easily to more complex structures.

Example 1. Draw the Influence Line for Moment at a Given Section of a Fixed-Ended Beam with Constant Cross Section.—The deflection y_B of point B in Fig. 4(a) can be determined by Mr. Stewart's traverse method,[7] imposing a rotation, θ, at that section. Designating the traverse angle associated with M_B as 4, the corresponding angle in length BC must be 5 since it also is associated with M_B. By equating the deflection at point B:

$$\Delta_1 = \frac{5}{4}\Delta_2 + \frac{9}{8} \quad \ldots\ldots (15)$$

in which Δ (see Fig. 4(b)) is the relative curvature in the given length resulting from an end moment. From the moment diagram,

$$M_B = M_A + \frac{4}{9}(M_C - M_A) \quad . (16)$$

but, in relative terms, $M_A = (1)\,\Delta_1 = \Delta_1$; $M_B = (1)\,4 = 4$; and $M_C = 0.8\,\Delta_2$. Substituting these values in Eq. 16 and solving simultaneously with Eq. 15, $\Delta_1 = \frac{36}{7}$; and $\Delta_2 = \frac{45}{14}$. Solving for θ, by summation of rotations from point A to point C, $\theta = -\frac{243}{4}$. For $\theta = 1$ the traverse angles must then be, in order, $\frac{72}{243}$, $\frac{56}{243}$, $\frac{70}{243}$, and $\frac{45}{243}$, respectively. From geometry, $y_B = \left(\frac{72}{243}\right) \times \left(\frac{8}{27}\,l\right) + \left(\frac{56}{243}\right)\left(\frac{4}{27}\,l\right) = 0.122\,l$. Other ordinates for the influence line (Fig. 4(c)) may be computed as desired using Eq. 10.

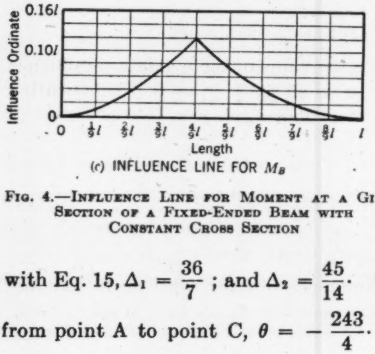
(b) TRAVERSE



(c) INFLUENCE LINE FOR M_B

FIG. 4.—INFLUENCE LINE FOR MOMENT AT A GIVEN SECTION OF A FIXED-ENDED BEAM WITH CONSTANT CROSS SECTION

Example 2. Draw the Influence Line for the Fixed-End Moment at the Haunched End of a Fixed Beam.—Imposing the unit rotation at end A of the beam in Table 3 solve for the statical condition of the beam using column analogy.[8] With the results listed in Table 3, assuming a unit angle load at end A, the end moments are, respectively: $M_A = \frac{1}{26.15} + \frac{11.21 \times 11.21}{697.7} = +\,0.2189$; and $M_B = \frac{1}{26.15} - \frac{11.21 \times 8.79}{697.7} = -\,0.1031$. The final computations of influence ordinates are arranged in a manner similar to Table 2.

[a] L = length AB; d = depth of the uniform section; x = distance from center of beam to centroid of each segment; $a = 12\,L/d^3$; and $i_x = 1/12\;a\,L^2$.

Example 3. Shear at the Support of a Fixed-Ended Beam.—Assume a beam of uniform cross section, fixed as shown in Fig. 5, with a unit deflection imposed at end A. In this instance the boundary conditions for the differential equations of flexure are: $y_A = 1$; $y_B = 0$; $\theta_A = 0$; and $\theta_B = 0$; and the general solution is to be found in Eq. 10 which reduces to

$$y_x = 1 - k_1 \, (1 - k^2_2 + k_1\,k_2) \quad (17)$$

and which is used to compute the influence line (see Fig. 5(*b*)).

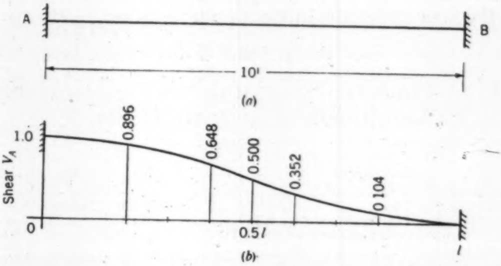

FIG. 5.—INFLUENCE LINE FOR SHEAR AT END A

Example 4. Find the Maximum Value of M_C on the Frame of Uniform Cross Section in Fig. 6 Due to a Moving Load of 10 Kips. (*Also Find the Moment at Joint* C *Due to a Uniform Load of 1.5 Kips per Ft*).—From the slope-deflection equations,

$$\theta_{DC} = 0 = \frac{10\,M_{DC}}{3\,E\,I} + \frac{10\,M_{CD}}{6\,E\,I} + \frac{y}{10} \quad \text{(18a)}$$

$$\theta_{CD} = -\,\frac{10\,M_{DC}}{6\,E\,I} - \frac{10\,M_{CD}}{3\,E\,I} + \frac{y}{10} \quad \text{(18b)}$$

$$\theta_{CB} = \frac{10\,M_{BC}}{6\,E\,I} + \frac{10\,M_{CB}}{3\,E\,I} \qquad (18c)$$

$$\theta_{BC} = -\frac{10\,M_{BC}}{3\,E\,I} - \frac{10\,M_{CB}}{6\,E\,I} \qquad (18d)$$

$$\theta_{BA} = \frac{6\,M_{BA}}{3\,E\,I} + \frac{y}{6} \qquad (18e)$$

$$\theta_{AB} = -\frac{6\,M_{BA}}{6\,E\,I} + \frac{y}{6} \qquad (18f)$$

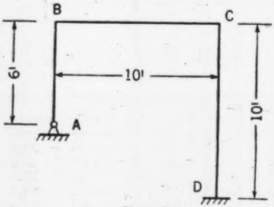

Fig. 6

in which y equals the horizontal displacement of points B and C due to side lurch. From geometry, remembering that a unit rotation is imposed at joint C:

$$\theta_{CD} - \theta_{CB} = 1; \quad \theta_{BC} - \theta_{BA} = 0 \qquad (19)$$

From statics,

$$M_{CD} = M_{CB}; \quad M_{BC} = M_{BA} \qquad (20)$$

and if H and V are the horizontal and vertical components of the reaction at point A:

$$M_{DC} = 4\,H + 10\,V; M_{CD} = 10\,V - 6\,H; M_{BC} = 6\,H;$$
$$\text{and } M_{CD} - M_{BC} = 10\,V \qquad (21)$$

The simultaneous solution of Eqs. 18 to 21 yields: $M_{BA} = M_{BC} = -0.0444\,E\,I$; $M_{CD} = M_{CB} = 0.0972\,E\,I$; $\theta_{CD} = 0.603$; $\theta_{CB} = -0.398$; $\theta_{BC} = 0.310$; $\theta_{BA} = 0.311$; and $\theta_{AB} = 0.444$. From Eq. 12b: $k_{1m} = \frac{1}{3\,(0.310 - 0.398)}$ $(2 \times 0.310 - 0.398 \pm \sqrt{0.310^2 + 0.398^2 - 0.398 \times 0.310}) = 0.531$; and from Eq. 10: $y_m = 10\,[0.310 \times 0.531 \times 0.469^2 + 0.398 \times 0.531^2 \times 0.469] = 0.888$. Eq. 14 yields the area under the influence curve, thus: $\frac{1}{12}\,(10)^2(0.310 + 0.398) = 5.90$. The maximum moment at joint C due to a moving load of 10 kips, therefore, will be 8.88 ft-kips when the load is placed 5.31 ft from joint B (Fig. 5). The moment at joint C due to the uniform load will be 5.90 × 1.5, or 8.85 ft-kips.

Example 5. Find the Maximum Value of Moment at Joint B, Fig. 6, Using an Elastic Curve Traverse for Statical Analysis.—Impose the rotation θ at joint B. Beginning with a value of 1 for the lower elastic angle in column CD complete the traverse (Fig. 7), remembering that $M_{BC} = M_{BA}$. From Fig. 7(*a*), $\theta = 2.8 + 4.0 = 6.8$. Since sidesway has not been considered, these values must be corrected. The value of the unbalanced horizontal force is 1.467 EI. Assume the frame to be deflected sidewise without rotation of joints B and C (Fig. 7(*b*)). Assign the value Δ to the traverse angles and M to the end moments in CD. Since the "sidelurch" is equal for the vertical members the traverse angle in column AB must be 0.833 Δ and $M_{BA} = \frac{5}{6} \times \frac{5}{3} \times M = 1.389\,M$ (see line 2, Table 4).

Figs. 7(*c*) and 7(*d*) are solved for unbalanced moments at joints B and C. The unbalanced moment in each case is 17. If the value M in Fig. 7(*b*) is made equal to 17 then the moments for Fig. 7(*b*) may be computed and the sidesway correction made. The final moments must be divided by 6.8 to reduce to the condition of unit deflection at joint B. Starting at point D with these moments and changing to the equivalent angle units the corrected traverse may be constructed as shown in Fig. 7(*e*). From Eq. 12*b*, $k_{1m} = 0.474$ and, from Eq. 10, $y_m = 0.838$.

Example 6.—The influence line for vertical deflection at the center of span BC, Fig. 6, may be calculated by placing a unit vertical load at the center of the span and computing the resulting deflection curve. The values of M_B and M_C for this loading can be obtained from Eq. 10 using the values of θ_{BC} and θ_{CB} from Examples 4 and 5:

$$M_B = 10\,(0.369 \times 0.5^3 + 0.295 \times 0.5^3) = 0.830$$
$$M_C = 10\,(0.310 \times 0.5^3 + 0.398 \times 0.5^3) = 0.885$$

From statics, $V_B = 0.4945$, and $V_C = 0.5055$, and the moment diagram, Fig. 8(*a*) can be drawn. Applying Eq. 2 between points B and C, $\theta_{BC} = -\frac{2.02}{EI}$ and $\theta_{CB} = \frac{1.92}{EI}$ for the struc-

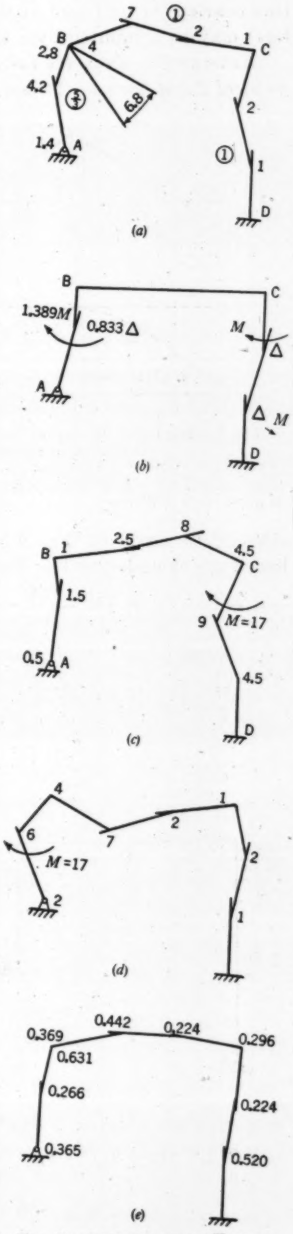

FIG. 7.—ANALYSIS OF AN UNSYMMETRICAL BENT

ture bearing the unit load at the center. The elastic curve (required influence line) may be computed by a tabulation using Eq. 3*a* (see Fig. 8(*b*)).

Example 7. Draw the Influence Line for M_{BC} for a Vertical Load on a Symmetrical Rigid Frame. (What Is the Moment at Joint B (Fig. 9) Due to a Horizontal, Uniformly Distributed Load of 500 Lb per Ft on Member AB?).—The method of moment distribution will be used in exploring this question. Impose a unit rotation at joint B. The fixed-end moments in member BC are then $M_{BC} = \frac{4\,E\,I}{l}$ and $M_{CB} = \frac{2\,E\,I}{l}$, respectively. The solution of Fig. 9(*a*) yields $M_B = -\,1.615\,\frac{E\,I}{l}$; $M_C = 0.461\,\frac{E\,I}{l}$; and $M_D = -\,0.230\,\frac{E\,I}{l}$. The unbalanced shear is $0.231\,\frac{E\,I}{l}$. Correction for sidesway is made by Fig. 9(*b*) and the corrected moments with sidesway allowed are encircled in Fig. 9(*a*). From the relation between end rotations and end moments, $\theta_{BC} = \frac{1.090}{3} + \frac{0.273}{6} = 0.409$; and $\theta_{CB} = \frac{-\,1.090}{6} - \frac{0.273}{3} = -\,0.273$. Since $\theta_{BA} = \theta_{BC} - 1 = -\,0.591$, Eqs. 8 yield, for member AB:

$$M_{AB} = 0 = -\,2\left(2\,\theta_{AB} - 0.591 - \frac{3\,y}{l}\right) \qquad (22a)$$

and

$$M_{BA} = -\ 1.090 = 2\left[\ \theta_{AB} - 2\,(0.591) - \frac{3\,y}{l}\right]\ldots\ldots\ldots(22b)$$

in which y is the displacement due to sidesway. Solving simultaneously, $\theta_{AB} = -\ 0.046$ and $y = -\ 2.277$. From Eq. 12*b* for member BC: $k_{1m} = 0.456$ and, from Eq. 10, $y_m = 0.862$. From Eq. 14 for member AB: $Q = \frac{10}{2}\,(-\ 2.277) + \frac{1}{12}\,10^2\,(-\ 0.046 + 0.591) = 6.848$. Consequently, the moment at joint B due to a uniformly distributed horizontal load of 500 lb per ft on member AB is $M_B = 6.848 \times 500 = 3{,}424$ ft-lb.

FIG. 10.—HAUNCHED RIGID FRAME

Example 8. Haunched Rigid Frame.—Using the traverse method trace influence line for M_B for the frame of Fig. 10 due to vertical load on beam BC. What is the value of M_B for a uniform load of 1.5 kips per ft? Using this method, the traverse angle occurs at the center of gravity of the $\frac{M}{E\,I}$-diagram considering one end of the member to be loaded with a moment and the other end to be hinged. The distance to the center of gravity point is designated by $\bar{x}$. Solution procedures for these points and for the stiffnesses of members are demonstrated in Tables 5 and 6. In Table 5 a moment of $1{,}000\,\frac{E}{12}$ is applied at joint B to member BC, Fig. 10. From this table, $\bar{x}_{BC} = \bar{x}_{CB} = \dfrac{\sum \frac{M}{EI}(\Delta x)(x_n)}{\sum \frac{M}{EI}(\Delta x)} = \dfrac{35{,}075.4}{1{,}711.18} = 20.44$ ft and the stiffness (the moment required to produce unit rotation in beam BC) is calculated by $\dfrac{1{,}000\,\frac{E}{12}}{1{,}711.18} = 0.585\,\dfrac{E}{12}$.

From Table 6, $\bar{x}_{BA} = \dfrac{1{,}613.8}{209.8} = 7.71$ ft; $\bar{x}_{AB} = \dfrac{1{,}611.6}{279.6} = 5.77$; and

$$\text{Stiffness BA} = \frac{1{,}000\,\frac{E}{12}}{209.8} = 4.77\,\frac{E}{12}$$

$$\text{Stiffness AB} = \frac{1{,}000\,\frac{E}{12}}{279.6} = 3.58\,\frac{E}{12}$$

A rotation is imposed at joint B and the traverse, Fig. 10(c), is drawn ignoring sidesway. The traverse is started at point A and carried to point B, and independently at point D and carried to B. Since $M_{BA} = M_{BC}$, the right-hand side is correlated with the left-hand side by multiplying the right-hand side rotations by $\dfrac{15{,}040}{23{,}830}$. Corrected rotations are shown encircled.

The total unbalanced shear in the vertical members is $1{,}010\,\dfrac{E}{12}$. The solution procedure for an imposed horizontal force at joint B is demonstrated by Fig. 10(d). From symmetry, the traverse angles in beam BC are equal. Assuming them to be equal to 1,000 the traverse is completed as shown. The value of the horizontal force, Fig. 10(d), is $167.5\,\dfrac{E}{12}$. For a horizontal force corresponding to that of Fig. 10(c) the angles must be multiplied by $\dfrac{1{,}010}{167.5}$. Corrected angles are encircled in Fig. 10(d). These angles are then added algebraically to the corresponding angles of Fig. 10(c) to arrive at the correction

due to sidesway. The resulting angles are shown underlined in Fig. 10(*c*). The value of the imposed rotation at joint B is 1,946 + 3,910 = 5,856. To reduce the rotation to unity it is necessary to multiply all the angles by $\frac{1}{5,856}$. These angles are shown in Fig. 10(*e*). Using Eq. 3*a* the elastic curve for beam BC (influence line) is computed in Table 7. The area under the influence line is given by $\Sigma y_n \Delta x$ or $122.58 \times 2 = 245.16$ and the moment due to uniform load of 1.5 kips per ft is 367.74 kip-ft.

Example 9. Simply Supported Continuous Beam.—Using the indirect method and moment-distribution method draw influence lines for the continuous beam in Fig. 11. The analysis for the effect of undistributed moments of +100 at joint B and joint C is made in Fig. 11. (In this illustration the previous sign convention for moments has been temporarily discarded for convenience and moments acting clockwise on the joint are considered positive. For other computations involved in Example 9, the previous sign convention is used.)

For moment at support B a unit rotation is considered to be imposed at point B. Assuming this to be imposed on span AB alone the resulting fixed-end moment, M_{BA}, is $3\,E\,K$ and, since the stiffness, $E\,K$ is equal to 2, $M_{BA} = 3 \times 2 = 6$. Distributing this fixed-end moment in accordance with the distribution of Fig. 11 the moments are found to be $M_B = 4.120$, $M_C = -0.729$, and $M_D = 0.121$; and the end rotations are calculated as follows:

$$\theta_{AB} = -\frac{4.120}{6}\,\frac{1}{2} = -0.34$$

$$\theta_{BA} = +\frac{4.120}{3}\,\frac{1}{2} = +0.69$$

$$\theta_{BC} = -\frac{4.120}{3}\,\frac{1}{4} + \frac{0.729}{6}\,\frac{1}{4} = -0.31$$

$$\theta_{CB} = \theta_{CD} = \frac{4.120}{6}\,\frac{1}{4} - \frac{0.729}{3}\,\frac{1}{4} = +0.11$$

$$\theta_{DC} = \theta_{DE} = -\frac{0.121}{3}\,1 = -0.04$$

$$\theta_{ED} = +\frac{0.121}{6}\,1 = +0.02$$

For the reaction at support B a unit deflection is imposed at point B, Fig. 11. The corresponding fixed-end moments must be applied:

$$M_{BA} = \frac{3\,E\,K}{l} = +\,\frac{3 \times 2}{30} = +\,0.200$$

$$M_{BC} = \frac{6\,E\,K}{l} = +\,\frac{6 \times 4}{30} = +\,0.800$$

$$M_{CB} = \frac{6\,E\,K}{l} = -\,\frac{6 \times 4}{30} = -\,0.800$$

Using the distribution of Fig. 11 the resulting moments are computed to be

$M_B = +\,0.298$, $M_C = -\,0.194$, and $M_D = 0.032$; and the corresponding rotations, remembering that $\delta_B = -\,1$, are:

$$\theta_{AB} = -\,\frac{1}{30} - \frac{1}{6} \times 0.298 \times \frac{1}{2} = -\,0.0583$$

$$\theta_{BA} = \theta_{BC} = -\,\frac{1}{30} + \frac{1}{3} \times 0.298 \times \frac{1}{2} = +\,0.0164$$

$$\theta_{CB} = \theta_{CD} = +\,\frac{1}{3} \times 0.194 \times \frac{1}{2} - \frac{1}{6} \times 0.032 \times \frac{1}{2} = +\,0.0296$$

$$\theta_{DC} = \theta_{DE} = -\,\frac{1}{3} \times 0.032 = -\,0.0107$$

$$\theta_{ED} = +\,\frac{1}{6} \times 0.032 = +\,0.0053$$

Conclusions

Influence lines may be computed exactly as the elastic curve due to a unit displacement corresponding to the "action" being studied and placed at the section under consideration. The computation of such an influence line involves (1) a statical analysis of the structure bearing only the displacement and (2) computation of as many points on the elastic curve as may be necessary. This is somewhat more work than a single statical analysis of the structure bearing a conventional load although the additional labor of calculating deflections is offset somewhat by the fact that the statical analysis is generally simplified since it involves only the unloaded structure. The statical analysis may be made using whatever method the designer prefers. It may be made indirectly by first distributing an unbalanced moment at each of the joints and then summing up proportionately a set of fixed-end moments corresponding to the required deflection. The elastic curve is calculated by geometry, or by equations or methods based on geometry. (Methods of analysis, as such, do not come within the scope of discussion.)

Fig. 11.—Simply Supported Continuous Beam

In many cases complete elastic curves are unnecessary. For prismatic members the location of the load for maximum effect, and the amount of the effect, are given by Eqs. 12. For uniform load on prismatic members the area under the influence line is given by Eq. 14.

DISCUSSION

Ralph E. Spaulding,[9] M. ASCE.—The fundamental differential equation of flexural geometry, $\frac{d^2y}{dx^2} = \frac{M}{E\,I}$ (in which I is the moment of inertia of a geometric plane cross section of the beam), does not apply to curvalinear or angular beams. The centroidal axis, in bending, of a curvalinear or angular beam is not at the geometric centroid of a plane cross section of the member. The formula is accurate only for beams (including continuous beams), whose geometric axis is a straight line. Its relative inapplicability depends on the relative deviation from a straight line, which may be caused by the angularity of curvature of the member under study—whether this deviation is caused by a curved knee, an angular knee, or a haunch.

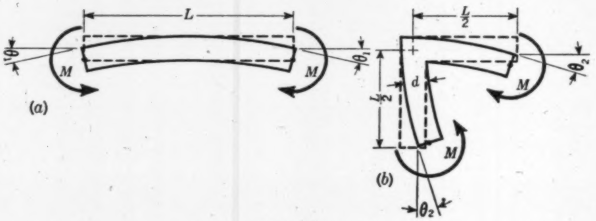

Fig. 12.

It would seem advisable to emphasize the fact that the foregoing basic formula is not applicable to homogeneous rigid frames such as shown in Figs. 6 and 10. Before it may be so used, it is necessary to build up the knee in each case to the point where its stiffness as an angular beam is equal to that of the straight beam adjoining it.

For example, Fig. 12(*a*) represents a homogeneous beam having an uninterrupted straight axis and Fig. 12(*b*) represents a similar beam of the same length except that it has a right-angle knee. Equal moments being applied to the ends of both beams, the rotation θ_2, in the beam containing the knee will be substantially greater than θ_1 in the straight beam; whereas $\theta_1 = \frac{M\,L}{2\,E\,I}$ and $\theta_2 = \frac{M}{2\,E\,I}(L + d\sqrt{2})$, approximately.

Ralph W. Stewart,[10] M. ASCE.—The various examples demonstrated by the author all relate to the influence line for some one specific point, or to the influence lines for supports only.

In the design of reinforced concrete rigid frame bridges, it is desirable and entirely practicable to construct the envelope that passes through the maximum influence line ordinates for all points of the structure. This will enable the computer to plan the reinforcing bars so that they will conform accurately to the requirement at each point.

---

[9] Cons. Engr., Jacksonville, Fla.

[10] (*Retired*), Los Angeles, Calif.

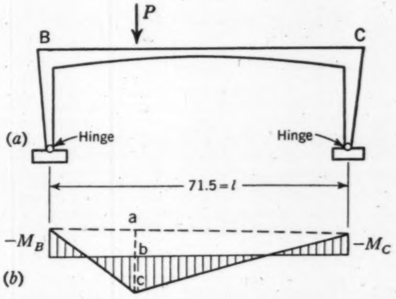

FIG. 13

Fig. 13(*a*) indicates a single-span rigid frame bridge. Modern design specifications require the decks of such bridges to be designed as if the bases were hinged.[11]

The constants of flexure for the deck and abutments are determined and a traverse constructed[12] as shown in Fig. 14(*a*). This shows the effect of a fixed-end moment of 7.28 applied at the left end only of the deck with sidesway prevented. To determine the properties of the structure for any symmetrical loading simply reverse Fig. 14(*a*) on itself and combine the moments. The result, Fig. 14(*b*), shows the haunch moments (5.69) produced by symmetrical fixed-end moments of 7.28. To determine the effect of a single fixed-end moment corrected for sidesway, divide the haunch moments in Fig. 14(*b*) by 2 and write them in Fig. 14(*d*); also, write the fixed-end moment 7.28 at the left end of the deck and Fig. 14(*d*) will then show the effect of this fixed-end moment with sidesway permitted.

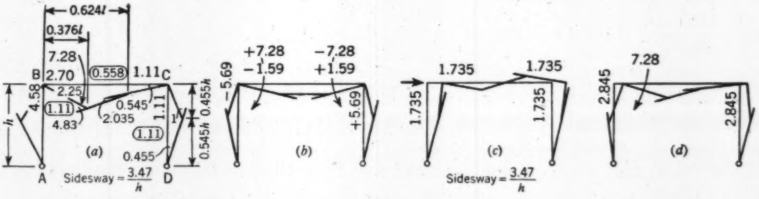

FIG. 14

A more easily understood but longer method of correcting for sidesway is to note that the sidesway force in Fig. 14(*a*) is $\frac{3.47}{h}$. Since the structure is symmetrical, one half of this goes to each abutment, thus yielding Fig. 14(*c*). Now combine Fig. 14(*a*) with Fig. 14(*c*), and Fig. 14(*d*) is again obtained.

Figs. 14(*b*), 14(*c*), and 14(*d*) now cover all conditions of flexure. Fig. 14(*a*) is simply a means to this end and can be abandoned thereafter. For this very simple structure Fig. 14(*a*) need not have been constructed. A traverse for symmetrical loading, similar to Fig. 14(*b*), can be constructed directly by two slide rule settings. A figure similar to Fig. 14(*d*), will then, as already shown, follow directly from it. For more general cases, however, a diagram corresponding to Fig. 14(*a*) must be drawn.

[12] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, ASCE, Vol. 104, 1939, p. 527, Fig. 4.

Cols. 1 and 2, Table 8, show the fixed-end moment coefficients by which ($P\,l$)-values are multiplied to compute the fixed-end moments for concentrated loads at each of the $\frac{1}{12}$ length points along the span. There are several available tables and charts giving these coefficients. With structural symmetry and hinged bases the haunch moments of this frame will always be equalized by the sidesway; therefore, the computer can combine the items in each line of Cols. 1 and 2 and obtain Col. 3.

TABLE 8.—FIXED-END MOMENT COEFFICIENTS FOR CONCENTRATED LOAD (FIG. 13)

Load of unity at point[a]	COEFFICIENTS FOR: (FEM)$_L$ (1)	COEFFICIENTS FOR: (FEM)$_R$ (2)	Col. 1 plus Col. 2 (3)	$M_{BC} = M_{BA}$ (4)	Simple beam moment[b] (5)	Moment under load[b] (6)
1	0.0744	0.0053	0.0797	2.22	5.46	3.24

3	0.1628	0.0463	0.2091	5.84	13.40	7.56
4	0.1750	0.0785	0.2535	7.08	15.90	8.82
5	0.1679	0.1136	0.2815	7.85	17.38	9.53
6	0.1455	0.1455	0.2910	8.12	17.88	9.76

[a] Point 6 is the center line of the span. [b] See Fig. 13(*b*): The moment under the load (bc) equals the simple beam moment (ac) minus ab.

Each haunch moment for a unit load recorded in Col. 4, Table 8, will then be $\frac{2.845}{7.28}$ (Fig. 14(*d*)) multiplied by the adjoining item in Col. 3 and the length of the deck member. The simple moments shown in Col. 5 are then computed. By deducting the moments in Col. 4 from the simple moments the moments under the load are obtained as shown in Col. 6, Table 8. Fig. 13(*b*) illustrates this computation for the general condition. The ordinate ac will be recognized as the maximum simple beam moment and the ordinate bc of the shaded area ($\overline{ac} - \overline{ab}$) is the moment under the load. For symmetrical structures with hinged bases it will not be necessary to interpolate to obtain the ordinate ab as M_B and M_C are equal for all positions of the load.

To construct Table 9 first write in the values under point 0 which show the moments at ends B and C. These are taken from Col. 4, Table 8. The underscored items running diagonally across the upper half of Table 9 are the moments under the load taken from Col. 6, Table 8. Each is written where its line number intersects its column number. All other items in Table 9 are computed by horizontal interpolation. A property of this tabulation for a symmetrical frame is that it is symmetrical in all directions about the point where line 6 (Table 9) intersects the last column, point 6; in other words, about the center of the structure. Therefore, Table 9 may be constructed for only half the length of the deck as shown. The vertical columns can now be plotted and will give the influence lines for a unit load shown in Fig. 15.

The summation of the positive and negative influence line ordinates in Table 9 serves two purposes—(1) placing discontinuous sections of uniform live load on the span to get maximum moments, and (2) checking the accuracy of the table. The check is as follows: The simple moment for a load of 1 kip

TABLE 9.—INFLUENCE ORDINATES FOR A UNIT CONCENTRATED LOAD[a]

[a] Point 0 is at end B, Fig. 13(*a*), and the same values, by symmetry, apply to end C (point 12).

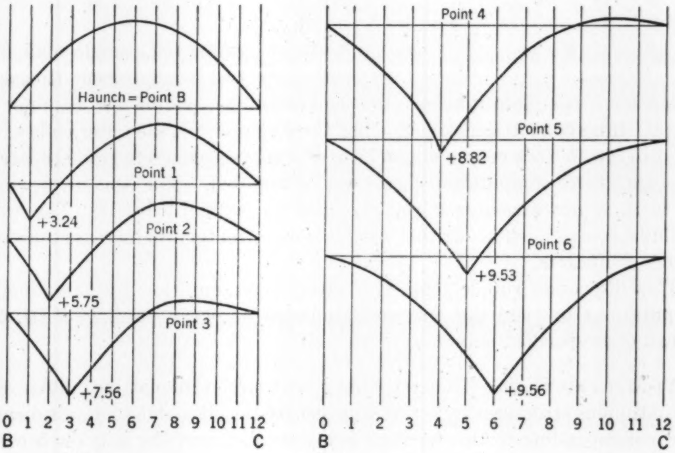

FIG. 15

per ft on the 71.5-ft span is $(71.5)^2 = 638$ ft-kips. From the first column of Table 9 (point 0, line 12), $M_B = 62.48 \times \frac{71.5}{12} = 373$. Subtracting M_B from the simple moment gives 265 ft-kips as the moment at the center of the span.

From the last column of Table 9 (point 6, line 13) the moment at the center of the span is $44.7 \times \frac{71.5}{12} = 266$ ft-kips, which checks.

After this check is accomplished Fig. 16 may be drawn. This shows maximum positive and maximum negative moments all along the span due to a concentrated moving load of unity. From Table 9 or the influence line graphs, the moments caused by any live load are readily computed and combined with the dead load, temperature, and other moments so that the required reinforcement for every cross section along the member can be determined. It is not necessary to plot the influence lines (Fig. 15) except to detect errors in the computations which will be disclosed if the points on the curves are obviously out of line.

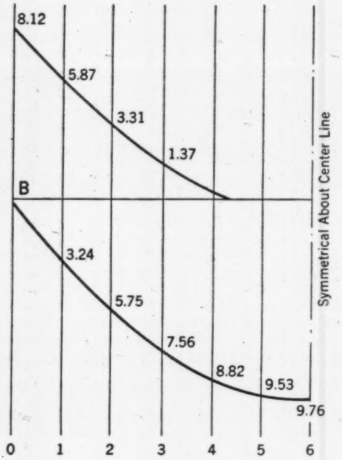

FIG. 16

Many engineers and writers whose opinions carry weight have stated that the computation of influence lines is seldom desirable and that the time and expense of such computations can be saved.

For a symmetrical, single-span structure only two computation sheets are needed for a complete influence line computation covering the bending moments. If a symmetrical structure has three spans with the outer ends simply supported (which is a very common form of reinforced concrete grade-separation structure), three computation sheets will be required. The time or expense of this work is not excessive if the computer is familiar with it. The author should be commended for writing a paper which will tend to increase the supply of such computers.

This discussion supplements the author's presentation by extending the computations to yield the maximum moment at every point in a structure instead of at specified points.

YI-MAI YAO,[13] ESQ.—The author has given a method of plotting influence lines for continuous structures by computing the elastic curve due to a unit displacement corresponding to the "action" being studied, and the unit displacement being located at the section under consideration. The formula for computing the ordinates of an elastic curve, such as Eq. 10, involves the joint rotation θ. The θ-value can be obtained directly and quickly by balancing the angle changes[14] produced by the "unit displacement," a method presented by L. E. Grinter, M. ASCE.

[14] "Analysis of Continuous Frames by Balancing Angle Changes," by L. E. Grinter, *Transactions*, ASCE, Vol. 102, 1937, pp. 1020–1067.

According to equations derived by Professor Grinter[15] the modified stiffness κ_{ABm} and the modified carry-over factor γ_{ABm} for the direct distribution process are as follows:

$$\kappa_{ABm} = \frac{4\,\kappa_{AB}}{3 + \dfrac{\kappa_{BA}}{\Sigma\kappa'_{Bm}}} \quad \ldots\ldots\ldots\ldots \quad (23)$$

and

$$\gamma_{ABm} = -\frac{2\,\dfrac{\kappa_{AB}}{\Sigma\kappa'_{Bm}}}{3 + \dfrac{\kappa_{BA}}{\Sigma\kappa'_{Bm}}} \quad \ldots\ldots\ldots\ldots \quad (24)$$

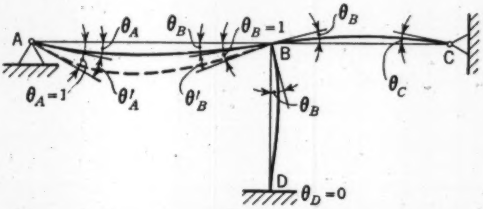

FIG. 17

in which $\Sigma\kappa'_{Bm}$ indicates the summation of the modifier stiffness of the member tributary to joint B except BA plus the unmodified stiffness of BA.

The simply supported continuous girder in Example 9 can be solved easily by direct distribution, as shown in Table 10, for plotting the influence lines for moment M_B and reaction R_B.

Line 3, Table 10, shows the unmodified stiffness of member, κ. Line 4 shows the modified stiffness κ_m by Eq. 23; for example, $\kappa_{CBm} = \dfrac{4 \times 4}{3 + \dfrac{4}{4+2}} = 4.36$ and $\kappa_{DCm} = \dfrac{4 \times 2}{3 + \dfrac{2}{2 + 4.36}} = 2.41$. Line 5 shows the $\dfrac{\kappa_m}{\Sigma\kappa_m}$-value, and line 6 shows the modified carry-over factor γ_m; for example, $\gamma_{CBm} = -\dfrac{2\,\dfrac{4}{4+2}}{3 + \dfrac{4}{4+2}} = -0.363$ and $\gamma_{DCm} = -\dfrac{2\,\dfrac{2}{2+4.36}}{3 + \dfrac{2}{2+4.36}} = -0.187$. Line 7, Table 10, shows the "unit displacement" corresponding to the influence line for M_B; line 8 shows the direct distribution—for example, $\theta_{BA} = +1.00 \times 0.687 = +0.69$, which, carried over, yields $+0.69 \times -0.500 = -0.34$ to joint A. The rotation, $\theta_1 = 1.00$, must remain at joint B, and therefore, in line 6, -0.31 must remain in member BC. Consequently, $-0.31 \times -0.355 = +0.11$ is car-

ried to joint C; + 0.11 × − 0.363 = − 0.04 is carried to joint D; and −0.04 × − 0.500 = + 0.02 is carried to joint E. The influence line for M_B can be plotted with θ-values, −0.34, +0.69, −0.31, +0.11, −0.04, and +0.02, as shown in Table 10(*b*). Line 9, Table 10, shows the angle changes $-\theta = 1/30 = 0.0333$ due to a "unit displacement" of support B when joints A, B, and C are hinged (see Table 10(*c*)); line 10 shows the results of balancing the angle change −0.0333 at AB, which member keeps the entire amount since joint A remains hinged. Line 11 shows the results of balancing the quantity −0.0333 at BA. The end BA keeps −0.0333 × 0.313 = − 0.0104. The quantities carried over are, for example, −0.500 [−0.0104 − (− 0.0333)] = − 0.0115 from BA to AB; −0.335 × − 0.0104 = + 0.0037 from BC to CB; and − 0.363 × + 0.0037 = − 0.0014 from CD to DC. Lines 12 and 13, Table 10(*c*), show the balancing process of angle changes +0.0333 at BC and CB. Line 14, Table 10(*d*), shows the final joint rotation θ, the sum of lines 10 to 13 in Table 10(*c*). The influence line for R_B can be plotted by means of Eq. 10 using the unit rise at support B, and the joint rotations listed in the various columns of Table 10(*d*).

The theory supporting Professor Peterson's method is not new; it is merely the modified form of the Müller-Breslau principle. The fundamental Eq. 10 can be derived by the classical moment-area method without any knowledge of "geometry." The author gives a rapid and accurate procedure for computation. Although so many different methods of statical analysis can be used, the writer has considered Professor Grinter's method to be the best, especially for the prismatic member, which avoids the tedious moment computation. Its utilization will increase the value of the author's paper.

OTTO GOTTSCHALK,[16] ESQ.—The neat arrangement of this paper, conforming with current practice, is commendable. The thing that the writer would like to see corrected is the abstract symbolism used in most of the recent papers on structural design, including this one. At an alarming rate, this field is accumulating barriers of learned thought instead of simple methods based on elemental geometrical analysis. Although the author implies that geometrical methods are used, he applies abstract symbols of geometrical units as loads, which is not the same.

A characteristic of the geometrical method of analysis is that the several steps are visible and, thereby, they are an aid to a designer's intuition. Abscissas, ordinates, radii, curvatures, linear or angular displacements or deformations, and the separation or the breaking of originally continuous parts are all visible in a truly geometrical method of analysis. Stresses and stress functions and moment and other stress areas are not visible and therefore are not used.

For purposes of analysis, rigid structures are geometrical bodies and must be analyzed by geometrical methods. Every step away from this principle leads to complications. If a given structure is said to be rigid, any geometrical disturbance at one end of one of its members is resisted by the stiffness of adjacent members, so that a unit geometrical displacement at any given section causes deformation all over the structure, bending the originally straight members into curves which are the influence lines. (Generally, the designer is not

interested in the true shape of the curve at every point, but in the value of selected ordinates.)

The cross sections at either end of every straight beam or column are perpendicular to the axis before loading. When the structure is deformed these sections are either rotated or translated, or both. When such beams are prismatic, they can be analyzed easily by purely geometrical methods because their curvature changes in proportion to their abscissas, so that, graphically, if the curvature is represented by the ordinate, the curvature at any point is represented by the straight line[17] that joins the ordinates representing curvature at the ends. In true geometrical analysis loads are considered external to the structure. They are not a part of it and do not enter into the analysis. They are only factors with which to multiply ordinate values determined by the geometry of the problem.

By applying equations of influence lines such as those developed by the writer (which the author has cited[3]), the laborious work of computing the tables required by the author is made unnecessary. For prismatic members (span AB, Fig. 11) the equation of the influence line[3] is

$$y = \frac{x\,x'\,(x\,\theta' + \theta\,x')}{l^2} \quad \text{.....................(25)}$$

in which, conforming to the notation of the paper, l is the span length AB; x and x' are the abscissas; and θ and θ' are the rotations of the points A and B, respectively. As the author indicates (see "Synopsis"), the methods in current use require the computation of a considerable number of points to obtain an influence line. By contrast, the geometrical formula, Eq. 25, requires only one point in each span plus one more point in the span where the deformation occurs. This simple formula, therefore, makes the influence line a most handy tool for all designs involving the laws of statics. For beams with haunches, the results obtained for prismatic members are modified by values selected from precalculated tables.

A demonstration of the reduction of work made possible by a true geometrical analysis of influence lines is presented in Table 11, for comparison with Fig. 11. Let $k = i/L$ equal the stiffness; S and S', the relative stiffness (resistance to rotation) at the left and right ends of the various spans; and $S'_n + S_n + 1 = K_j$, the joint stiffness at a support. Also, m is the ratio of end rotations. The computation of m and S begins at point D of span DE and progresses toward the left; and the computation of m' and S' begins at point B in span BA, progressing to the right. Table 11(a) includes a computation for support D, which is not included in Fig. 11. By moment-distribution methods this would require the same labor as that for support B.

It is thus shown that, by geometrical analysis, the stiffness percentages at both sides of supports can be obtained directly, and accurately, with less than one fifth of the work required by the distribution method, and with about one tenth the chance of error.

In Table 11(b) the same continuous beam has been analyzed, but with support A fixed. Values of m and S are the same as for the simply supported condition (Table 11(*a*)). Incidentally, these results show that, by fixing point A, the stiffness distribution is changed considerably at point B but scarcely at points C and D.

---

[17] "Calculo Estático de Estructuras Rigidas sobre Bases Naturales," by Otto Gottschalk, Librería Hachette, Buenos Aires, Argentina, p. 14, Fig. 13.

The foregoing shows that geometrical analysis is not made more complex by the fixing of exterior supports. Furthermore, it shows that the concepts of statical indeterminacy and redundancy are man-made inventions which are uncalled for in design procedure and therefore obsolete. All in all, the writer agrees with the author that, in future design of rigid, or continuous, structures, the influence line will be a most valuable tool, but only when it is applied in the fundamental geometrical sense, as presented herein.[18,19,20,21]

DEAN F. PETERSON, JR.,[22] Assoc. M. ASCE.—Mr. Spaulding's criticism that the fundamental equation of flexure, $\frac{d^2y}{dx^2} = \frac{M}{E\,I}$, does not apply to curved members is a criticism of all the modern methods for analyzing stresses in frames—from the classical theorems of strain energy to moment distribution and the elastic curve traverse. All common methods of frame analysis are based on Eq. 1 and give identical results. A discussion of the shortcomings of the basic assumptions of these methods is beyond the scope of this paper. Part of the writer's purpose was to demonstrate how to utilize these methods of solving for the end rotations and deflections of the members of unloaded frames subjected to the proper relative deflections to produce the desired influence line. The basic thesis of the paper will not be amended by greater refinement in the application or the premises of these methods.

Considerable progress has already been made toward understanding the action of knees and curved members subjected to flexure. The work of Bruce Johnston, M. ASCE and Edward H. Mount[23] and a paper by Mr. Stewart[24] are valuable contributions toward explaining the action of structural joints, including knees in framed structures. Such amendment in procedure as may be necessary is easily accomplished by interpretation and clarification of Eq. 1. The action of curved beams is treated by standard texts on strength of materials and unless the curvature is relatively great—that is, unless the radius of curvature approaches the depth of the beam—the corrections to Eq. 1 are immaterial.

Eq. 1 is also used by the writer for determining the ordinates to the elastic curves of the various members of the frame. Curvature of the members of frames is so small that corrections to Eq. 1 when thus used become unnecessary.

The contribution by Mr. Yao is valuable in that it demonstrates an additional method for finding the end rotations of the members of the unloaded structure subjected to the desired strain conditions.

[24] "Analysis of Frames with Elastic Joints," by Ralph W. Stewart, *Proceedings*, ASCE, December, 1947, p. 1499.

Mr. Gottschalk criticizes the writer's use of nongeometrical methods for determining the end rotations of the various members of the structure bearing the imposed strain conditions. The writer claims to have used geometrical methods only for computing the deflection curve after the end rotations have been determined. Calculation of the end rotations of the members can be made by any method the designer desires. Whether he uses methods based principally on geometry, such as the elastic curve traverse, or the method proposed by Mr. Gottschalk (Table 11) is immaterial to this paper. Examples are given using several methods, although the writer's personal preference is for the geometrical methods.

The writer agrees with Mr. Gottschalk that modern structural theory is cluttered with unnecessary symbolism. It is more fundamental and just as easy, for example, to consider a change in the inclination of the tangents at two points of a beam as an angle (which it really is), instead of as the shear or weight borne by an imaginary beam. On the other hand, the writer believes a realization, for instance, of the relationship between bending moments and beam curvature to be essential. Use of real bending moments to express curvature is not believed to be "abstract symbolism."

Mr. Gottschalk states that, for prismatic beams, "* * * the laborious work of computing the tables required by the author is made unnecessary," and suggests Eq. 25. Of the seven tables, six concern computation for nonprismatic members. In all examples for prismatic members, the writer used Eq. 10 which is a generalized statement of Eq. 25.

Table 11 shows a method for obtaining the distribution factors on both sides of the support of a continuous beam. This method is given as a substitute for moment distribution and is therefore interesting. Mr. Gottschalk does not make clear, however, the method for finding the distribution of an unbalanced rotation at a remote joint—for example, the distribution at point D resulting from a rotation at point C. Moment distribution is only one of the many methods by which rotations over the supports of the continuous beam with unit rotational strain imposed at point B (Fig. 11) may be deduced. These may be found with great rapidity, for example, using the elastic curve traverse.[25] The method to be used depends somewhat on the personal preference and training of the designer.

In conclusion, the writer believes that the influence line computed as the deflection curve of the unloaded structure subjected to the proper strain conditions furnishes the simplest method of analyzing the stress condition of a structure if more than one loading is to be considered. The work involved in solving for the influence line in the manner proposed is about equal to that involved in a stress solution for any single set of loads.

DRAINAGE OF AIRPORT SURFACES—SOME BASIC DESIGN CONSIDERATIONS

By Stifel W. Jens,[1] M. ASCE

With Discussion by Messrs. H. M. Williams, W. I. Hicks, E. J. A. Gain, E. F. Brater, Carl F. Izzard, and Stifel W. Jens

Synopsis

For determination of runoff from the flat turf surfaces encountered on the inter-runway areas of airports, a methodology is presented employing the newer knowledge concerning retention, infiltration, and overland flow. Since determination of supply rates is required, a detailed procedure is given that takes into account not only the fact that in nature antecedent precipitation within the storm reduces infiltration capacity values, but also the fact that in many storms rainfall rates are less at times than the related infiltration capacities.

Within most turfed areas a peak-reducing pondage is available and practical procedures are developed for obtaining the outflow rates from the ponded areas. Two examples of design are presented. These illustrate that, once pipe sizes are selected and a hydraulic balance is achieved for runoff from rainfall of a selected frequency and duration, the capacity of a system varies but little for other frequencies or durations due to the relation of large changes in mass pondage to very small changes in depths.

Introduction

To permit safe and satisfactory landing and take-off of airplanes, the removal of surface runoff is generally the primary problem in airport drainage. At properly selected airfields, only isolated and relatively small parts of the area ordinarily will require subdrainage. For scheduled airline operation or any other use that does not require all-over landing, a basic drainage requirement has been established by government regulatory authorities, airport managers, and engineers that surface runoff from rains occurring once in two years be removed to the extent necessary to prevent pondage on runways, taxiways, or aprons—or within about 50 ft of their edges. This requirement

---

Note.—Published in September, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Partner, Horner and Shifrin, St. Louis, Mo.

offers grading and drainage engineers a remarkable opportunity to minimize the cost of the drainage facilities.

In setting the pavement and inter-runway grades, consideration should be given to the possibilities for providing maximum pondage capacity below a horizontal plane surface whose nearest edge approaches within 50 ft of the pavement edges. Thus, practically the entire field can be served by inlets at low points in turf areas surrounded by paved runways and taxiways. The dominant character of this type of drainage is illustrated by the fact that, for a major transport field, such as the Lambert-Municipal Airport at St. Louis, Mo. (Fig. 1), about 80% of the total area requiring artificial drainage within the airport boundaries can be handled in this manner. This paper is confined to a discussion of the basic requirements of design for drainage of such inter-runway pockets, in most of which it is possible to develop useful pondage.

FIG. 1.—DRAINAGE DIAGRAM FOR EXPANSION OF THE LAMBERT-ST. LOUIS MUNICIPAL AIRPORT

GENERAL DISCUSSION OF METHOD

Operational requirements limit the rate of grade for the turf off the paving; consequently, the shaping of each pocket is possible within a relatively narrow range of plane slopes. Thus, for each pocket the designer has a tributary area of accurately determinable drainage characteristics such as length and slope of sheet flow, and depth and extent of available pondage, as well as actual amounts of pervious and impervious areas. Determination of flow rates to and from each ponded area lends itself especially well to methods employing the newer knowledge concerning retention, infiltration, and overland flow.

The so-called rational method is inapplicable in view of the availability of better hydrologic knowledge and the lack of data or experience on which to base selection of the runoff coefficient C of the rational formula—

$$Q = C\,I\,A \qquad (1)$$

—in which Q is the rate of runoff, in cubic feet per second; I is the intensity of rainfall, in inches per hour; and A is the drainage area, in acres.

Using only accepted hydrologic engineering principles and generally available data, it is possible to develop a procedure whereby values of q, the discharge per unit width, may be directly determined. Such procedures involve: (1) Choice of gross rainfall patterns or critical rates for various durations for the agreed frequency (in this case two years); (2) selection of an infiltration capacity curve representative of soil and cover conditions under average antecedent circumstances; (3) correlation of the infiltration capacity curve with the gross rainfall, to secure a net supply pattern; (4) further correction of the net supply pattern by abstraction of retention from the first excess rainfall; (5) determination of the effect of surface detention in altering the shape and peak of the net supply pattern through the requirements of overland or sheet flow; and (6) determinations, required for the ponded areas in the airport, of the effects of pond storage on the shape and peak of the inflow hydrograph in its translation to an outflow hydrograph. For urban areas, similar procedures have been developed as in Los Angeles,[2] Calif., and St. Louis.[3] Also, the United States Engineer Department has adopted a general procedure for the design of airport drainage,[4] and is making systematic observations of rainfall and runoff at selected military airports for the purpose of checking and improving design procedure.

Organization of Basic Rainfall Data

The customary rainfall-duration curve for any specific frequency, such as is shown in Fig. 2, gives only the average precipitation intensity for any particular duration and supplies no information as to how the intensity varies from the average during the duration period—and the intensity practically always does vary in nature. Neither does the curve suggest how these isolated periods are involved in storms as a whole.

Since detailed knowledge of both these matters is necessary to the methodology presented, a special analysis is carried out in the following manner: For the St. Louis area,[5] detailed rainfall data forming the basis of the statistical studies for the development of the two-year frequency rainfall curve shown in Fig. 2 are available. For each duration a sample of about twelve

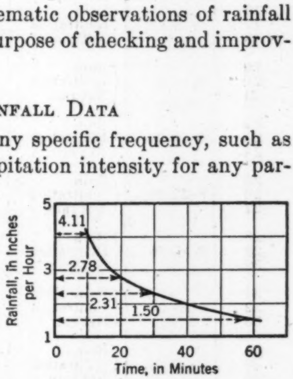

Fig. 2.—Rainfall-Duration Relation for Two-Year Frequency in the St. Louis Area

individual storms was chosen, well distributed throughout the series, with the same average precipitation rate for the critical period as that shown on the two-year frequency curve.

INFILTRATION CAPACITY OF TURFED AREAS

The United States Department of Agriculture, through measurements of flow from small watersheds and from infiltrometer applications, has produced a large number of infiltration capacity curves for various soils with grass cover, generally for agricultural areas used as meadow or pasture. At least two studies have been made of the infiltration capacity of such turfed areas as would be normal for airfields. These areas would be similar in surface condition to city lawns. One such series was carried out at St. Louis for lawn grass on a yellow clay subsoil; the other in Anacostia Park, at Washington, D. C., for lawn grass on hydraulic fill subsoil consisting of mud dredged from the Potomac River. For similar antecedent conditions the values for these two areas are very nearly identical. Curve (*a*), Fig. 4, is representative of the values at either location for generally wet seasonal conditions and heavy rainfall within the preceding 24 hours. Curve (*b*) is representative of St. Louis conditions under average summer monthly rainfall with no considerable application of precipitation for the preceding three days. Undoubtedly, for very dry summer conditions with considerable soil checking, a much higher series of values would prevail.

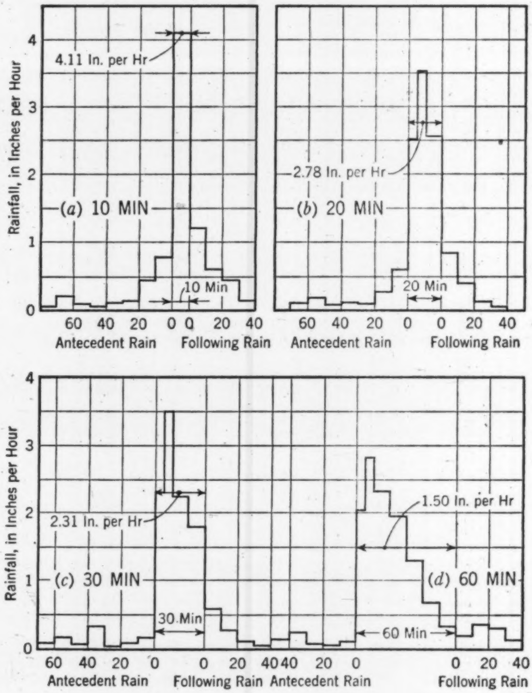

FIG. 3.—AVERAGE RAINFALL PATTERNS FOR STORMS OF VARIOUS DURATION PERIODS IN THE TWO-YEAR FREQUENCY SERIES

Infiltration capacity values shown in Fig. 4 may be accepted as reasonably representative of the values for a turfed cover for a rather wide range of soils. There is little artificial compaction such as would occur from trampling of the surface under intensive recreational use or from walking over city lawns. In all probability, representative curves for city lawns would be slightly lower than those shown. For sandy loams or sands, values would be materially higher.

RELATING INFILTRATION CAPACITY TO RAINFALL OCCURRENCE

Since the objective is to develop runoff values which on the average will be equaled or exceeded once in two years, the sample critical rainfalls previously discussed should be matched by an infiltration capacity curve which is normal for the turf areas at the time of occurrence. Also, the curves should be properly related on the basis of the rainfall preceding the critical period. For the sample rains, the average elapsed time to the preceding rain was 3 days, and the average mass of the preceding rain was about 0.4 in. These conditions compare closely to normal summer conditions for the area and result in the conclusion that, on the average, curve (*b*), Fig. 4, is properly applicable during the occurrence of these storms. Applying an initial value of 3 in. per hr as the probable infiltration capacity rate at the beginning of rainfall, curve (*b*), Fig. 4, was matched to the rainfall pattern in each of the representative sample storms.

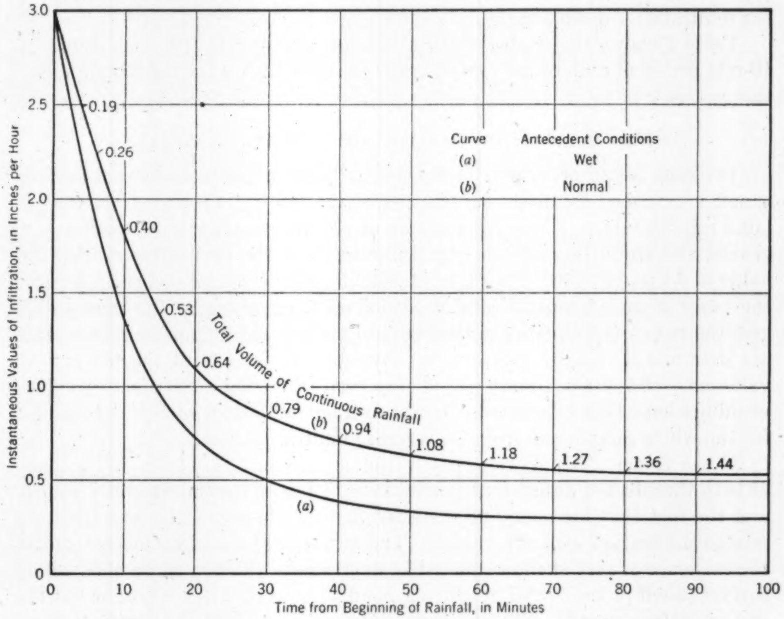

FIG. 4.—INFILTRATION CAPACITY CURVES FOR WET AND NORMAL ANTECEDENT CONDITIONS OF TURF AREAS

To obtain infiltration values (such as are given in Table 1) that would apply to each 5-min or 10-min rainfall period, the following principle was used: On curve (*b*), Fig. 4, are indorsed, at various points, the mass infiltration that could occur up to each time if the rainfall at all times until then equaled or exceeded the rates shown on the infiltration capacity curve. For example, at capacity rates, the total possible mass infiltration between 15 min (0.53 in.) and 20 min (0.64 in.) is 0.11 in. Whenever the rainfall rate exceeds the infiltration capacity rates throughout any one time period, the drop in average infiltration capacity from one period to another follows curve (*b*), Fig. 4. Whenever the rainfall rate falls below the infiltration capacity values for normal antecedent conditions, the position of the actual infiltration rate at the end of such a time period is assumed to be at the value shown by the infiltration capacity curve corresponding to the same actual incremental mass infiltration interpolated on the curve. This relationship between infiltration capacity, actual rate, and mass is only approximate, but it is sufficiently well indicated to justify its use in positioning the infiltration capacity curve.

Table 1 shows the related infiltration and rainfall rates for each 5-min or 10-min period of each of the representative sample storms for the 20-min duration period.

NET SURFACE RUNOFF FOR 100% PERVIOUS AREAS

For each 5-min or 10-min period of the rains in Table 1, the net surface runoff is obtained by direct subtraction of the infiltration rates from the related rainfall rates. These rates represent production of surface runoff at the ground and are further adjusted by deducting from the first excess rainfall the value of 0.1 in. to allow for surface retention. The results so secured represent the series of surface supply rates produced on the average by the rains which give the two-year frequency critical 20-min period. More particularly, values are determined rain by rain and no averaging is done until the net supply values in each 5-min or 10-min period have been calculated. Satisfactory values could not have been calculated from the average rainfall for each 10-min period for the whole sample and from the average infiltration rate.

These values of supply rates result from a procedure that takes full account of both the effect of antecedent rainfall in reducing infiltration capacity values, and the fact that for many storms rainfall rates are sometimes less than the related infiltration capacity values. The adjustment for retention recognizes the existence of very shallow saucer-like depressions which must be filled before surface runoff proceeds and in which a small amount of water is retained at the end of surface runoff. The procedure also makes evident the infiltration capacity rates that will exist after the end of production of net supply, and therefore permits evaluation of the additional infiltration that will result from overland flow during the recession of the hydrograph.

RUNOFF FROM PARTLY IMPERVIOUS AIRPORT AREAS

The procedure thus far gives fully realistic values of runoff from wholly pervious surfaces where infiltration is proceeding throughout. However, in the majority of the ponded interpavement areas, water is discharged from half-runways or half-taxiways on to the turf. These mixed areas are designated by the percentage of impervious surface.

It should be possible to evaluate such mixed areas satisfactorily by assuming that the discharge from the pavement, after a slight deduction (0.05 in.) for retention on the pavement, can be considered as resulting from a proportionate increase of rainfall on the turfed area. For example, for a 30% impervious area, the impervious part is three sevenths of the turfed part, and the rainfall pattern accordingly can be increased item by item to ten sevenths of the original value. This procedure has been followed for each of the selected sample rains in each of the duration series and for imperviousnesses of 10%, 30%, and 50%—the range of values encountered in airport drainage.

With these modified rainfall patterns, infiltration capacities were recomputed for each successive time period for each sample rain, and new patterns of supply were prepared in the same manner as in Table 1. When the antecedent rainfall on the turf is assumed increased in this manner, infiltration capacities at the beginning of the critical duration are successively reduced below those originally computed, and hence the resulting supply rate patterns are increased not only by higher rainfall rates but also by reduction of infiltration capacity. Fig. 5 shows patterns for one rainfall duration and four percentages of imperviousness.

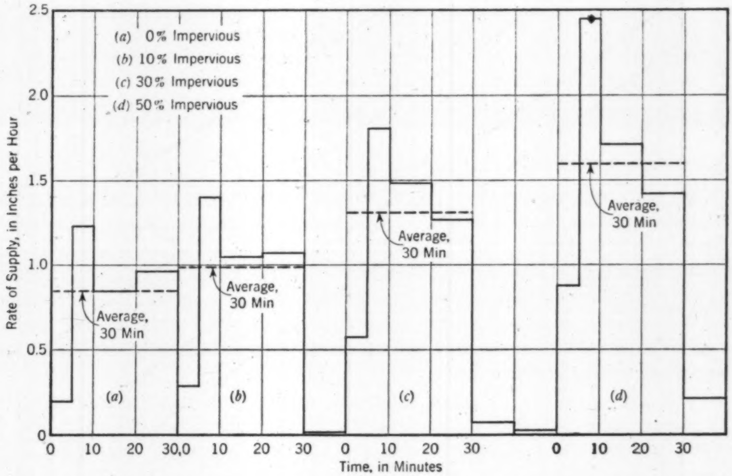

FIG. 5.—PATTERNS OF SURFACE RUNOFF SUPPLY RATES FOR 30-MIN RAINFALL PERIOD AND VARIOUS PERCENTAGES OF IMPERVIOUSNESS

The question naturally arises as to the physical propriety of treating water poured on the upper margin of the turf from the pavement as the equivalent of additional distributed rainfall over the turf. This matter has been subjected to rough analytical checks. Generally the velocities of flow over the turf are sufficiently high so that some of the water entering the upper margin near the beginning of the rain will arrive at the outlet by the end of the critical period. The water from the pavement should become distributed over the turf strip within a critical duration. No doubt, the actual distribution is not the same as that resulting from the assumption, but this difference does not seem great enough to alter either the average detention on the turf or the critical rate of outflow from the lower margin of the turf.

Fig. 6 shows the entire series of supply rates for the various durations and percentages of imperviousness considered. These two-year frequency values are related to an all-turf area and must be adjusted by multiplying by 0.5, 0.7, 0.9, and 1.0 to obtain the supply rates applicable to the entire area for 50%, 30%, 10%, and 0% imperviousnesses, respectively. The encircled points are those computed by averaging representative rains (properly related to the two-year frequency average intensities for various durations).

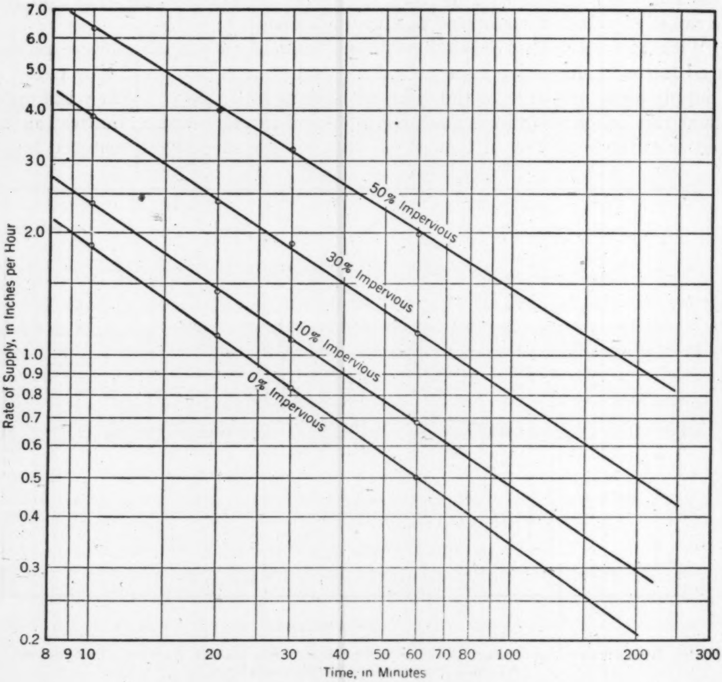

FIG. 6.—TWO-YEAR FREQUENCY SUPPLY RATES FOR VARIOUS PERCENTAGES OF IMPERVIOUSNESS AND DURATIONS OF MAXIMUM PERIOD OF SUPPLY

RATES OF INFLOW TO PONDS OR INLETS

With the supply patterns available for various durations and various percentages of impervious area, it becomes necessary to determine the hydrographs of inflow to the ponds or inlets. Thus, an evaluation of the effects of overland flow is required.

On the impervious areas, the supply for surface runoff quickly develops a thin film through which flow takes place down the slope to the upper edge of the adjacent turf. For the lengths and slopes involved in half-runways and half-taxiways, flow is quite rapid and reaches equilibrium in from about 2 min to 5 min; thereafter, for a constant supply rate, discharge from the pavement on to the turf continues equal to the supply rate. As discussed previously, the assumption is made that the effects of runoff from the pavement may be treated by adjustment of the rainfall on the turf.

Characteristics of flow over turf are quite different. As the rainfall builds up supply within the grass, flow takes place down the slope between the grass blades at comparatively low velocities. For determining the outflow rate at the lower margin of a turf strip and the related depth of surface detention on the turf, the following formula developed by the late R. E. Horton,[6] M. ASCE, have been used:

$$q = \sigma \tanh^2 \left(\frac{K \sqrt{3{,}520}\, S^{0.25} \sigma^{0.50} t}{60\, l^{0.50}} \right) \dots\dots\dots\dots\dots (2)$$

and

$$\delta = \frac{l^{0.5} \sigma^{0.5}}{S^{0.25} \sqrt{3{,}520}} \tanh \left(\frac{K \sqrt{3{,}520}\, \sigma^{0.5} S^{0.25} t}{60\, l^{0.5}} \right) \dots\dots\dots\dots (3)$$

in which q is the outflow rate, in inches per hour, at the lower margin of a turf strip; σ is the supply rate, in inches per hour; tanh is the hyperbolic tangent; t is the time of supply, in minutes; δ is the depth of flow, in inches, at the lower margin of the turf; l is the length of overland flow, in feet; S is the absolute slope of the turf strip; and K is the reciprocal of the ratio of the average depth to that at the margin. The numerical coefficient 3,520 was selected from pertinent experimental data for good bluegrass turf—closely checking the n-value of 0.400 used by the United States Army Engineers.[7] This n-value is not strictly comparable to the Manning n. An average overland flow slope of 1.75% has been used for all pervious areas.

Mr. Horton found that, for overland flow over turf, the profile is essentially parabolic with an average depth two thirds of that at the margin. Where additional supply is poured on to the upper margin from pavement, the profile will involve greater depths in the upper part of the turf strip and the average depth will be somewhat greater than two thirds. For 50% impervious areas the average depth has been assumed as fourth fifths and intermediate values were used for the lesser amounts of imperviousness.

Eqs. 2 and 3 are for strips of uniform width and are, therefore, rigorously applicable only to a rectangular area where the flow arrives along one margin. In practically all airfield grading, the pockets are essentially inverted pyramids with the flow converging toward a central inlet. The flow, therefore, may be visualized as occurring on triangular strips with an average width of 1 ft. For this situation, the overland flow hydrograph is so complex that it cannot be reduced to usable mathematical equations. A rough analysis indicates that the total detention on the triangular strip may be slightly less than that of the equivalent rectangular strip, and the discharge at the lower margin may be slightly greater. The differences, however, are not great and the basic formulas have been used to determine the rates of flow into the pond or inlet.

age supply rate for the critical period. The differences are not great and, in all computations for peak rate to the inlet, the average supply rate has been used. Examination of a number of such hydrographs indicates that a straight line, C, can be adopted without appreciable error, with the shaded area representing water in detention storage at the end of the critical period. This water, reduced by some further infiltration, supplies the recession side of the hydrograph marked A before correction for additional infiltration and, after such correction, hydrograph R. A number of recession curves indicate again the propriety of a straight line for design purposes and in all cases the overland flow hydrograph has been assumed to be a triangle as shown in Fig. 7, with the peak rate q_p constituting the altitude and with the area of the triangle equal to the mass runoff, m.

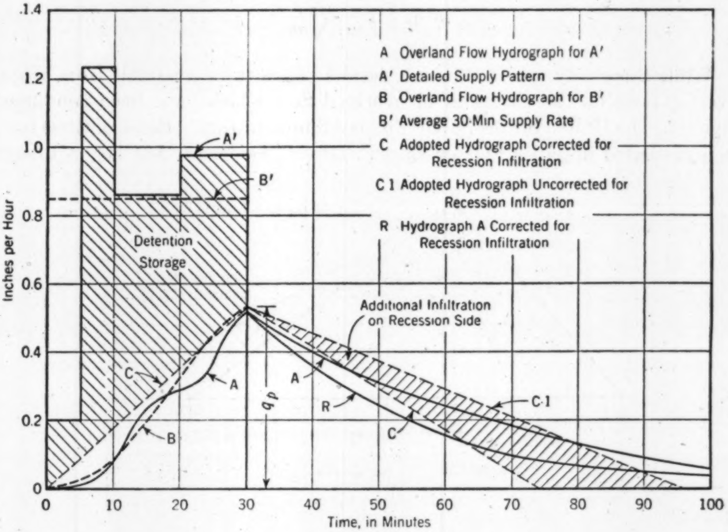

FIG. 7.—SUPPLY AND RUNOFF CURVES FOR 30-MIN SUPPLY ON 0% IMPERVIOUS AREA WITH OVERLAND FLOW LENGTH OF 185 FT AND SLOPE OF 1.75%

Likewise, the method of correcting for recession infiltration is shown in Fig. 8 and Table 2. In Fig. 8, area ABC represents the corrected mass runoff, m (Col. 10, Table 2); area A′BC′ represents p, the available mass pondage; and area CBD represents F, the mass infiltration, on the recession side of the hydrograph. All mass units are in inches of depth over the entire tributary area. In these determinations it has been assumed that the average infiltration capacity rate f is fully effective during only one third of the entire recession time. This assumption is necessary because the receding sheet of overland flow after cessation of supply covers a diminishing part of the total area and consequently the infiltration opportunity progressively becomes less. Thus,

$$F = \frac{q_p X}{2 \times 60} = \frac{(t_r - X) f}{3 \times 60} \qquad \text{(4)}$$

and

$$X = \frac{t_r f}{1.5\, q_p + f} \quad\text{.........................}(5)$$

Also, from similar triangles,

$$q_o = q_p \left(1 - \sqrt{\frac{p}{m}} \right) \quad\text{.....................}(6)$$

While this study was in progress, results began to be available from actual investigations on the character of overland flow which have been conducted largely by the United States Public Roads Administration. Some of these have been presented in papers[8,9,10] by Carl F. Izzard, Assoc. M. ASCE. Although the studies were primarily on pavement surfaces, including aprons and runways, a number of runs were made on turfed surfaces.

FIG. 8.—SCHEMATIC REPRESENTATION OF TRIANGULAR HYDROGRAPH SHOWING ADJUSTMENT FOR INFILTRATION ON RECESSION SIDE

Several comparisons have been made between the data developed by Mr. Izzard and those computed by the Horton formulas. For 30-min rains and overland flow lengths of from 150 ft to 200 ft, the two sets of values are very closely in accord. However, on 10-min rains, Mr. Izzard's values are only about two thirds of those computed by the Horton equation. There is a question, therefore, whether the application of the Horton equation to periods of short duration may not indicate excessive values of inflow to the ponds.

In Tables 3 and 4, design values are prepared for a three-inlet system for duration periods of from 10 min to 60 min. If Mr. Izzard's data are applicable, the 10-min flows to the ponds will be reduced to about two thirds of those shown and the 20-min inflow rates will be slightly reduced. Thus, for this particular system, the 20-min or 30-min rain would be critical and the correct design rate for the outlet pipe would be about 12 cu ft per sec instead of 14 cu ft per sec. If the outlet were actually designed for a flow of 14 cu ft per sec, there would

be less utilization of storage in the ponds, so that the ponds would stand at slightly lower levels than those indicated in Table 3 and Fig. 9.

Since the overdesign is apparently not great (in fact in this instance it would have been impossible to use a smaller commercial pipe size), and since all the basic design data are predicated upon the Horton equations, the illustrative examples will be calculated from those data.

BASIC DESIGN DATA

For the two-year frequency rainfall, the values of the peak rate of runoff, q_p, in inches per hour or in cubic feet per second per acre, and the values of the related mass runoff m, in inches, have been determined. These values have been calculated directly from the supply rates for the 10-min, 20-min, 30-min, and 60-min durations; for other durations, such as 45 min and 90 min, corresponding supply rates have been extrapolated from Fig. 6. The values have been determined separately for areas of 0%, 10%, 30%, and 50% imperviousnesses, and for turf lengths of overland flow of from 100 ft to 500 ft. Different plottings have been prepared to make available the best facility for interpolation. Figs. 10 and 11 show typical sheets relating q_p and m to length of overland flow for 30% imperviousness and for various times of supply.

USE OF HYDROGRAPHS IN DESIGN

Where no deliberate storage ponding is possible, the inflow hydrograph to the inlet may be assumed to be triangular with its peak flow rate and mass runoff determined by selection from the basic design data. Such hydrographs may be offset by the time of flow from one inlet to another, and the peak rate of flow below any inlet may be determined by the addition of ordinates.

Where pondage is practicable, the triangular hydrograph represents inflow to the pond from which a simple determination can be made for the outflow rate as reduced by detention storage in the pond. In Fig. 8, from the properties of a triangle, the relation between inflow, outflow, pondage, and mass runoff can be expressed as Q_o (in cubic feet per second) = Q_p (in cubic feet per second) $\times \left(1 - \sqrt{\frac{p}{m}}\right)$, with both p, the mass pondage, and m, the mass runoff, in inches of depth over the entire tributary area. For any particular inlet area, the values of Q_p (q_p from design graphs times the total area), m (from the design diagrams), and p (the permissible pondage developed from the field grading plans) are available. Then Q_o is the minimum outflow capacity that must be provided if the pondage is not to exceed that computed as the desirable maximum. However, it should be remembered that the pyramidal shape of the ponds permits an appreciable change in volume without any large change either in depth, or in the distance from margin of pond to pavement. To accommodate commercial pipe sizes, the initial or optimum values of p obtained from the grading plan may, therefore, be varied somewhat in the course of design. Changes in pond depths are assumed to vary with the cube roots of the related pond volumes.

FIG. 9.—PROFILE AND HYDRAULIC FACTORS FOR THREE-POND SYSTEM

APPLICATION OF BASIC DATA AND HYDROGRAPHS IN ACTUAL DESIGN

The principle of designing the field drainage system, which takes advantage of permissible ponding in the intra-runway pockets, requires that the outlet capacity from any one pocket be the same as the calculated outflow rate from that pocket when the inflow to it has been reduced by the available detention storage. Thus, the objective of the design of the pipe system is to develop pipe capacities which will throttle the outflow from the ponds to such an extent that the permissible pondage will be utilized.

If the grading plan provides a series of pockets with the water surface elevations descending in order toward the outlet of the system, it is entirely feasible to provide pipes of such capacity that the ponds will "float on the line." Where this can be done, inlet manholes with adequate gratings can be placed at the low point in each pond. In actual operation a water column will be descending through the manholes and the acceleration of the water from zero velocity in the pond to the velocity in the outgoing pipe will utilize a velocity head equal to $\frac{V^2}{2g}$. In addition, there will be entrance losses through the grating and at the bottom of the manhole; and, to provide for this, the total entrance head including velocity head and entrance losses has been treated as $1.5\,\frac{V^2}{2g}$. Thus, the hydraulic gradient in the pipe line at any particular inlet manhole must be lower than the level of the pond in the amount indicated by this expression, and pipe capacities must be based on the hydraulic gradient so determined.

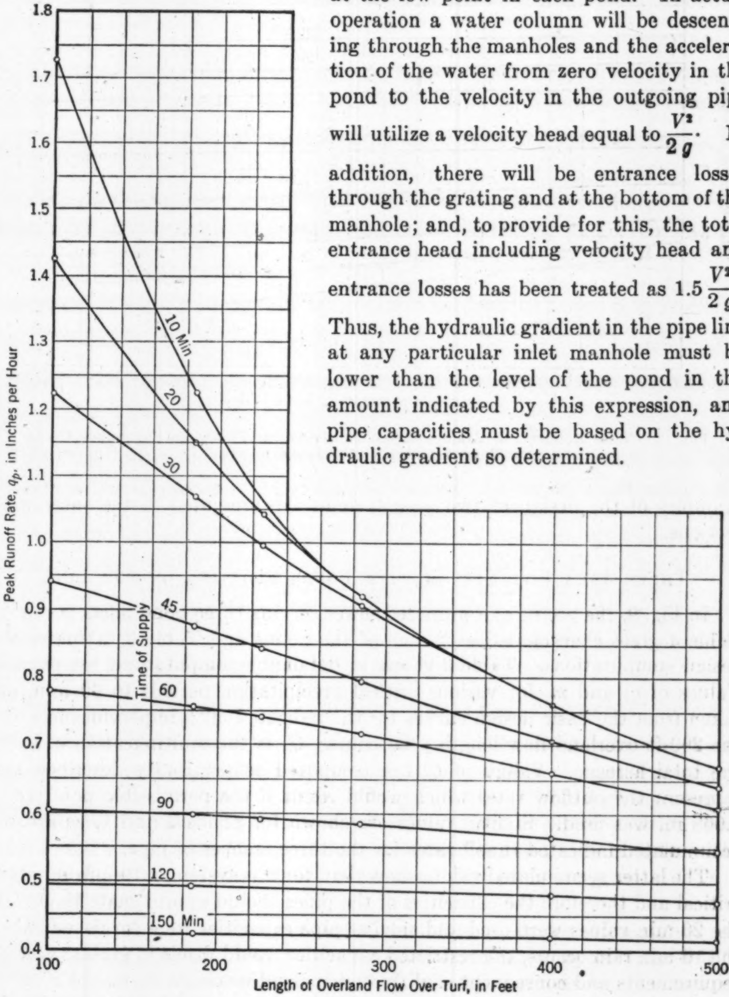

FIG. 10.—PEAK RUNOFF RATES FOR VARIOUS DURATIONS OF RAINFALL IN TWO-YEAR FREQUENCY CYCLE ON TURF AREA WITH 30% IMPERVIOUSNESS

Obviously, when the nearest commercial size pipes have been selected, both the flow rates in the pipes and the concordant surface elevations of the ponds will, in the state of equilibrium, become stabilized with slightly different values than those indicated by permissible storage from the ponds alone. Actual examples of the design of two pipe systems are presented in the succeeding sections.

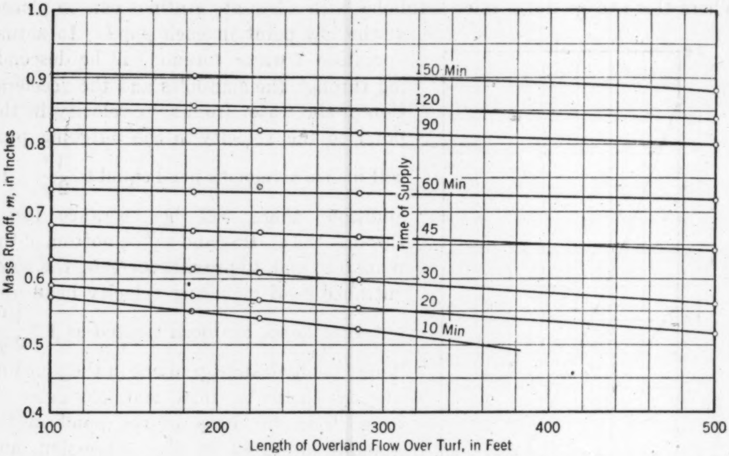

FIG. 11.—MASS RUNOFF FOR VARIOUS STORM DURATIONS IN TWO-YEAR FREQUENCY CYCLE ON TURF AREA WITH 30% IMPERVIOUSNESS

THREE-AREA PIPE SYSTEM WITH PONDS FLOATING ON THE LINE

In Fig. 9, the profile of a proposed sewer serving three-pond inlets is shown. Table 4 gives characteristics of each of the ponds and Table 3 tabulates the design computations. Table 3 shows in detail the computations for pond 3. Values of q_p and m, for various critical precipitation periods to 60 min, are taken from the basic design curves for the indicated 30% imperviousness and the 200-ft overland flow length. Of course, Q_p is the multiplication of q_p by the total acreage. Values of Q_o are computed as previously described and represent the outflow rates which would result if the permissible pondage of 0.068 in. was used. Similar values are shown for ponds 2 and 1, as are the accumulated indicated runoff rates for the three reaches of pipe.

The latter accumulated values show that, for this system, a 10-min supply is critical and therefore the capacities of the pipes should approximate them. If the 20-min values were used and smaller pipe capacities were furnished, when the 10-min rain occurs, the restricted capacities would result in greater storage requirements and consequent slightly higher pond levels.

Using the 10-min runoffs an initial selection of pipe sizes can be made based on differences in permissible pond levels. This procedure gives the hydraulic grades shown in Col. 8, Table 3; and, for $n = 0.013$, pipe sizes of 19 in., 18 in., and 17 in. shown in Col. 9; obviously the commercial 18-in. pipe is indicated.

As will be noted later, design is practically complete. The pipes may be laid at satisfactory construction grades and will operate under pressure with the ponds floating on the system at slightly different elevations than those originally chosen. However, the actual outlet discharge rate must be accurately checked; and it is also desirable to demonstrate as a matter of experience just how the ponds will adjust themselves.

Accordingly, the chosen pipe system is re-analyzed in detail. The first step involves recognition of the entrance head and other minor losses required for the individual ponds. Col. 11, Table 3, shows the approximate values of $1.5 \frac{V^2}{2g}$, which, when plotted down from the chosen pond levels, give the revised hydraulic grades shown in Col. 12. At this point it is possible to visualize very nearly the values that will enter into an equilibrium condition in the system. For line 1–2, the final grade will probably be a little greater and the quantity a little smaller, since an 18-in. pipe is being used instead of the 19-in. pipe ideally indicated. Line 2–3 will involve a somewhat greater quantity because of a slightly higher gradient. Since the quantity coming in from line 1–2 will be somewhat less than the original value, it is clear that the discharge from pond 2 will be appreciably more than it was originally.

The 18-in. pipe is somewhat large for the line 3-outlet. However, some of this disadvantage is offset by the lower available grade; and, consequently, there should be a slight increase in discharge to the outlet.

From the foregoing it seems probable that the equilibrium flow rates with ponds floating on the line would be about as shown in Fig. 9. The equilibrium conditions determined from the use of these revised discharges are also shown in Fig. 9 and indicate that pond 3 will stand 0.08 ft below the originally chosen value; pond 2, 0.10 ft below; and pond 1, 0.04 ft above. Ponds 2 and 3 are now in exact balance and pond 1 is within 0.01 ft of an exact balance.

Any check to within about 0.02 ft is considered satisfactory since the theoretical changes in pipe flows and pond levels accompanying such very small corrections would not affect the design in a practical way.

THREE-POND SYSTEM UNDER 30-MIN, TWO-YEAR FREQUENCY SUPPLY

Since the critical storm for the main trunk sewer into which the three-pond system discharges will be much longer than 10 min, it is necessary to investigate the rate of discharge that will occur for longer storms. Table 5 gives an analysis of the 30-min values for Q_p and m, with Q_o equal to the pipe capacities which were found to represent an equilibrium condition for the 10-min supply. The mass pondages and depths related to these outflow rates are given in Cols. 6 and 7.

From Table 5, it can be concluded, therefore, that, for storms of longer duration, the discharge from the chosen commercial-sized pipe system will be slightly less than the discharges for short storms, but less by so small an amount that the original value can be used in the design of the trunk system over a wide range of durations.

THREE-POND SYSTEM UNDER 30-MIN, TEN-YEAR FREQUENCY SUPPLY

Since the trunk sewer will carry an "off-field" flow based upon a ten-year frequency rainfall it is important to determine not only the rate of discharge from the three-pond system, but also the pond levels under the less frequent but greater rains. A preliminary calculation indicates that, for the higher supply rates of the ten-year rains, the 30-min duration produces the worst condition of ponding. This condition results because the longer rain permits overland flow more nearly to reach equilibrium, and the peak rates at the end of the rain are actually higher for the 30-min than for the 10-min duration. Also, the 30-min mass runoff is appreciably greater and hence uses more pondage volume.

TABLE 5.—ANALYSIS OF THREE-POND LINE FOR 30-MIN RAINFALL OF TWO-YEAR FREQUENCY

Pond No. (1)	Inflow, Q_p (cu ft per sec) (2)	Mass runoff, m (in.) (3)	Outflow, Q_o (cu ft per sec) (4)	Ratio, $\frac{Q_o}{Q_p}$ (5)	Mass pondage, p (in.) (6)	Pond depth (ft) (7)	Equilibrium outflow (cu ft per sec) (8)	Outflow below pond (cu ft per sec) (9)	Final pond depth (ft) (10)
1......	6.1	0.83	6.90	1.13	0	0	6.0	6.0	0
2......	6.0	0.61	2.37	0.39	0.23	0.95	3.10	9.10	0.81

Total..	19.2	....	14.95	....	....	....	14.90	....	....

The values in Table 6 are closely representative of an equilibrium condition under the occurrence of a ten-year frequency, 30-min rain, and it may be concluded that the discharge under the more severe conditions would increase a negligible amount (about 2%). Therefore, in the design of the main trunk sewers to carry the runoff from a ten-year frequency rain on the "off-field" area, the contributions of the ponded laterals can be taken to be the same as those obtained from the two-year frequency analysis.

1........	2.60	4.04	2.6	1.23	10.50	6.9	0.65	0.15	0.80
2....	2.25	5.84	2.05	1.09	11.97	2.4	0.20	0.70	1.38
3........	2.25	6.90	2.05	1.09	14.14	6.0	0.43	0.35	1.10
3-outlet...	....	....	....	....	36.61	15.30	....	....	....

For the half-foot higher pond elevations due to a ten-year storm, the edge of the ponds will be about 25 ft from the nearest pavement edges. Since this condition will occur on the average only once in ten years, and then will persist for only one or two hours, it is clear that no appreciable intrusion of soil moisture under the pavement subgrade will result, and the condition is one which may be safely accepted.

SEVEN-POND SYSTEM WITH "NONFLOATING" PONDS

Fig. 12 is a condensed profile in which the upper five ponds descend in order of elevation, but ponds 6 and 7 ascend. Obviously, no hydraulic grade could permit these two ponds to float on the line. In actual design the pipes connecting the upper five ponds are treated in the same manner as the previously discussed three-pond system; open grated manholes can be installed at the low points of these ponding areas.

FIG. 12.—PROFILE AND HYDRAULIC FACTORS FOR SEVEN-POND SYSTEM

For ponds 6 and 7, similar inlet manholes will be constructed but they will be connected to the main system by small laterals so chosen in size and length as satisfactorily to throttle discharge from the ponds. Discharge from the ponds will then be determined in no direct way by the capacity of the pipes in the main system.

Determination of outlet rates as related to the permissible pondage for each of the areas is given in Table 7. It is interesting to note that, for pond 7, Q_o is given as 0 for the 10-min time—because the permissible pondage is greater than the whole of the mass rainfall. However, an outlet pipe is required to drain the pond and a specific discharge rate will exist during the rain. In

Table 8, it will be noted that a nominal value of 1 cu ft per sec has been initially assumed.

The totals at the outlet as shown in Table 7 indicate that the 10-min critical rainfall produces the largest runoff, and the design of the pipe system is worked out to handle these rates adequately (Col. 8, Table 7) without appreciably exceeding the desirable pond depths.

Table 8 summarizes the design information. Final equilibrium gradients and pond levels are shown in Fig. 12.

It must be understood that equilibrium flow conditions require not only a balanced scheme of hydraulic gradients but also outflow rates from the ponds (which make up the discharge values of the pipe system) resulting from the pondage depths which are in balance with the hydraulic grades of the pipe system. For example, at pond 5, the hydraulic grade of the outgoing pipe is 110.63, the velocity in the pipe is 3.6 ft per sec, and 1.5 times the velocity head is 0.31 ft. In other words, the elevation of the pond floating on the line at a static elevation which will provide the necessary velocity and entrance loss heads is 110.63 plus 0.31 or 110.94. From Table 7, it is noted that the peak flow rate to this pond is 13.5 cu ft per sec; and the outflow rate is 7.12 cu per sec (Table 8). For the pond to reduce the runoff rate by this amount, the volume of pondage must be 0.20 in., equivalent to a 0.99-ft depth. When this value is added to the elevation of the inlet grating, the surface of the pond checks the 110.94 elevation obtained, indicating that the pipe system and the detention pondage are in accord. As previously stated, any check to within about 0.02 ft is ordinarily considered satisfactory.

Total..	....	....	....	....	84.7	....	22.2	77.4	....	21.2

To complete the design of this system, the connecting pipes for ponds 6 and 7 must be selected. For pond 6, the desired outflow of 1.5 cu ft per sec occurs when the pond level is 111.20 and the available fall from this water surface to the hydraulic gradient of the pipe line is 1.19 ft. If an 8-in. pipe is used, the velocity head plus entrance loss is 0.42 ft. Thus, 0.77 ft is available for friction loss; and, since the 8-in. pipe requires a gradient of 0.0152, the necessary resistance would accordingly be provided by a pipe connection 50.6 ft long. A similar analysis for a flow of 2.3 cu ft per sec from pond 7 results in an 8-in.

pipe connection 26.5 ft long. The computed connection lengths are quite important and must actually be used in the plan if outflows from these ponds are to be throttled to the amounts indicated.

RELATION OF FLOW TIME THROUGH PIPES TO OUTLET DISCHARGE RATE

In the foregoing discussion the flow through any reach of pipe has been taken as the sum of the inflows at all points upstream. This procedure is correct since all hydrographs resulting from restricted pond outflow will have flat tops of such considerable duration as to overlap. Fig. 13 shows this characteristic of the outflow hydrographs for the seven-pond system.

Table 9 gives pertinent data required for the preparation of the hydrographs. Cols. 2, 3, and 4 are taken from Tables 7 and 8. Col. 5 represents the time length of the rising side of the hydrograph, obtained by multiplying the 10-min time at which Q_p would have occurred if no pondage were available by the ratio of Q_o to Q_p. This relationship arises out of the properties of the assumed triangular hydrograph.

Col. 6 is the average time length of the hydrograph from the center of the rising side to the center of the recession. It is obtained by changing the values of m in Col. 4 to cubic feet and then dividing by Q_o. Col. 7 gives the times of flow in each reach of pipe. These times between ponds are based on length and average velocity as it is believed that for these small lines the higher flow rate of wave velocity can be ignored, particularly inasmuch as the summation would not be affected by the changes that refinement would produce.

Direct addition of the ordinates of all the hydrographs gives the hydrograph of discharge at the outlet for the system. The exact shape of the rising side is necessarily approximate since the discharges are based on the critical hydraulic grades for maximum discharge; and, during the rising side, partial flows, lower hydraulic grades, and somewhat different discharges from the ponds can take place. The error in ignoring this condition is quite small and affects only the shape of the rising side, not the peak values.

For this seven-pond system with a 16-min pipe flow time, under the application of the two-year, 10-min rain, the maximum discharge will be reached in about 10 min and will persist for somewhat longer than 40 min from the beginning of the critical 10-min rain. Particularly noteworthy is the fact that for a period of more than 20 min all hydrographs are flat topped and their values can be added directly.

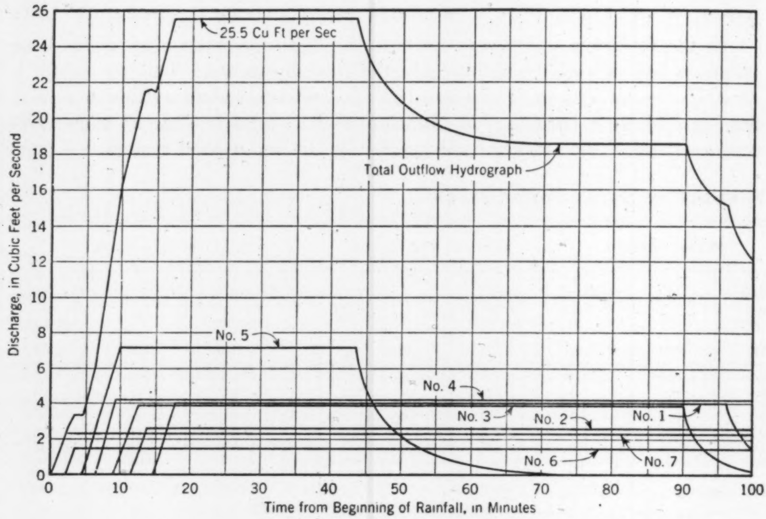

FIG. 13.—SUMMATION OF HYDROGRAPHS FOR SEVEN-POND SYSTEM

For the three-pond example, it was shown that there would be no appreciable difference in the discharge rate at the outlet under the occurrence of the

two-year, 10-min rain, the two-year, 30-min rain, or the ten-year, 30-min rain. Plotting similar to that of Fig. 13 shows that both the first and last of these rains, which represent the most severe conditions, have long flat topped hydrographs extending for 20 min or more. The two-year, 30-min rain, because two of the inlets use very little pondage, comes almost to a peak, but still has a flat top of about 5-min duration.

SUMMARY

Where surface drainage of airports permits the development and utilization of pondage in the flat turfed areas, accepted hydrologic knowledge concerning retention, infiltration, and overland flow is directly applicable. The development of supply rates requires an analysis of actual storms and their related infiltration values so selected as to result in surface supply rates produced, on the average, by the rains which give the critical average rates of the desired frequency. For facility of design, hydrographs of inflow to ponds can be considered triangular in shape.

The pondage resulting from the very flat grades required in airports can be allowed to "float" on the line and has the fortuitous characteristic of very small depth changes (and consequent minor differences in actual hydraulic gradient between ponds) for relatively large pondage volume changes. Once commercial pipe sizes are chosen for a definite duration and frequency, their capacities vary insignificantly for rains of longer duration or greater frequency. Pondage so flattens the hydrograph that direct addition of pond outflow rates can be used, obviating the laborious offsetting of each outflow hydrograph.

ACKNOWLEDGMENTS

This paper resulted from studies initiated by W. W. Horner, Past-President, ASCE, and had the benefit of his collaboration and constructive criticism. The studies were part of a "Report on Basis of Design for Field and Off-Field Drainage Systems for Lambert-St. Louis Municipal Airport" submitted to Milton M. Kinsey, president of the Board of Public Service of St. Louis, and reviewed by Guy Brown, M. ASCE, chief engineer, and E. J. A. Gain, Assoc. M. ASCE, engineer, Division of Sewers and Paving, Board of Public Service of St. Louis,

DISCUSSION

H. M. Williams,[11] **Assoc. M. ASCE.**—With the increasing tendency for airport planning, design, and construction to become major fields of endeavor for the private engineer, there is a definite need for such papers as Mr. Jens' excellent contribution on airport drainage, which crystallizes recent technical developments. Certain phases of the paper, however, do excite further discussion.

The assertion that airfield drainage areas have "accurately determinable characteristics" (see "General Discussion of Method") should be viewed with discretion. Such features may be accurately determined on the drafting table, but when translated to field construction and field maintenance conditions they frequently suffer major divergencies from the design plans. In recent field drainage investigations by the Corps of Engineers, United States Army, inability to define drainage boundaries permanently and accurately has been encountered—even where low dikes or artificial drainage divides were constructed with a degree of engineering control not usually possible in normal construction operations. Inability to maintain constant drainage areas usually resulted from vehicular or airplane traffic over the turfed areas, or from the gradual consolidation and deterioration of the small drainage divides. Rutting by wheeled traffic has also been observed to cause concentration or channeling of flow with a resultant change in the runoff characteristics of the drainage area. Erosion, in some cases, resulted in increasing or decreasing the design drainage area. In one unusual condition a turfed airfield test area about 75 acres in extent frequently indicated runoff in excess of 100%, despite careful and extensive investigation and examination of automatic measuring devices, drainage divides, topography, soils, and ground-water conditions. In connection with paved surfaces, several instances have been noted where an apparent increase in drainage area resulted from wind driving surface water over low drainage divides. The foregoing data are presented, not to discredit the desirable design refinements suggested in this excellent paper, but rather to remind the reader of the wide gap that frequently exists between the design and the actual construction and functioning of field installations. It is suggested that use of reasonable safety factors, based on sound engineering judgment and experience, must still be provided, despite the niceties of design justified by recent hydrologic research.

Reference is made to the method used in several recent airport drainage papers (including the author's) for determining the outflow peak discharge by subtracting the available storage from the peak of the inflow hydrograph. The method assumes a constant head-discharge relation on the drain inlet and results in an outflow hydrograph with an extended flat peak (see Fig. 8). This assumption is an acknowledged approximation that has hitherto been considered not to introduce serious error. However, current studies in the Airfields Branch Office of the Chief of Engineers on design methods for combination drains have indicated that, when a varying head-discharge relation more nearly reflecting field conditions is used, a considerable increase in the peak outflow may be expected over that obtained by the author's method.

---

[11] Senior Engr., U. S. Corps of Engrs., Washington, D. C.

In the case of the combination drain it was noted that the peak discharge obtained by routing with the variable head-discharge relation was approximately 1.5 times the average discharge obtained by the author's method for conditions where the ratio of volume of storage to supply was greater than 30%. Between storage supply ratios of 30% and zero, the ratio of the routed peak to the average peak apparently decreased from 1.5 to unity as a straight-line relation. In the case of a typical field inlet where the flow is collected at a point rather than along a length of combination drains, it is believed that the foregoing ratio of 1.5 reduces to approximately 1.3. This relation conforms, in general, with the results of other routing studies.[12]

The writer is not fully convinced of the necessity of using storm patterns in the design of airfield drainage systems. Inability to predetermine infiltration values accurately, the "leveling effect" on the hydrograph of a relatively small amount of storage, and the major divergencies between the storm pattern for a given occurrence and the average pattern, all contribute to this conviction.

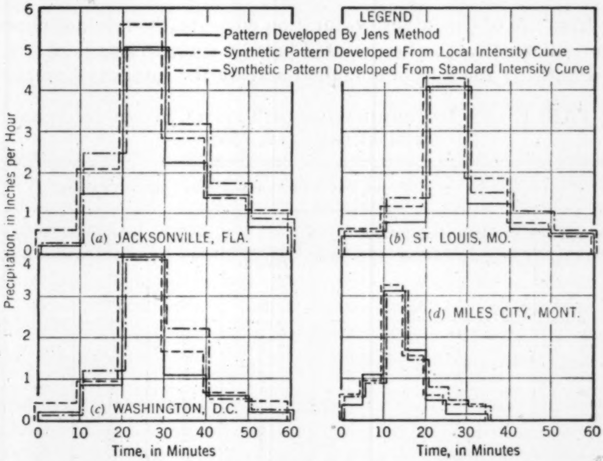

FIG. 14.—COMPARISON OF RAINFALL PATTERNS DEVELOPED BY VARIOUS METHODS FOR SELECTED LOCALITIES

However, when justification for using storm patterns is present, the amount of work required in developing the pattern may discourage its use, particularly in the case of small projects with limited engineering funds. In such cases it appears possible to approximate the storm pattern with a minimum amount of effort by an analysis of the rainfall-duration relation for the locality. This approach is suggested by the similarity between the procedure used by the author to secure intensities for storm patterns and the normal procedure for determining the intensity-duration curve. Disregarding pattern arrangement and considering only intensities, the author's method indicates the design frequency only for the selected critical period (other periods having intensities generally less than design frequency), whereas the use of the intensity-duration curve will give design frequency for all periods. However, the differences resulting from use of the intensity-duration curve method do not appear to be serious, as indicated by the four rainfall pattern comparisons shown in Fig. 14, developed both by the author's method and by the intensity-duration curve.

In Fig. 14, it should be noted that the local intensity curves are based on 10-year records except for St. Louis, Mo., where Fig. 2 was used. A typical computation for the synthesized pattern is indicated in Table 10.

The order in which the various intensities are to be assembled into a complete pattern can be obtained by a brief study of the relative magnitudes of the component parts of a few typical storm patterns. The procedure is illustrated in Table 11 for Miles City, Mont. It is interesting to note the similarity of the pattern arrangement obtained in Fig. 14, regardless of the widely separated geographical locations involved. Also of interest is the reasonable pattern obtained by use of the standard rainfall intensity-duration curves proposed by G. A. Hathaway,[4] M. ASCE, with the resultant elimination of the work necessary to establish the intensity-duration curve.

It should be noted that the rainfall data used for this study were taken from the annual weather bureau reports for the period prior to 1936. The method of reporting excessive intensities used since 1936 makes the use of these later records exceedingly difficult for developing storm patterns by the author's method. However, it should be noted that intensity-duration curves developed from records prior to 1936 are normally low by from 5% to 10%, as pointed out by the late D. L. Yarnell,[13] M. ASCE.

W. I. HICKS,[14] ESQ.—In this exposition of the fundamental principles used in drainage design for the Lambert-Municipal Airport at St. Louis (Mo.), it should be noted that the computations are based on data for a specific location, and that the data probably will be altered elsewhere. The method is based on utilization of a depressed turfed area, lying between paved runways, for the reduction of runoff volume by soil infiltration and for the reduction of runoff intensity by ponding. The interposition of open soil between the paved area and the drainage inlet allows the maximum use of these reductive factors. The paper shows conclusively that, when turfed impounding areas are available, a substantial saving in cost can be effected in drainage construction.

The method of developing the supply curve (Table 1) departs from the conventional analysis, which would involve computation of net rainfall for the significant rainstorms of record, development of a probability series for the different time durations, and determination of the predominant pattern of net rainfall intensities. The author has used a method of averaging gross and net rainfall of storms selected so as to make the average of the gross rainfall intensity identical with the two-year rainfall-duration curve in Fig. 2. The frequency of the selected values of gross rainfall intensity ranges from about ten years to less than one year (as determined by W. W. Horner, Past-President, ASCE, and F. L. Flynt,[15] Assoc. M. ASCE).

Comparison of the net rainfall patterns of the individual storms in Table 1 with the uniform rate pattern shows wide divergence with durations of individual storms varying from 5 min to 20 min within the significant 20-min duration. If Eq. 2 is altered in form for a supply duration of 20 min, a length of 185 ft, a slope of 1.75%, and a 0% imperviousness, and if it is set up for actual durations of 20 min, 15 min, 10 min, and 5 min, the results are, for the respective durations,

$$q = \sigma \tanh^2 (0.795\, \sigma^{0.5}) \qquad (7a)$$

$$q = 1.33\, \sigma \tanh^2 (0.689\, \sigma^{0.5}) \qquad (7b)$$

$$q = 2.00\, \sigma \tanh^2 (0.561\, \sigma^{0.5}) \qquad (7c)$$

and

$$q = 4.00\,\sigma \tanh^2 (0.398\,\sigma^{0.5}) \qquad (7d)$$

In Eqs. 7, the value of σ used is that for the 20-min duration of supply.

For a 20-min duration $\sigma = 1.0$ in. per hr, the values of q for actual time durations of 20 min, 15 min, 10 min, and 5 min, respectively, are 0.435, 0.480, 0.524, and 0.576 in. per hr, with added amounts explained by the fact that the supply ceases before equilibrium flow has been established; and the excess detention above equilibrium detention for given values of q causes the intensity of runoff to increase for a short time after the supply ceases. This increase is greater for small durations of supply than for large ones. The author apparently has used the method of G. A. Hathaway,[4] M. ASCE, in deriving the values in Table 2 and Fig. 10, with possibly some alteration because of infiltration after cessation of supply. For a 20-min duration $\sigma = 2.0$ in. per hr; similar values of q (before the addition in intensity because of surplus detention at the end of supply) are 1.30, 1.50, 1.76, and 2.14 in. per hr.

These analyses show a fairly wide divergence in values of q derived from a given volume of net rainfall when its duration varies from 20 min to 5 min, and suggest the alternative of basing the conception of duration on net rainfall rather than on gross rainfall. The effect of the change in analysis would be most significant in cases of summing hydrographs where no deliberate ponding is possible.

The infiltration curves in Fig. 4 are reasonably safe for all soils in which artificial compaction does not occur; it might be assumed that an open sandy soil would dispose of all rainfall by infiltration, with some temporary ponding for heavy storms, if it were possible to prevent clogging of the sand by the washing in of fine detritus and oil. The shape of the curve (rate of infiltration decreasing with time), the small value of antecedent precipitation for the heavy thunderstorms prevalent in St. Louis, and the frequent occurrence of the "advanced" type of storm make the tendency toward uniform supply rates greater in St. Louis than in Los Angeles (Calif.). There the heavy antecedent precipitation and the "delayed" type of storm reduce the infiltration rate to practical uniformity, particularly for the high intensities used in design. However, Table 1 indicates no universal trend toward uniformity.

In studying the derivation of the triangular hydrograph in Figs. 7 and 8, the writer derived an expression for the time required to secure practical equilibrium (t_e) in terms of average equilibrium detention (δ_a) and supply intensity (σ). When the parenthetical expressions in Eqs. 2 and 3 reach a value of 2.45, the square of the hyperbolic tangent is approximately 0.97, and practical equilibrium has been attained

$$t_e = \frac{2.45 \times 60\, l^{0.5}}{\sqrt{3{,}520}\, K\, S^{0.25}\, \sigma^{0.5}} = \frac{2.475\, l^{0.5}}{K\, S^{0.25}\, \sigma^{0.5}} \qquad (8)$$

Using the relation, $\delta_a = \delta/K$, and a value of 2.45 for the parenthetical expression, Eqs. 3 and 8 are combined to produce

$$t_e = \frac{150\,\delta_a}{\sigma} \qquad (9)$$

The writer has conducted a series of tests of overland flow on a number of surfaces, including clipped sod.[16] An examination of the data discloses, for clipped sod, the relation,

$$t_e = \frac{96\,\delta_a}{\sigma} \qquad \text{.........................(10)}$$

A comparison of the triangular intensity hydrograph with the one derived by Eq. 2 shows that, when the time duration of supply is less than 0.6 of the equilibrium time (as defined by Eq. 9), the intensities on the ascending leg of the triangular hydrograph exceed those of the hydrograph in Eq. 2, and the triangular hydrograph is overly safe. When the duration of supply is about 0.6 of the equilibrium time, the straight leg of the triangular hydrograph averages with the curved line from Eq. 2; and when the duration of supply equals and exceeds the time of equilibrium, the triangular hydrograph becomes increasingly deficient on the ascending leg.

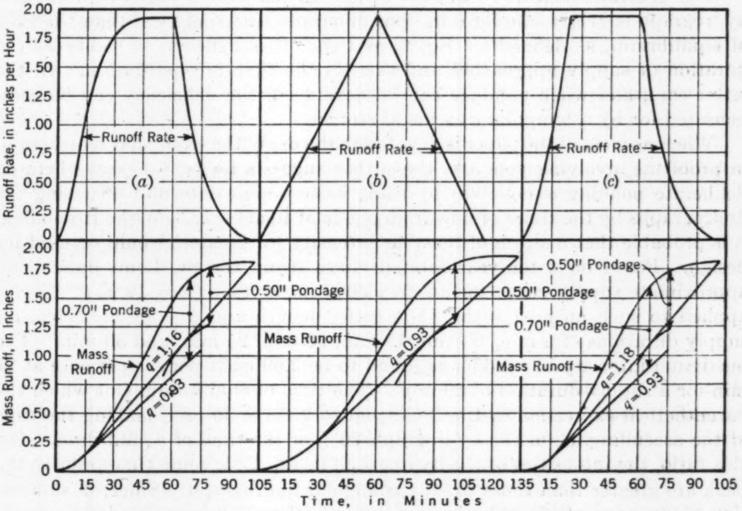

FIG. 15.—COMPARISON OF HYDROGRAPHS ON 50% IMPERVIOUS AREA WITH TURFED LENGTH OF 185 FT AND SLOPE OF 1.75%

For examining the effect of this divergence on the outflow curve under ponding, hydrographs were constructed for an area 50% impervious with a turfed length of 185 ft, a slope of 1.75%, and an approximate ten-year uniform supply curve for 60-min duration (3.86 in. per hr on the turfed area) using: (*a*) Eq. 2, (*b*) the triangular hydrograph derived from Eq. 2, and (*c*) Eq. 10 and the value of δ_a derived from Eq. 3.

These hydrographs are delineated in Fig. 15; in the top row are the intensity hydrographs and in the bottom row, the mass hydrographs. The intensity hydrograph in Fig. 15(*c*) is derived from the mass hydrograph, the reason being that the experimental runoff data for this case were measured volumetrically, not as intensities. The close agreement of the mass runoff curves in Figs. 15(*a*) and 15(*c*) furnishes experimental confirmation for Eq. 2, in so far as storage problems are concerned.

---

[16] Discussion by W. I. Hicks, of "Surface Runoff Determination from Rainfall Without Using Coefficients," by W. W. Horner and S. W. Jens, *Transactions*, ASCE, Vol. 107, 1942, pp. 1099, et seq.

An allowable pondage of 0.50 in. was assumed and measured downward from the mass hydrographs to form short arcs. The outflow intensity is measured as the slope of a straight line tangent to the inflow hydrograph on the accretion side and also to the short arc. The outflow intensity for the triangular hydrograph in Fig. 15(*b*) is 0.93 in. per hr, approximately 80% of the average intensity for the hydrographs in Figs. 15(*a*) and 15(*c*). The storage volume required to make the outflow intensities in Figs. 15(*a*) and 15(*c*) equal to the intensity of the hydrograph in Fig. 15(*b*) is approximately 0.70 in., or a 40% increase; the increase in depth of pondage is 12%.

The general conclusion from the foregoing analyses is that the triangular hydrograph is overly safe for durations of supply materially less than the time of equilibrium, as defined by Eq. 9, and that it is deficient in safety as the duration of supply approaches and exceeds the time of equilibrium. In the latter case, and when pondage can be developed, the deficiency can be compensated for by a temporary excess of storage.

Whereas most of the paper is devoted to the use of the triangular hydrograph in problems involving pondage, the author suggests its use (in cases where no deliberate ponding is possible) by using basic design data and offsetting the hydrographs by the times of flow from one inlet to another. Without ponding, it is probable that a storm of ten-year intensity (or greater) would be used for design. Based on a ten-year rainfall curve (from the St. Louis data[15]), an approximate supply curve for an area 50% impervious ($\sigma = 19.05\, t^{-0.38}$) was applied to such an area with 185-ft turfed length and a slope of 1.75% for supply durations of 5 min, 10 min, 15 min, 20 min, 25 min, and 30 min. The maximum intensity of runoff was found to be 2.69 cu ft per sec per acre at 21 min for a supply duration of 20 min. The time of equilibrium (for which the parenthetical expression in Eq. 2 is equal to 2.45) is 30 min, making the time of the ascending leg of the hydrograph 70% of the time of equilibrium. For this ratio, the intensities of the hydrograph in Eq. 2 for some time prior to the peak are greater than those for the triangular hydrograph. Since, in summation, the process of offsetting hydrographs for time of flow in the drain usually requires adding the peak of the local hydrograph to the ascending leg of the drain hydrograph, use of the triangular hydrograph can lead to an unsafe cumulative error. Using a sparse turf cover, which will diminish the time of equilibrium, would accentuate such an error.

In Figs. 9 and 12 the summations of entrance head (1.5 h_v) and friction head (h_f) in the tabulations are in excess of the difference between the surface elevations of the upper pond and of the pool into which the pipe system empties. This is caused by the measurement of the entrance head plus the friction head for a given length of pipe from the surface of the upstream pond to a point below the surface of the downstream pond. In Fig. 9 the entrance head is 0.34 ft and the friction head is 2.16 ft; these are measured downward from the upper pond at El. 128.34 to El. 125.84 in the downstream pond. If the full velocity head of 0.24 ft were recovered, the lower pond could not rise above

El. 126.08, whereas El. 126.30 is used for the next reach of pipe. The elevations on the two profiles have been computed precisely and it would be helpful if the author were to elaborate on his computation of the hydraulic grade lines.

To summarize, the writer suggests the use of an alternative method of determining the frequency and intensity pattern of the net rainfall, and the exclusion of the triangular hydrograph in cases where ponding cannot be used. The flexibility of the ponding method of design allows the use of the triangular hydrograph with its comparative ease of computation. The fundamental conception of the full use of infiltration and pondage in reducing the cost of drainage structures cannot be questioned.

E. J. A. Gain,[17] M. ASCE.—The methods given by the author were used by him to design the drainage system for the expansion of the Lambert-Municipal Airport at St. Louis, Mo., and were presented for approval in the unpublished "Report on Basis of Design for the Field and Off-Field Drainage Systems." Since the proposed methods were relatively new and had no precedent in the sewer design practice of the City of St. Louis, they were examined critically and reviewed with respect to their fundamental equations, assumptions, basic data, and their proposed uses.

In his recommendations to the chief engineer of sewers and paving (Guy Brown, M. ASCE) the writer presented the following summary to indicate the author's basis of design and its departure from current practice:

1. It is proposed to design drainage facilities for the runoff produced at the following rainfall rates—

Terrain	Frequency
Field areas	2 years
Terminal area	10 years
Off-field area	10 years

2. The rainfall available for storm runoff is termed the "supply" and is equal to rainfall minus losses due to soil infiltration, depression storage, and surface retention on plant cover. Variation of rainfall rates within the period of assumed uniform design rate and the effect of preceding rainfall on infiltration capacities are recognized factors affecting the supply.

3. Supply develops into surface runoff flowing to a collecting pond or inlet, or to the margin of a collecting stream or channel according to equations of surface flow developed by the late Robert E. Horton, M. ASCE. The effects of (*a*) length of overland flow, (*b*) slope, and (*c*) retention are recognized factors in the equation.

4. Variations in the supply rates are reflected in variable runoff rates which are reduced in intensity during the period of overland flow by the retarding effects of overland surfaces and by the storage capacity of the flowing sheet of runoff.

5. These variations in rates are further modified and their fluctuations reduced during the period of stream or channel flow by the storage capacity of the channel so that, by the time that runoff reaches the entrance of the inlet or pipe system, the large fluctuations in rainfall rates have been reduced and

---

[17] Engr. in Chg. of Sewer Design, Board of Public Service, Dept. of the President, St. Louis, Mo.

leveled to rates which are substantially uniform for considerable lengths of time.

6. The proposed basis of design as outlined in paragraphs from 1 to 5 is based on the work of Mr. Horton.[6,18,19] Experimental work by C. F. Izzard, Assoc. M. ASCE, of the United States Public Roads Administration, suggests that Mr. Horton's equations do not hold strictly true for all conditions of flow and that further research is necessary. Nevertheless, the Horton equations are the best that are available and the method is much better than any of the former methods in use. It differs essentially from older methods in current use in that the transformation of rainfall of a given rate to design flow of a determined rate follows the same course as that which occurs in nature, with recognition being given to all the factors modifying that course (within the bounds of existing knowledge, data, and economic expediency). The older methods usually simplified the transformation by using a given percentage of the rainfall rate to give the design unit flow. Slope, length of flow, shape of drainage area, and kind of surface cover were acknowledged only in a general way to cover only a few general cases.

7. The proposed design of field drainage embodies the use of storage ponds in interrunway areas, thereby enabling a reduction in size of required pipe lines for design flow and also providing considerable reserve capacity for the retention of excessive runoff without greatly exceeding design limits. By their use, lines designed for a runoff from a two-year storm can accommodate a ten-year storm with only a slight rise in pond elevation.

(Steps 8 to 10 are omitted from this discussion.)

11. The basis of design proposed in this paper follows more closely the conditions that actually occur in nature than any system used before because recognition is given to all the factors pertaining to them which are known or recognized. It is in keeping with the most recent advances in hydrology and their application to design, reducing the range of guesswork and allowances for the unknown or uncertain factors entering into a design; and it makes possible a design that is rationally expected to function more closely as designed. It thus makes possible a design that will be more economical for a given set of design assumptions than any other so far proposed.

Viewed as a whole, the author's methods are an excellent example of the application of two factors in drainage which, until about 1938, received little attention—namely:

a. Determination of realistic values of runoff from a storm of a given frequency by taking into account the infiltration, surface slope, kind of surface, depression storage, and surface storage of the flowing sheet; and

b. Allowance of storage whether in sheet flow, ponds, scuppers, channels, or sewers in determining the design capacities of pipe lines or storm channels. His work is a distinct contribution in furthering the use of more refined methods of drainage design.

[18] "Analysis of the Hydrograph," by Robert E. Horton, *Publication No. 101*, Soils Science Soc. of America, 1935, p. 73.

[19] "Analysis of Runoff Plat Experiments with Varying Infiltration Capacity," by R. E. Horton, *Transactions*, Am. Geophysical Union, Pt. IV, 1939, pp. 693–711.

In application, the methods require a high degree of completion of designed surface elevations. To know the size of subdrainage areas is not sufficient. This must be supplemented by additional information concerning the site, ground slopes, ponding areas, type of surface, and allowable distance and elevations. Changes in the latter can affect the design even if there is no change in the size of the subarea. The necessary computations are considerably increased in complexity, in detail, and in amount. This is a condition that usually characterizes refined methods in design, which are justified by the following results—(*a*) closer conformity of predicted to actual functioning; (*b*) greater economy in initial cost and in operation; and (*c*) the intangible satisfaction of the designer with the results of his work. Although, in many cases encountered in municipal engineering, the increased work involved may be a deterrent to its wider application (and so may help to retain the wide use of the more easily applied but less accurate so-called rational method), the increased accuracy of the newer method can be combined with the greater ease of application of the rational method by using the former to determine a convenient and full range of P-values in the well-known formula, $Q = A\ P\ I$, for the many typical conditions common in the larger municipalities. In this equation P is the ratio of runoff to rainfall for given conditions.

The use of designed ponds has special application to airport drainage and relatively little to municipal practice, except possibly for large park areas under limited conditions. The saving in cost of drainage by their use can be determined by noting in Table 7 the considerable difference between inflow rates and outflow rates. This indicates that, with ponding, pipe sizes can be reduced to accommodate storm flows that average from one fourth to one third of the values accumulated without ponding. Although individual values vary considerably from the average for the entire line, they indicate clearly the importance of using ponding whenever it is feasible.

There is a great need for necessary research to supplement the relatively small amount of available data required for a satisfactory application of the newer methods, and to confirm the data that have already been obtained. Available records, particularly of rainfall, need to be retabulated to put them in the detailed form that is needed for newer uses. Fortunately, the work that is necessary is not wasted since it is also applicable to other related problems. Data concerning local rainfall patterns, kinds of soil, and infiltration values for different soils and different cover are required; but, except for rainfall data, such information is not generally available, even for the larger centers of population where the need is probably greatest. The information that is available leaves much to be desired in necessary data.

E. F. Brater,[20] Assoc. M. ASCE.—This welcome addition to the literature of surface runoff gives in detail a practical technique for selecting a design rainfall pattern and infiltration capacity curves, as well as methods for determining the benefits of pondage in reducing peak discharge—all of which should prove useful to the designing engineer. Mr. Jens suggests that the form of the hydrograph may be determined by Eq. 2, which is a formula developed by the late R. E. Horton,[6,21] M. ASCE. The writer recognizes that the validity of this formula is not of major consequence in the over-all picture of Mr. Jens' paper. However, there are such definite limitations inherent in this expression that a discussion of them seems to be warranted. The writer wishes to outline briefly Mr. Horton's derivation of this formula and then mention what seem to be its more serious weaknesses. The notation of the original derivation will be changed wherever necessary to agree with that of the author.

---

[20] Associate Prof. of Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

The storage equation is written in differential form as

$$\sigma\, dt - q\, dt = d\delta_{av} \qquad (11)$$

It is then assumed that the relationship between discharge and depth of detention at the lower margin is

$$q = K_s\, \delta^m \qquad (12)$$

and that

$$\delta = K\, \delta_{avg} \qquad (13)$$

in which K_s, m, and K are constants for any given runoff plot. The value of q from Eq. 12 and the value of δ from Eq. 13 may now be substituted in Eq. 11, which gives

$$dt = \frac{1}{K} \frac{d\delta}{(\sigma - K\, \delta^m)} \qquad (14)$$

If σ is held constant and m is taken as 2, Eq. 14 may be integrated to obtain

$$t = \frac{1}{K\, K_s\, 2 \sqrt{\frac{\sigma}{K_s}}} \log \left[\frac{\sqrt{\frac{\sigma}{K_s}} + \delta}{\sqrt{\frac{\sigma}{K_s}} - \delta} \right] + C \qquad (15)$$

The value of C is found to be zero by assuming that $\delta = 0$ when $t = 0$. Eq. 15 may then be solved for δ, giving

$$\delta = \sqrt{\frac{\sigma}{K_s}} \frac{(e^B - 1)}{(e^B + 1)} \qquad (16)$$

in which, for simplification of typography,

$$B = 2\, K \sqrt{K_s\, \sigma} \qquad (17)$$

If Eq. 16 is introduced into Eq. 12,

$$q = \sigma \frac{(e^B - 1)^2}{(e^B + 1)^2} \qquad (18)$$

Eq. 18 may also be written in the form,

$$q = \sigma \tanh^2 2\, K \sqrt{\sigma\, K_s}\, t \qquad (19)$$

Mr. Horton then assumed that K_s could be evaluated from the Manning formula,

$$V = \frac{1.486}{n} r^{2/3} s^{1/2} \qquad (20)$$

---

[21] "Hydrologic Interrelations of Water and Soils," by R. E. Horton, *Proceedings*, Soils Science Soc. of America, Vol. 1, 1937, p. 401.

Assuming that r may be replaced by $\delta/12$, and multiplying both sides of Eq. 20 by δ, the following expression for discharge per foot width of channel is obtained:

$$q' = \frac{1.486}{n}\left(\frac{\delta}{12}\right)^{5/3} s^{1/2} \dots\dots\dots\dots (21)$$

Converting from cubic feet per second to area-inches per hour and regrouping terms, Eq. 21 becomes

$$q = \frac{1{,}020}{n\,l}\, s^{1/2}\, \delta^{5/3} \dots\dots\dots\dots (22)$$

in which l is the length of the plot in feet. By comparing Eqs. 12 and 22, it will be seen that

$$K_s = \frac{1{,}020\, s^{1/2}}{n\,l} \dots\dots\dots\dots (23)$$

If this value of K_s is substituted in Eq. 19,

$$q = \sigma \tanh^2\left(\frac{2\,K\,\sigma^{1/2}\sqrt{1{,}020}\, s^{1/4}\, t}{n^{1/2}\, l^{1/2}}\right) \dots\dots\dots\dots (24)$$

Eq. 24 is equivalent to Eq. 2 if $\frac{2\sqrt{1{,}020}}{n^{1/2}}$ is taken as $\frac{\sqrt{3{,}520}}{60}$.

Even the least of Mr. Horton's many contributions to hydrology often served the important function of stimulating study and discussion. The preceding derivation is surely one that causes the reader to probe more deeply. The runoff process provides a most complex hydraulic problem, and it would indeed be surprising if the answer were to be found in such a simplified mathematical treatment. In the first place, as in ordinary open channel problems, there are the slope, roughness, Reynolds' number, and outlet conditions to evaluate. In addition, the inflow to the plot is not only a variable with time but it varies spatially as well. Furthermore, the flow conditions deviate even farther from normal flow conditions because the raindrops, falling on the surface with nearly zero momentum in the direction of flow, cause a readjustment in the velocity distribution. A similar effect on the velocity distribution is caused on pervious areas by the draining off as infiltration of the low velocity water in contact with the ground surface. It would seem that a correct mathematical treatment would have to include most of the foregoing conditions. Because many of them were not considered in this derivation, the effect of their omission on the accuracy of the results to be expected from the use of Eq. 24 must be considered.

The first assumption made was that supply (σ) is a constant. Even if precipitation rate were assumed to be constant, σ varies with time somewhat in the manner shown by

$$\sigma = p - c_1 - c_2\, e^{-kt} \dots\dots\dots\dots (25)$$

in which p is the precipitation rate, and c_1, c_2, and k are constants. It will readily be seen that the presence of this expression for σ in Eq. 14 would have required a different integration process. Furthermore, if the integration were carried out with σ replaced by a function of t, there is no reason to believe that the result would be of the same form as Eq. 19. One very apparent consequence of the assumption that σ is a constant is that Eq. 24 shows q to become zero at the instant that σ becomes zero, thus making the recession side of the hydrograph a vertical line. Consequently, it is necessary to derive the recession curve by another method.

The second assumption was that *m*, the exponent of δ in Eq. 12, equals 2. This value was probably chosen by Mr. Horton because it is within the range of values of *m* and at the same time it made Eq. 14 easy to integrate. Eq. 14 may also be readily integrated for values of *m* equal to 1 and 3, but the resulting equations are quite different from Eq. 19. Although it is possible for two equations of different form to represent similar paths over limited regions, this cannot be assumed to be the case unless it has been demonstrated. It follows then that Eqs. 19 and 24 may only be used with assurance for plots having *m* equal to 2. The question thus arises as to whether 2 is a frequently occurring value of *m*. In the case of steady, uniform, laminar flow, both theory and experimental results show that *m* equals 3, whereas, for turbulent flow, test results culminating in the development of the Manning formula (Eq. 20) show that *m* is approximately 5/3. This is illustrated by the test results plotted in Fig. 16, for which the values of *q* and δ were obtained from studies[22] at the U. S. Waterways Experiment Station at Vicksburg, Miss. It should be noted that the points plotted in Fig. 16 follow the slope of 3 in the laminar flow region and the slope of 5/3 in the turbulent range. In the transition range, the plotted points show that *m* does not change gradually from 3 to 5/3, but changes rather quickly from 3 to 1 or less, and then gradually changes to 5/3. Thus, the region in which *m* equals 2 seems to be limited to a short range of Reynolds' numbers. Tests reported by W. O. Ree[23] and V. J. Palmer[24] for uniform steady turbulent flow through heavy grass cover show that *m* is approximately 5/3 for this case also.

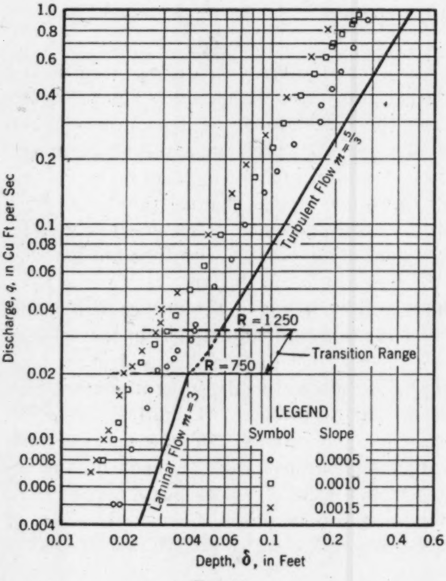

FIG. 16

One cannot predict with assurance that the relations between average depth and discharge for the unsteady conditions found on runoff plots will follow the same pattern as the uniform steady flow data plotted in Fig. 16. However, results obtained by C. F. Izzard,[10] Assoc. M. ASCE, for runoff resulting from the application of artificial rainfall on paved and turfed surfaces indicate that m equals 3 in the laminar range. Mr. Izzard's tests did not extend into the transition or turbulent ranges. The writer has encountered a number of plots[25] for which m equals 1 or less, thus indicating the presence of a transition range similar to that shown in Fig. 16.

[22] "Studies of River Bed Materials and Their Movement, With Special Reference to the Lower Mississippi River," *Paper No. 17*, U. S. Waterways Experiment Station, Vicksburg, Miss., January, 1935.

[23] "Some Experiments on Shallow Flows Over a Grassed Slope," by W. O. Ree, *Transactions*, Am. Geophysical Union, 1939, Pt. IV, p. 653.

[24] "Retardance Coefficients for Low Flow in Channels Lined with Vegetation," by Vernon J. Palmer, *ibid.*, April, 1946, p. 187.

Mr. Horton recognized that m would not usually equal 2 and suggested that Eq. 24 might still be made to give approximately correct results by a corresponding distortion of the values of K_s.[20] However, it should be noted, with reference to Fig. 16, that varying K_s simply changes the vertical position of any straight line. Therefore, a line having a slope of 2 can have but one point in common with a set of test results which falls along a slope other than 2. Consequently, a hydrograph synthesized on the basis of arbitrarily chosen values of K_s and m will arrive at the ultimate peak on a path which must be different from the correct one. If a particular rate of precipitation were to continue long enough for outflow to become equal to supply ($q = \sigma$), the error introduced is probably of little importance, but for storms of lesser duration there will be an error in the predicted peak discharge. When $q = \sigma$, no equation is needed to determine the peak discharge, because it is equal to the precipitation rate minus the infiltration capacity.

Although that part of the derivation of Eq. 24 previously discussed is based on the assumption that m equals 2, the value of K_s is determined from a formula for fully developed turbulent flow, applying only to the case where m equals 5/3. Furthermore, the expression for K_s (Eq. 24) so obtained does not apply to laminar flow, because in that case the exponent of s is 1 rather than $\frac{1}{2}$, and n does not vary with the roughness, but only with the Reynolds' number. The same limitations would apply in varying degrees to flow in the transition range.

Finally, before using Eq. 24 it is necessary to estimate K, which is the ratio of the depth at the margin to the average depth as shown by Eq. 13. Mr. Jens has used the value of 1.5 as suggested by Mr. Horton. However, K varies with the slope, outlet conditions, roughness of the surface, infiltration capacity, and rainfall intensity. For very flat surfaces the depth will increase in the upstream direction and K will be less than 1. For slopes less than critical, the profile is influenced by the presence of critical depth at the outlet, whereas for steeper slopes this is not the case. For any slope, the outlet may be drowned out, causing backwater, and in the case of slopes greater than critical, a hydraulic jump would occur. Sheet flow over irregular surfaces at high velocities is characterized by the presence of many small hydraulic jumps and standing waves. All these factors briefly mentioned heretofore combine to add to the difficulty of choosing a suitable value of K. The writer suggests that Eq. 12 could be written in terms of δ_{avg} rather than δ, thus avoiding the necessity of estimating K.

It is believed that the previous discussion shows that the derivation of Eq. 24 is based on a number of assumptions that are not entirely consistent with one another and that are likely to differ from the conditions prevailing on any particular runoff plot. Consequently, despite the fact that it was derived from the basically correct storage equation, Eq. 24 is an empirical formula. Two of the assumptions influenced the method of integration to such an extent that the form of Eq. 24 probably bears little resemblance to what might be called the correct form. The fact that K_s must be distorted to overcome arbitrary assumptions as to m introduces one of the weaknesses found in the "rational formula." Finally, it is necessary to employ some other method for deriving the recession side of the hydrograph—Eq. 24 being applicable only to the rising side. Perhaps none of these objections would be serious if the magnitude of the deviation of results obtained by the use of Eq. 24 from the correct results could be predicted for any set of conditions. Because this apparently cannot be done, the writer prefers a method in which the effect of the various assumptions is clearly evident.

[25] "Sprinkled Plat Runoff and Infiltration Experiments on Arizona Desert Soils," by E. L. Beutner, R. R. Gaebe, and R. E. Horton, *Technical Publication No. 38*, SCS, U.S.D.A., September, 1940.

A graphical procedure which permits the derivation of both the rising and falling sides of the hydrograph, similar to that described by W. W. Horner, Past-President, ASCE, and Mr. Jens[3] in connection with gutter flow and by C. R. Hursh and the writer[26] for determining outflow from channel storage on small watersheds, might be used. In this method, the storage equation, together with a relation between discharge and average depth of detention—

$$q = K_s \, \delta^m_{\text{avg}} \qquad \text{(26)}$$

—are solved for successive time intervals. The constants in Eq. 26 must be determined from tests on terrain comparable to that upon which they are to be used, and are usually determined from the recession side of a hydrograph. Although the values of K_s and m are usually somewhat different for the rising and falling sides of a hydrograph, the magnitude of the error introduced in this manner can be tested by using the relation derived from the recession curve to synthesize the rising side of a known hydrograph. Many such checks made by the writer indicate that this effect is small.

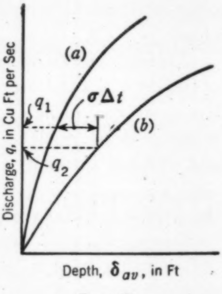

FIG. 17

The storage equation is written

$$\delta_1 + \sigma \, \Delta t - \frac{(q_1 + q_2)}{2} \Delta t = \delta_2 \qquad \text{(27)}$$

in which the subscripts 1 and 2 denote values occurring at the beginning and end, respectively, of a time interval Δt, and σ is the average supply during an interval. Eq. 27 may be rearranged as follows:

$$\left(\delta_1 - \frac{q_1 \, \Delta t}{2} \right) + \sigma \, \Delta t = \left(\delta_2 + \frac{q_2 \, \Delta t}{2} \right) \qquad \text{(28)}$$

Values of $\left(\delta - \frac{q \, \Delta t}{2} \right)$ and $\left(\delta + \frac{q \, \Delta t}{2} \right)$ may then be plotted against corresponding values of q, as illustrated by curves (*a*) and (*b*) of Fig. 17. Knowing the discharge at the beginning of any interval (q_1), the value of $\sigma\ \Delta t$ may be added to the corresponding abscissa of curve (a) and the value of q_2 read from curve (b) in the manner illustrated. The process is then repeated for successive intervals until the entire hydrograph is derived.

---

[26] "Separating Storm-Hydrographs from Small Drainage-Areas into Surface- and Subsurface-Flow," by C. R. Hursh and E. F. Brater, *Transactions*, Am. Geophysical Union, 1941, Pt. III, p. 863.

Carl F. Izzard,[27] Assoc. M. ASCE.—The main purpose of this discussion is to present pertinent data on the hydraulics of overland flow as related to airport drainage. As noted by the author, the United States Public Roads Administration conducted, with the cooperation of the United States Soil Conservation Service on the experimental phase, an investigation of overland flow on paved and turf surfaces. A report summarizing these studies[28] indicates that the rate of runoff under a uniform rate of supply can be determined for any surface by use of a single dimensionless hydrograph that takes the place of the Horton formula (Eq. 2). The latter was developed from very limited ex-

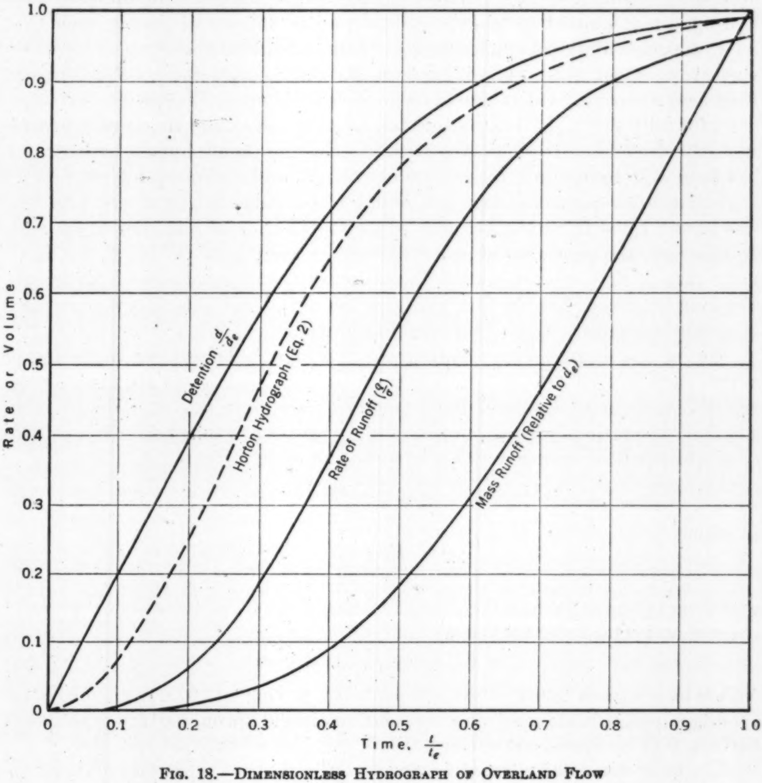

FIG. 18.—DIMENSIONLESS HYDROGRAPH OF OVERLAND FLOW

perimental data on short plots, whereas the dimensionless hydrograph integrates the results of several hundred tests on a variety of lengths, slopes, and surfaces with two different rainfall intensities. The principal difference between the two curves, as shown in Fig. 18, is that the Horton curve starts rising sooner after the beginning of supply. Aside from the fact that the dimensionless hydrograph affords a more accurate representation of overland runoff, it is also easier to use because a single curve takes the place of the families of curves needed to facilitate use of the Horton equation. Although the dimensionless hydrograph is limited to lengths of flow and intensities of supply such that $\sigma\, l < 500$, this limitation includes most of the conditions occurring on interrunway areas on airfields. When experiments being conducted by the Corps of Engineers are completed, it should be possible to determine detention characteristics for fully turbulent flow beyond the limits of the Public Roads Administration experiments. However, the writer, using the dimensionless hydrograph, has been able to obtain a reasonable reproduction of an actual hydrograph on a combined pavement and turf area where the average length of overland flow was about 1,000 ft with maximum supply intensities of 5 in. per hr on turf. In this case, the peak rate of runoff did not exceed 0.5 in. per hr, so the maximum rate of flow was within the limitation of the dimensionless hydrograph. For long lengths of flow on turf, the duration of the high intensity supply rates is always a small fraction of the equilibrium time.

---

[27] Senior Highway Engr., Public Roads Administration, Washington, D. C.

[28] "Hydraulics of Runoff from Developed Surfaces," by Carl F. Izzard, *Proceedings*, Highway Research Board, National Research Council, Vol. 26, 1946, pp. 129–150.

Use of the dimensionless hydrograph is simple. Time from beginning of supply is measured as a ratio to the time of equilibrium (t/t_e) required for the runoff rate to become substantially equal to the supply rate σ. The ordinate q/σ gives the ratio of rate of runoff to supply rate at the time t/t_e. To evaluate t_e in minutes it is necessary to know detention at equilibrium, d_e. Thus,

$$t_e = \frac{120\, d_e}{\sigma} \qquad (29)$$

in which

$$d_e = \frac{K_d\, L^{1/3}\, \sigma^{1/3}}{2.92} \qquad (30)$$

and is measured in inches; the detention coefficient K_d is expressed in terms of slope S and retardance coefficient c as

$$K_d = (0.0007\, \sigma + c)\, S^{-1/3} \qquad (31)$$

Values of c are as follows: Smooth asphaltic pavement, 0.007; crushed slate roofing paper, 0.0082; concrete pavement on airfield apron, 0.012; tar and sand surface, 0.017; clipped sod surface, 0.046; and dense bluegrass turf, 0.06.[28]

The dimensionless hydrograph can also be used to compute rates of runoff resulting from storms involving varying rates of supply. The method is described in detail elsewhere[28] and depends on the principle, developed from study of experimental data, that the rate of runoff is a function of the detention at any time. Thus, when the supply rate changes, the rate of runoff immediately adjusts to the rate which would have existed at the new supply rate with the given amount of detention. For runoff on turf, especially with pondage, which is almost always involved, the writer agrees with Mr. Jens that the average supply rate can be used to determine the peak rate, so that it is not ordinarily necessary to compute hydrographs with varying supply rates.

A dimensionless curve has also been developed to compute rates of runoff during recession.[28] This curve is in terms of a function which involves the detention and rate of runoff at the beginning of the recession so that the total area under the recession curve will equal the amount of detention. Inasmuch as the present discussion is concerned with triangular approximations of hydrographs, there is no necessity of using the dimensionless recession curve.

The Public Roads Administration experiments included a few tests on turf plots with various percentages of impervious area draining across the turf. The typical hydrograph shows a sharp increase in rate of runoff as soon as runoff from the impervious area reaches the lower margin of the turf.[28] A fair approximation of the rising hydrograph can be obtained by using the dimensionless hydrograph if the amount of detention in Eq. 29 is reduced in proportion to the reduction in detention resulting from having pavement instead of turf on the upper part of the area. A simple equation to determine this reduction is

$$\frac{d_c}{d_t} = 1 - \left(\frac{l_p}{l}\right)^{4/3} \left(1 - \frac{K_p}{K_t}\right) \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which d_c and d_t are equilibrium detention values for the composite area and a turf area of the same length l, respectively; l_p/l is the ratio of paved to total length; and K_p and K_t are detention coefficients for the paved and turf areas, respectively. The equation thus takes into consideration different slopes on paved and turf areas, since that factor is included in Eq. 31. The detention (for the composite area) used in Eq. 29 is the detention for a turf area of the same total length multiplied by the ratio d_c/d_t. The supply rate used is the supply rate for the turf as determined by Mr. Jens (with a proportionate increase in rainfall intensity to determine infiltration on turf area) converted to equivalent supply rate for the total length of overland flow, including the paved area.

To illustrate this procedure, the overland flow length of 185 ft shown in Fig. 7 is taken, and it is assumed that the upper 50 ft are paved, making the ratio of paved to turf area 0.27. The net supply rate on the composite area is 0.85 in. per hr for 30 min. From Eq. 31, values of K_p and K_t are 0.07 and 0.233, respectively, assuming slopes of 0.01 (on concrete pavement) and 0.0175 (on dense turf) and a rainfall intensity of about 3 in. per hr (on pavement). Detention on 185 ft of turf of uniform slope is 0.43 in. based on a supply rate of 0.85 in. per hr. This value is multiplied by 0.88 (computed by Eq. 32) to obtain 0.38 in. for the detention at equilibrium on the composite area. From Eq. 29 the equilibrium time is found to be 54 min so that the value of t/t_e at the time supply ended is $30/54 = 0.56$ and that of q/σ is 0.65 from the dimensionless hydrograph. The rate of runoff at 30 min is thus $0.65 \times 0.85 = 0.55$ in. per hr.

A slight error is involved in this method because the actual supply rate on the paved area is different from that on the turf area. The error is negligible because detention on the pavement is a very small proportion of the total detention on inter-runway areas.

Commonly, the width of paved area will be greater than the average width of turf area. To allow for the increased detention volume on pavement resulting from this situation, the ratio of areas may be substituted for the ratio of lengths used in Eq. 32.

Values of q_p computed by the dimensionless hydrograph method for the supply rates given in Table 2 give closely similar results except for short durations on 0% impervious areas, where the values were about 75% of those in Table 2. The reason for the difference is probably the fact that the Horton equation gives higher rates of runoff where the duration of supply is substantially less than the time of equilibrium. Using Eq. 32 in estimating detention on 30% impervious areas, the values of q_p are practically the same as those in Table 2 for all durations, but tend to be a little higher than those in Table 2 for the shorter durations.

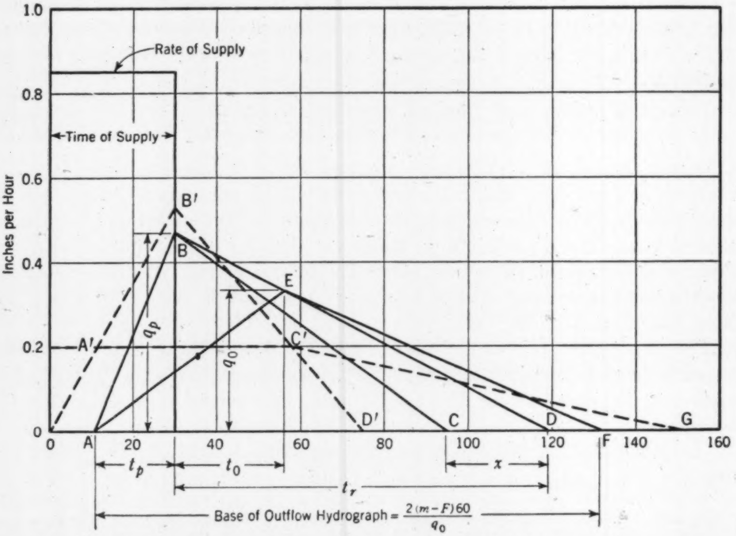

FIG. 19.—COMPARISON OF TRIANGULAR HYDROGRAPH WITH FLAT TOPPED HYDROGRAPH

With reference to the method of computing the rate of outflow from a pond as illustrated in Fig. 8, the writer, after examining actual hydrographs of runoff from ponded areas on airfields,[29] feels that the flat topped outflow hydrograph is not a good representation and that a triangular hydrograph as shown in Fig. 19 would be more nearly correct. The latter is more consistent with actual hydrographs because ponding begins at the beginning of the inflow hydrograph and reaches a maximum at a time after the ocurrence of the peak rate of inflow.

The example in Fig. 7 is used to illustrate this point. The average supply rate for 30 min is 0.85 in. on 185 ft of turf on a 1.75% slope. From Eqs. 31 and 30, it is determined that $K_d = 0.233$ and $d_e = 0.431$ in., from which $t_e = 61$ min by Eq. 29. At 30 min, $t/t_e = 30/61 = 0.49$. In the dimensionless hydrograph, Fig. 18, $q/\sigma = 0.55$ for this value of t/t_e, and therefore

---

[29] "Report on Drainage Verification at Military Establishments," Louisville Engr. Dist., Ohio River Div., Corps of Engineers, War Dept., Louisville, Ky., June, 1947.

$q_p = 0.55 \times 0.85 = 0.47$ in. per hr; also, from the detention and mass runoff curves (Fig. 18), detention $= 0.81 \times 0.431 = 0.349$ in. and mass runoff $= 0.17 \times 0.431 = 0.073$ in. The sum of detention and mass runoff is 0.422 in., which checks the amount of rainfall (0.85 in. per hr × ½ hr) within 0.003 in., the error being due to using only two significant figures in reading the values from the curve. Knowing q_p (0.47 in. per hr), the rising time t_p is computed as $\frac{2 \times 0.073 \times 60}{0.47} = 19$ min, which places the beginning of the runoff at 11 min after beginning of supply. The recession time t_r similarly becomes $\frac{2 \times 0.349 \times 60}{0.47} = 89$ min. The latter time can be adjusted by Mr. Jens' method for infiltration during recession. Thus, if $f = 0.26$ in. per hr, by Eq. 5, $X = \frac{89 \times 0.26}{(1.5 \times 0.47) + 0.26} = 24$ min.

The peak rate of outflow is estimated as

$$q_o = q_p \left(1 - \frac{p}{m}\right) \qquad (33)$$

in which p is represented by the area ABE (Fig. 19) and m is the runoff in inches before deducting infiltration during recession on the assumption that the total supply is effective in producing the peak outflow. The time after end of supply at which peak outflow occurs is

$$t_o = t_r \left(\frac{p}{m}\right) \qquad (34)$$

In the example, if $p = 0.125$ in., then $\frac{p}{m} = \frac{0.125}{0.425} = 0.29$ and $q_o = 0.47 \times 0.71 = 0.33$ in. per hr, occurring at $t_o = 89 \times 0.29 = 26$ min after the end of supply. The base of the outflow hydrograph must be such that the area equals supply minus infiltration during recession. The latter amounts to $\frac{0.47 \times 24}{2 \times 60} = 0.094$ in., making net runoff $= 0.425 - 0.094 = 0.331$ in. The base of the outflow hydrograph, therefore, is $\frac{2 \times 0.331 \times 60}{0.33} = 120$ min.

For comparison, the dotted lines show the inflow and outflow hydrographs which would result from using the same assumptions in Mr. Jens' method. Triangle AEF is believed to be a more true representation of outflow from a pond, because the peak occurs after supply has ended, which is necessarily the case, whereas the flat peak A′C′ begins before any substantial runoff has occurred. Summation of a series of hydrographs with flat tops would give an excessively high rate of runoff early in the storm. Summation of triangular outflow hydrographs would come closer to giving true peak outflow rates, if hydrographs are offset to allow for routing through conduits.

Mr. Jens does not indicate how the ponded water is discharged during recession. In Fig. 19, this has been shown as C′G with area C′D′G equal to area A′B′C′, the volume of pondage. In Fig. 13, the recession curves are not shown as straight lines, which raises a question as to what method Mr. Jens used for computing recession curves.

The writer was unable to determine how the use of the triangular outflow hydrograph would affect the final design of a system, since insufficient basic data were given in the example. It would be instructive if the author could recompute one set of data by this principle giving the results in his closing discussion.

The basic concept of the triangular outflow hydrograph was used by the writer in an unpublished report written in November, 1941. The method was not applied then because no good procedure for estimating the peak rate of inflow had been developed.

The writer doubts that the method of developing average supply patterns as illustrated in Table 1 is logically correct. As an analogy, the arithmetic mean of the number of spots on a die is 3.5 but the probability of rolling 3.5 is zero. In other words, the arithmetic mean has no possibility of occurring. On the other hand, the probability of rolling any given number from 1 to 6 is 1 in 6.

The probability of a given amount of rainfall in a given duration is fairly well established from rainfall intensity-frequency data such as those compiled by the late D. L. Yarnell,[13] M. ASCE. Table 1 shows that there is considerable variation in the pattern of rainfall intensities. Certain patterns result in higher rates of runoff than others. Obviously, the probability of encountering one of the critical patterns is not the same as the probability of equaling or exceeding a given total amount of rain in a given period. For example, if the probability of the amount of rain is 1 in 2, and the probability of the pattern being critical is 1 in 3, then the resultant probability is 1 in 6. The other five storms would not be critical.

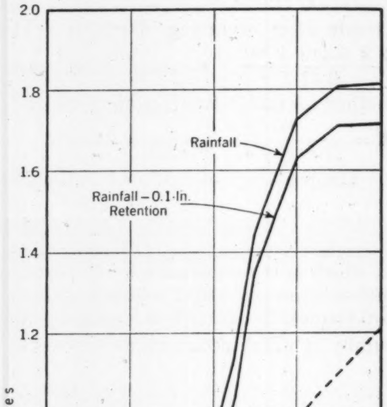

FIG. 20.—MASS CURVES FOR STORM OF SEPTEMBER 12, 1925, FROM TABLE 1

The writer is not prepared to suggest exactly how the statistical analysis should be made. That study should be undertaken by a mathematical statistician who is fully aware of the limitations of statistical methods.

The writer wishes to suggest a method of estimating the supply rates for a given rainfall intensity pattern and infiltration capacity curve which gives results closely comparable to those in Table 1 and is easier to follow. The method requires only a mass rainfall curve, a mass infiltration curve, and an estimate of the initial retention. For example, Fig. 20 shows mass rainfall for the storm of September 12, 1925, taken from Table 1. The curve is replotted 0.1 in. lower to allow for 0.1-in. retention. Then the infiltration mass curve is moved over until it touches at one point only—namely, at 50 min. Prior to that time, rainfall intensity was lower than infiltration rate so all the rainfall was absorbed. Beyond 50 min, rainfall intensity exceeds infiltration rate and in the next 10 min the excess is 0.10 in., as shown by the net mass rainfall curve. The net rainfall rate for that period is thus 0.6 in. per hr. At 90 min, the rainfall rate drops below the infiltration rate and no additional net rainfall occurs. Whether or not infiltration capacity recovers during periods when rainfall is less than infiltration is not fully established. It might be assumed, however, that the infiltration curve could be shifted to the right until the ordinate measured to the mass rainfall less retention curve is 0.65 in. at the time when excess rainfall resumes, 0.65 in. being the maximum net mass rainfall previously attained.

In conclusion, the writer believes that the principles for estimation of peak rates of runoff from ponded inter-runway areas on airfields as suggested by Mr. Jens are fundamentally sound. These changes relate to detailed procedures and are presented so that other engineers working on similar problems may consider the alternatives and develop still better procedures.

Stifel W. Jens,[30] M. ASCE.—Messrs. Williams, Hicks, and Izzard all question the validity of the technique involved in processing the rainfall data. Mr. Williams doubts the need for establishing a storm pattern, and recites some of the reasons why he believes the considerable effort involved in setting up a correct storm pattern is not warranted. Acknowledging the reasonableness of these criticisms, the method of the paper does approach the realities whereas the more usual "rational method" techniques, which utilize one average intensity only, clearly do not. There can be no denial that the amount of detailed work is likely to discourage its use, and Mr. Williams' constructive suggestion for a simpler approach is very interesting. The striking similarity of the storm patterns for the widely separated geographical locations is encouraging. Use of the method illustrated by Tables 10 and 11 should recognize, however, that a pattern made up entirely of intensities taken from the ordinary intensity-duration curve, rearranged in an order suggested by a brief analysis of the average pattern of a number of recorded storms, is an almost impossible combination of events. Certainly such a storm pattern departs more from the statistically valid pattern than do those developed as suggested in the paper.

The user of the Williams method should also keep in mind the fact that a pattern rainfall incorporating all the intensities for the various durations for one frequency, necessarily will result in a generally higher net rainfall pattern, because the infiltration capacity will be equaled or exceeded earlier and oftener.

---

[30] Partner, Horner and Shifrin, St. Louis, Mo.

A correct pattern of net supply would undoubtedly have more intervals of rainfall intensities lower than the related infiltration capacities.

The incidental illustration of the usefulness of the Hathaway standard rainfall intensity-duration curves points to a possible utilization of these for areas in which no satisfactory local record is available. To the writer, the Yarnell[13] curves are preferable, if used carefully with an understanding of their limitations. The supposition that the paper uses the method of G. A. Hathaway, M. ASCE, with some modifications is correct, but the background and initial application of the infiltration-overland flow technique were originally developed by W. W. Horner, Past-President, ASCE, in the studies made for the drainage of the Washington (D. C.) National Airport in 1939.

Mr. Hicks calls attention to the fact that only one third of the twelve storms of Table 1 have net rainfalls of 20-min duration; of the remaining eight, two have 15-min net rainfalls, four have 10-min supplies, and two sustain a supply rate for only 5 min. The wide variation in outflow rates for each of these different net supply rates leads Mr. Hicks to the sound conclusion that the intensity-duration curve should be based on the duration and intensity of net rainfall. The objective of the designer is to know, for any specific part of a drainage system, the frequency with which certain rates of flow will be equaled or exceeded. Obviously, if the true frequency of supply rates of different durations could be determined, the foregoing objective would be immeasurably closer. Lack of sufficient data, together with the need to recognize specifically, and in some detail, more of the many factors influencing net rainfall has made common the use of the frequency of gross rainfalls of various durations.

The probable gross rainfall pattern of a desired frequency is applicable to a sizable area. However, a different net rainfall pattern is required for each area with a different soil-cover-condition complex. Different soil, cover (and stage of growth), antecedent moisture, and season, to mention but a few of the many factors involved, each affect the net supply. The probabilities are that gross rainfall frequencies will continue for some time to come to be the guiding criteria in so far as frequency enters into storm sewer design. The important practical aspect of this fact is always to keep in mind the often considerable difference between the frequency of a given gross rainfall and the frequency of the runoff derived therefrom. Judgment will be better guided in the light of such recognition of the realities.

Mr. Izzard's illustration of the impossibility of an arithmetic mean actually occurring under certain circumstances does not seem to the writer to be altogether comparable to the determination of an average storm pattern. The desired objective was to evaluate the effects, on the critical period net rainfall, of immediately antecedent precipitation as it might occur on the average during the storm frequency under study. In the light of the almost infinite variety of patterns of rainfall intensities, it does not appear likely that a statistical study would reveal a storm that occurred on the average once every one, two, five, or ten years and actually repeated itself in every detail the number of times implicit in its indicated frequency. The method of developing average supply patterns, as illustrated in Table 1, is open to criticism of its statistical validity, but nonetheless it is believed to be a reasonable attempt to give quantitative expression to some of the actual happenings which are qualitatively known.

Professor Brater's review of the development of the Horton overland flow formula (Eqs. 2 and 24) and his analysis of its limitations are particularly convenient for comparison with Mr. Izzard's dimensionless hydrograph of overland flow. It is interesting to note that the latter's formula evaluates some of the factors Professor Brater lists as not reflected in the Horton equation. The additional retardance to sheet flow due to raindrop impact is recognized in Eq. 31 by the factor 0.0007 σ. The "effect on the velocity distribution * * * by * * * infiltration of the low velocity water in contact with the ground surface" is reflected indirectly in both Eqs. 2 and 7 in that the net supply rate is used and retention or depression storage and infiltration have been abstracted from gross rainfall.

Although Eq. 25 attempts to set up a mathematical expression for the variation of supply with time, practical application of either the Horton equation or the Izzard equation has involved the use of a stepped pattern net rainfall, each step considered to have a uniform rate over its short time. Mr. Izzard has indicated the principle on which both his and Mr. Horton's equations can be used to reflect changing rates of supply—namely, that the rate of runoff is directly related to the amount of detention at any time.

Both overland flow equations are admittedly only valid for the rising side of the hydrograph. In recognition of this, Mr. Izzard has developed from his experimental work another dimensionless equation[28] to compute rates of runoff during recession.

Professor Brater's illustration (Fig. 16) corroborates Mr. Izzard's experimental findings that for sheet flow, where $i L < 500$, the exponent $m = 3$, which indicates that the flow is steady, uniform, and laminar. Everyone interested in this matter awaits with eagerness the findings of the current experimental program of the Corps of Engineers to determine the interrelationships where the flow is fully turbulent. If the comparable curves computed by Eq. 2 with an exponent of 3 instead of 2 are added to Fig. 18, the close agreement of the two sets of curves is a tribute to the sound analytical approach of the late R. E. Horton, M. ASCE, and the careful experimental work of Mr. Izzard. The latter's dimensionless hydrograph for the rising side and his companion dimensionless recession hydrograph are based on analysis of a considerable volume of experimental data and from a practical viewpoint suggest that the theoretical limitations so well discussed by Professor Brater, even if individually serious, are apparently either canceled out in a compensatory fashion, or are properly reflected in the empirical formulas.

No one can quarrel with Professor Brater's preference for "* * * a method in which the effect of the various assumptions is clearly evident." One of the major objectives of the method discussed in this paper is an attempt to reflect more clearly the sequence of events as they occur. The writer prefers the approach involving the use of an overland flow equation such as the Izzard dimensionless hydrograph (simpler in form and easier to use than the cumbersome hyperbolic function of the Horton equation). Had the Izzard overland flow equations been available and understood, at the time of the studies leading to this paper, they would have been used. The very material amount of detailed computation required to change to the Izzard approach militated against a change-over.

The difficulties inherent in obtaining representative discharge storage relationships for both the rising and recession sides of the hydrograph of sheet flow are many and involve, in the writer's opinion, no less departure from the realities than the use of the overland flow equations. Professor Brater suggests that the constants of Eq. 26 "* * * are usually determined from the recession side of a hydrograph" of overland flow. That is exactly what Mr. Izzard has done in establishing the relationship between discharge and detention storage. It is believed that the effect of the sheet flow detention storage on the rates of net rainfall or supply is most practically expressed by an empirical formula. The many factors and their complex interrelationship, so well discussed by Professor Brater, will probably never be expressible in any practical rigorous mathematical form.

Mr. Gain has lent clarity to the paper in his succinct summary of the attempt by the method to follow logically and realistically the development of runoff from rainfall. Even if a workable combination of the more detailed and realistic methods, such as used in the paper, can be effected with the "rational" method, in the long run the more detailed method will be most desirable, because the designer can visualize the process much more clearly as it develops. Of course, it is highly probable that, in the evolution of better founded methods of predicting runoff from precipitation, some such intermediate step, as is suggested by Mr. Gain, may occur.

Although it is true that municipal practice ordinarily can make no use of the rate-reducing storage of deliberate pondage, in many very flat areas of intensive development (such as the wide, alluvial river bottoms at Kansas City, Mo., East St. Louis, Ill., and similar industrial developments along the great rivers of the United States), storm sewer design does not attempt to provide inlet and sewer capacities adequate for the very short times of concentration actually prevailing at upper ends of lines. The very small mass values of net rainfall involved in the very short-time high intensity rainfalls make it economic and practical actually to design upper end inlets and laterals for the lower intensities related to longer durations. In other words, in such circumstances, a minor amount of actual pondage around the inlets prevails for a relatively short period when the storm of design frequency occurs.

Everyone interested in the application of the newer hydrology seconds wholeheartedly Mr. Gain's plea for additional data and research. To cite one of the outstanding examples, the vast amount of experimental data on rainfall, infiltration, and runoff collected by the Soil Conservation Service at its experimental watersheds during the 1930's should be processed and be made available at the earliest possible moment.

The field investigations of airport drainage made by the Corps of Engineers and discussed by Mr. Williams constitute a valuable supplement to the hydrologic information used in design methods such as that suggested by this paper. Wheeled traffic over turfed airport areas should be practically nil on civil fields, but the other difficulties encountered in maintaining constant drainage areas indicate the need for conservative judgment in design. Because of the unavoidably flat ridges and drainage divides, the writer is particularly impressed by the possibility of "* * * wind driving surface water over low drainage divides." Since nothing practical can be done to prevent this, it can only be recognized through the employment of reasonable safety factors as suggested by Mr. Williams.

If Mr. Izzard's example to illustrate the use of Eq. 32 would use a value of net supply rate of 1.26 in. per hr for the composite area, it would employ the actual supply rate interpolated from Fig. 6 for a 27% impervious area and a 30-min duration of supply. The outflow rate at the lower edge of the composite area, as computed by Eqs. 7, 8, 9, and 10, is 1.06 in. per hr. Examination of Fig. 10 indicates a peak runoff rate of 1.12 in. per hr for 135 ft of turf length and 30% imperviousness—in keeping with Mr. Izzard's close check of the peak runoff rates in Table 2, except for short durations of supply on wholly pervious areas.

The limitations of the triangular hydrograph are brought out by Mr. Hicks' analysis as illustrated by Fig. 15 and by Mr. Williams' citation of the general conclusions arising out of studies of the Airfields Branch, Office of the Chief of Engineers, United States Army. Mr. Izzard indicates that brief examination of actual hydrographs suggests a peaked triangular outflow hydrograph as illustrated in Fig. 19. The criterion of the ratio of available pondage to mass runoff is an excellent guide to the designer. However, all the discussion points to the need for further study and research to develop a practical tool to take the place of the triangular hydrograph and at the same time to lend itself to reasonably accurate evaluation of pondage.

Mr. Hicks shows clearly the error of summating triangular hydrographs where ponding is not present. With the Izzard dimensionless hydrograph, actual inflow rate curves can be developed readily and then offset for addition. Mr. Hicks' discussion of Fig. 15 shows the small change in pondage depth necessary for an appreciable difference in required pondage volume. This fact is fortuitous. Examination of the dimensionless hydrograph supports Mr. Hicks' statement that, up to a duration of about 0.6 of the equilibrium time, the triangular hydrograph is overly safe; as it passes through that point and continues on to equilibrium, the straight ascending leg of the triangle falls below the curve values. The differences are not great until the duration involves a prolonged flow at equilibrium rate.

The writer cannot agree with Mr. Izzard's assumption that "* * * ponding begins at the beginning of the inflow hydrograph." Until the overland flow rate into the collecting inlet exceeds the capacity of the outlet, no pondage could result. One other assumption involved in the method illustrated by Fig. 19 assumes that the peak outflow rate occurs at the moment when the pondage has all been drained. This does not appear likely. If Mr. Izzard's triangular hydrograph of outflow from ponds is correct, it bears out his conclusion that the flat topped hydrograph, when summated, would give a considerably higher rate of runoff early in the storm.

In adding outflow rates for ponded areas, it was felt unnecessary to develop the recession part of the ponded hydrograph, inasmuch as the peak value was all that was significant for design purposes. If it had been necessary, it would have been developed on the assumption that Mr. Izzard makes in Fig. 19. The recession curves in Fig. 13 were sketched in with the area beneath them equal to the volume of pondage less infiltration during the recession side of the curve.

Fig. 20 indicates a variation in technique for the development of a net rainfall curve. This deserves consideration in evolving a less laborious methodology for handling the problem.

Mr. Hicks inquires concerning the hydraulic grade lines, as shown in Figs. 9 and 12. These were developed originally on the presumption that the pond would not have a free hydraulic relationship with the collecting pipe line—that is, an intervening short connection would prevent the pond from having a direct influence on the hydraulic gradient of the upstream pipe. Admittedly, the actual hydraulics involved in the pond is complex and suggests the need for some careful research to indicate the actual hydraulic conditions that would prevail under circumstances comparable to airport ponded drainage.

The writer is very appreciative of the considerable interest evidenced by the provocative discussions.

LEAST SQUARES ADJUSTMENT OF TRIANGULATION NET BETWEEN GEODETIC STATIONS

By E. F. Coddington [1] and O. C. J. Marshall,[2] Members, ASCE

With Discussion by Messrs. Julius L. Speert, C. H. Ney, H. W. Hemple, Lansing G. Simmons, and E. F. Coddington and O. C. J. Marshall

Synopsis

Local triangulation nets, both urban and rural, can be precisely adjusted to large-scale geodetic triangulation control with comparatively little effort if all the angle, distance, and azimuth relations involved are reduced to simultaneous equations expressed in terms of direction corrections and then adjusted by least squares methods. The derivation of the correction equations is illustrated by a sample net containing three quadrilaterals. Application of the method is also illustrated by adjustment of a local net for Logan County, Ohio.

Introduction

The United States Coast and Geodetic Survey (U. S. C. and G. S.) triangulation system, which has 25-mile spacing of stations as its goal, has been adjusted to the local triangulation systems of at least two cities. As a result, Pittsburgh, Pa., and Columbus, Ohio, each have a triangulation system for local horizontal control to which the U. S. C. and G. S. has adjusted the overall net. The triangulation system for each of these cities was completed before geodetic control was available, but the U. S. C. and G. S. program has progressed to such an extent that it is available or can be made so for any future local requirement.

On several occasions, local cadastral surveys have been conducted without making a complete connection to available geodetic control. The objective of this paper, therefore, is to describe a method that will enable engineers in charge of supplementary triangulation projects to make full use of the control which the U. S. C. and G. S. has made available.

Note.—Published in September, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

SAMPLE PROBLEMS

To illustrate the problems involved, assume a system of three complete quadrilaterals connecting two fixed triangulation stations (1 and n in Fig. 1) of the type established by the U. S. C. and G. S. It is assumed that for the sample net all eight angles in each quadrilateral have been measured with the same relative accuracy consistent with the requirements of the project and that the azimuth and length of a starting base line (1–2 in Fig. 1) have been determined with adequate precision. In this example, the azimuth and length of a terminal base line, 7–n, are also assumed, for the purpose of illustrating the formation and use of the azimuth and length equations. In practice, a terminal base line would seldom be needed so close to the starting base line.

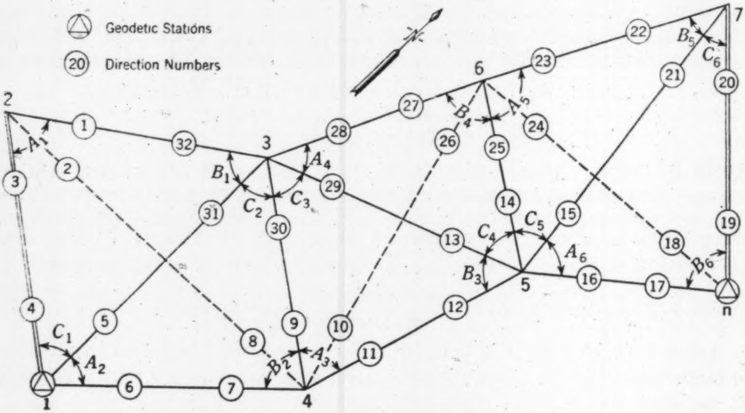

FIG. 1.—TRIANGULATION NET OF THREE COMPLETE QUADRILATERALS BETWEEN GEODETIC STATIONS

Several procedures are available for the preliminary adjustment, any of which will determine preliminary angles to be used in computing triangles from which the accumulated errors in latitude and departure between fixed stations can be found. In the first of these procedures the angle equations of each quadrilateral may be satisfied by the approximate method.[3,4] This is the equivalent of a rigid solution which disregards the relation of the sides, and is accomplished very rapidly where the figures are simple quadrilaterals or center point triangles with no overlapping figures involved. The preliminary solution also may be set up as a least squares solution involving the usual three angle equations and one side equation for each quadrilateral, leaving all tie equations for the final adjustment. Where there are no overlapping figures or other complications, these quadrilaterals may be adjusted separately. As a third possibility, the preliminary adjustment may also be made as a least squares solution including all condition equations involved in the net (angle, side,

[4] "Least Squares in Engineering," by E. F. Coddington and O. J. Marshall, Ohio State Univ., Columbus, Ohio, 1941.

azimuth, and length equations) except the latitude and departure equations. When this solution is completed, the resulting latitude and departure closure is likely to be smaller than when any less inclusive preliminary adjustment is used.

In the example illustrated in this paper, the first of the foregoing methods is used. The first step is the preliminary computation of a selected set of triangles of the net, starting with the base line 1–2 and proceeding through the strongest pair of triangles of each quadrilateral to the final station, n. The triangles used in this example are those adjacent to the diagonal shown by a full line in each quadrilateral. The other diagonal in each case (not used in computation of triangles) is shown by a dashed line. The stronger set of triangles should be selected by the "strength of figure" theory, but use of triangles adjacent to the shorter diagonal in each quadrilateral will generally result in the selection of the stronger figure.

A selected traverse from station 1 to station n may then be computed along any of these calculated triangle sides by latitudes and departures. The distance by which this computed traverse fails to fit the gap between the original and the final fixed stations represents the closing error of the survey. Because the preliminary adjustment makes the triangles used geometrically consistent, the closing error will be independent of the traverse route selected between 1 and n. In practice it is advisable to close each quadrilateral by latitudes and departures, since this procedure provides a needed check on the computation of the triangles. For purposes of obtaining the relative closure, however, the computed straight-line distance from station 1 to station n should be used as the length of the survey.

The closing error of the connecting traverse is then used to make a combined readjustment of the entire triangulation net so as to obtain an exact fit between fixed stations. To make this readjustment, two equations—one for latitude and one for departure—are used in combination with the equations resulting from other geometrical conditions of the net. The constant terms for all equations in this final adjustment are based on the corrected angles resulting from any preliminary solution. Hence, those condition equations which are used in both preliminary and final adjustments will show zero for the constant term in the final adjustment. All equations are handled simultaneously in the final least squares adjustment of the net.

DERIVATION OF TIE EQUATIONS

In deriving the previously mentioned equations, the measured base is considered as fixed in length and direction and as originating at one of the fixed coordinated points. The effect on the location of n, the end point of the connecting traverse line, caused by a change in each angle of the net is also considered.

Each triangle of the net is examined separately in deriving the relation between the angle changes and the change of the end point. Considering the triangle 123 (Fig. 1), the combined effect of its angle changes will be an expansion or contraction of the side 1–3, with point 1 remaining fixed, and a rotation of side 1–3 about point 1. The change of side 3–2 does not require consideration, because the rotation of side 1–3 will be due solely to the change in angle *C*, and the expansion of side 1–3 will be due to the combined effects of the changes in angles A and B.

EXPANSION AND CONTRACTION OF THE NET

In triangle 123,

$$\frac{1\text{–}3}{2\text{–}1} = \frac{\sin A}{\sin B} \quad \text{(1a)}$$

therefore,

$$1\text{–}3 = 2\text{–}1\left(\frac{\sin A}{\sin B}\right) \quad \text{(1b)}$$

and

$$\log(1\text{–}3) = \log(2\text{–}1) + \log\sin A - \log\sin B \quad \text{(1c)}$$

If the changes in the angles of this triangle are assumed to be v_A, v_B, and v_C, the tabular differences for log sin A and log sin B are assumed as δ_A and δ_B, respectively, and the length of the variable side 1–3 is designated by L, then

$$d\log_{10}\sin A = \delta_A v_A \quad \text{(2a)}$$

$$d\log_{10}\sin B = \delta_B v_B \quad \text{(2b)}$$

$$d\log_{10}(2\text{–}1) = 0 \quad \text{(2c)}$$

and

$$d\log_{10} L = \delta_A v_A - \delta_B v_B \quad \text{(2d)}$$

If it is also assumed that

$$\log_{10} L = N \quad \text{(3a)}$$

then

$$\frac{dL}{L} = \log_e 10\, dN \quad \text{(3b)}$$

However,

$$\log_e 10 = \frac{1}{\log_{10} e} \quad \text{(3c)}$$

therefore,

$$\frac{dL}{L} = \frac{dN}{\log_{10} e} = \frac{dN}{0.434294} = \frac{d\log_{10} L}{0.434294} \quad \text{(3d)}$$

Substitution of Eq. 2*d* in Eq. 3*d* gives

$$\frac{dL}{L} = \frac{\delta_A v_A - \delta_B v_B}{0.434294} \quad \text{(4a)}$$

from which

$$dL = L\left(\frac{\delta_A v_A - \delta_B v_B}{0.434294}\right) \quad \text{(4b)}$$

Numerical Illustration.—The validity of this formula may be demonstrated by assigning definite values to the angles of triangle 123 and a definite length to the base 2–1 in Fig. 1. From these original values the length 3–1 is first computed. Then, with changes to the three angles assumed as noted previously, the length 3–1 is recomputed. The difference, in these computed lengths, should correspond to the value of dL obtained by Eq. 4*b*. Thus, if it is assumed that angles A, B, and C measure 68° 24′ 17.81″, 59° 47′ 36.45″, and 51° 48′ 05.74″, respectively (making a total of 180° 00′ 00.00″); that v_A, v_B, and v_C are $+5''$, $-3''$, and $-2''$, respectively; and that 2–1 = 13,672.64: Then $\delta_A = 0.83$, $\delta_B = 1.22$, and log (3–1) = log 13,672.64 + log sin 68° 24′ 17.81″ − log sin 59° 47′ 36.45″.. Solution of this equation for 3–1 by seven-place log tables gives:

	Original angles	Corrected angles
log 13,672.64 =	4.1358523	4.1358523
log sin A =	+9.9683934	+9.9683976
	4.1042457	4.1042499
log sin B =	−9.9366229	−9.9366193
log (3–1) =	4.1676228	4.1676306
3–1 =	14,710.34	14,710.61
Difference =	....	0.27

Solving by Eq. 4b, $dL = L\left(\frac{\delta_A v_A - \delta_B v_B}{0.434294}\right) = \frac{14{,}710}{0.434294}(0.00000083 \times 5 + 0.00000122 \times 3) = 0.27$, which agrees with the difference previously found.

The values of δ_A and δ_B in this problem appear as eight places of decimals taken from a seven-place log table. This result is due to the fact that intervals in the table are for 10 sec of arc, whereas δ_A and δ_B are changes of log sin A and log sin B for a 1-sec change in the angle. Use of the sixth decimal place as the unit for the tabular differences δ_A and δ_B is also in accordance with the usual practice in setting up the side equation in adjustment of a quadrilateral.

General Application.—Returning to Eq. 4a, $\frac{dL}{L}$ is the relative change of the length of the side 3–1, due to the angle changes v_A and v_B. This ratio might be expressed as a percentage of change or rate of change. If no angle changes are made in the remainder of the net, all the remaining triangle sides will receive this same relative increase. Furthermore, all linear dimensions of the remainder of the net will receive this relative increase. The same may be stated concerning the line n–1 or any component of it, in which n is the designation of the end or final station.

Referring to Fig. 2, the x-component of n–1 is $x_n - x_1$. Let Δx be the change in the length of this component. Then $\frac{\Delta x}{x_n - x_1}$, the relative change in the length of this component, is

$$\frac{\Delta x}{x_n - x_1} = \frac{dL}{L} = \frac{\delta_A v_A - \delta_B v_B}{0.434294} \quad \text{(5a)}$$

from which

$$\Delta x = (x_n - x_1)\frac{\delta_A v_A - \delta_B v_B}{0.434294} \quad \text{(5b)}$$

which gives the amount the end point of the net is moved in an east-west direction as a result of a definite change in angles A and B of the beginning triangle.

Similarly,

$$\Delta y = (y_n - y_1)\,\frac{\delta_A\, v_A - \delta_B\, v_B}{0.434294} \dots\dots\dots\dots\dots\dots (6)$$

Both Δx and Δy are obtained as a product of two factors, either of which may be plus or minus. When the latter factor $(\delta_A\, v_A - \delta_B\, v_B)$ is positive, the net is expanded by the changes v_A and v_B; when it is negative, the net is contracted.

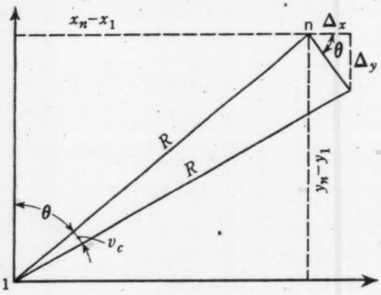

FIG. 2.—DISPLACEMENT FACTORS INVOLVED IN ANGULAR ROTATION ABOUT POINT 1

If an expanding net and positive $(x_n - x_1)$ are assumed, Δx is positive. If the end point falls west of the starting point, $x_n - x_1$ will be negative, which results in a negative Δx with an expanding net. A similar analysis also would apply to Δy. To derive Δx and Δy with proper signs, care must be taken to subtract the coordinate of the starting point from that of the end point. The computations indicated by these equations are accomplished in tabular form as illustrated by the numerical example to follow.

ROTATION DUE TO CHANGE OF ANGLE C

The effect of adding an increment to the C angle of the triangle under consideration is to produce a right-hand rotation of the line 3–1 about the fixed point 1, and such an angle increment is assumed as positive.

Any change in angle C produces a rotation of the whole net about the fixed point 1, so that the line n–1 rotates through the same angle increment as the line 3–1. Therefore, in Fig. 2, let v_C represent the increment to the angle C; let R be the distance n–1; and let θ be the bearing of line n–1. The length of the arc described by point n is $\frac{R\, v_C}{206{,}265}$, in which v_C is expressed in seconds. The east-west component of this arc is

$$\Delta x = \frac{R\, v_C}{206{,}265}\cos\theta = \frac{y_n - y_1}{206{,}265}\, v_C \dots\dots\dots\dots\dots (7a)$$

Also, the north-south component is

$$\Delta y = -\frac{R\, v_C}{206{,}265}\sin\theta = -\frac{x_n - x_1}{206{,}265}\, v_C \dots\dots\dots\dots (7b)$$

Eq. 7a with Eq. 5b, and Eq. 7b with Eq. 6, give

$$\Delta x = \frac{x_n - x_1}{434{,}294}\,(\delta_A\, v_A - \delta_B\, v_B) + \frac{y_n - y_1}{206{,}265}\, v_C \dots\dots\dots (8a)$$

and

$$\Delta y = \frac{y_n - y_1}{434{,}294}(\delta_A v_A - \delta_B v_B) - \frac{x_n - x_1}{206{,}265} v_C \qquad (8b)$$

In the triangle just completed A and B may be designated as expansion angles; and C, as the rotation angle. Line 3–1 may now be regarded as fixed and increments may be applied to the angles of triangle 134 to produce an expansion of line 4–3 and a rotation of this line about point 3, now also held fixed. Angle C is always at the intersection of the new fixed base and the next base to be established—in this case at point 3. Angle A must be opposite the next base or at point 1.

Expressions similar to Eqs. 8*a* and 8*b* can be derived to determine the components of motion Δx and Δy of the end point n caused by the application of increments to the angles of this second triangle, still holding the remaining angles of the net as fixed. With point 3 regarded as the initial point for this triangle, these equations become

$$\Delta x = \frac{x_n - x_3}{434{,}294}(\delta_A v_A - \delta_B v_B) - \frac{y_n - y_3}{206{,}265} v_C \qquad (9a)$$

$$\Delta y = \frac{y_n - y_3}{434{,}294}(\delta_A v_A - \delta_B v_B) + \frac{x_n - x_3}{206{,}265} v_C \qquad (9b)$$

It should be noted that the signs of the v_C-terms in Eqs. 9 are in opposition to those written for the first triangle—because the rotation point is at that end of the fixed line which gives a left-hand rotation when the angle at C is given a positive increment v_C.

In Fig. 1, triangle 345 has 3–4 as the fixed base with the point of rotation still at point 3. Thus, the signs in the equations for this triangle will be the same as in those for triangle 134. In this manner, all the triangles are used until the end point of the net is reached. The combined effect of the increments of the angles of each triangle applied in order is given by the expressions:

$$\Delta y = \sum \left[\frac{y_n - y_c}{434{,}294}(\delta_A v_A - \delta_B v_B) \mp \frac{x_n - x_c}{206{,}265} v_C \right] \qquad (10a)$$

$$\Delta x = \sum \left[\frac{x_n - x_c}{434{,}294}(\delta_A v_A - \delta_B v_B) \pm \frac{y_n - y_c}{206{,}265} v_C \right] \qquad (10b)$$

A sample numerical solution, based on the triangulation net of Fig. 1, is given in Fig. 3. Section (*a*) of these computations lists the fixed values of stations and bases; section (*b*), the angle adjustments for the entire net. Section (*c*) shows the preliminary angle adjustment for one quadrangle, on which the side equation, triangle computations, azimuths, and traverse computations of sections (*d*), (*e*), (*f*), and (*g*), respectively, are based. Together with similar computations for the remaining quadrangles of the net sections (*c*), (*d*), (*e*), (*f*), and (*g*) yield the preliminary coordinates shown in section (*h*) for all the stations in the net, as well as the *y*-component and *x*-component of the closure, as shown in section (*i*).

The side equation for one quadrangle, determined from section (*d*) of Fig. 3, is

$$\begin{aligned} &-3.30\,(1) + 5.77\,(2) - 2.47\,(3) - 1.57\,(4) + 3.66\,(5) - 2.09\,(6) \\ &\quad - 2.43\,(7) + 5.06\,(8) - 2.63\,(9) - 1.47\,(30) + 3.02\,(31) \\ &\qquad - 1.55\,(32) - 7.4 = 0 \ldots\ldots\ldots\ldots\ldots\ldots \quad (11a) \end{aligned}$$

EXPLANATION OF TABLE 1

Table 1, which contains the data necessary to compute the coefficients of the unknown angle corrections, provides a column for each triangle used. The headings of these columns are the number designations of the stations at which the C angles are located. Stations 3 and 5 are repeated because two C angles are located at each of them and these stations are featured in determining the algebraic signs of the coefficients. Reference to Eqs. 10*a* and 10*b* will show the significance of the numbers in the body of the table.

Extreme care should be taken in respect to the algebraic signs of the coefficients, with due regard for the order of differences and also for the signs of the products. These signs may be checked directly from Fig. 1. Considering the latitude coefficients, assume that all the *A* angles of the several triangles receive plus corrections, which will cause an expansion of each of the opposite triangle sides. This series of expansions indirectly will cause, for each triangle, an expansion of the line connecting the corresponding *C* angle station and the end station, n. When this expansion causes n to have a north component of motion, the corresponding sign of the coefficient will be plus. If the component of motion is south, the sign will be minus. Thus, if the *C* angle is south of n, the sign of the corresponding coefficient will be plus; if a *C* angle station lies north of n, the corresponding sign will be minus.

[a] Coordinates of end station: N = 50,615.18; E = 41,078.47.

There is an occasional exception to this rule; for example, when the *A* angle in question is greater than 90°, an increase causes a contraction of the opposite side and the sign in question is reversed.

Since an increase in the magnitude of any *B* angle causes a contraction of the side opposite *A*, the sign of the corresponding coefficient will be the reverse of that derived from the *A* angle. As in the case of the *A* angle, if the *B* angle is more than 90°, the resulting sign is again reversed.

The signs of the latitude coefficients due to an assumed plus correction to the C angles may now be considered. In this case, these displacements of n are due to a rotation of each of the lines connecting the C angle stations with station n. It must first be determined if the rotation is clockwise or counterclockwise about the C angle station in question, and then whether this rotation causes a north or south movement of n. The signs of the latitude coefficients in the problem under consideration may then be checked by Fig. 1.

Angle Change Coefficients.—Inspection of the A angles will show that the one in the second triangle at station 5 is greater than 90°, thus the sign of the v_A-coefficient will be reversed. Also, C angle stations 1, 3, and 5 are south of n, but station 7 lies north of n. Therefore, the first four are regular and plus, the fifth is minus because the angle is greater than 90°, and the last is minus because 7 lies north of n.

Since there are no angles greater than 90° among the B angles, all the v_B-coefficients will be minus except the last, which is plus because 7 lies north of n.

Determination of the v_c-coefficients for the various triangles gives the following: In triangle 1, the rotation is clockwise, and the displacement has a south component. The sign is therefore minus; in triangles 2 and 3, C angle station 3, the rotation is counterclockwise, which produces a north displacement of n, so that these two signs are plus; in triangles 4 and 5, C angle station 5,

the rotation is clockwise and the displacements of n are south, producing minus coefficients; and in triangle 6, *C* angle station 7, the rotation is counterclockwise, producing a north displacement and plus coefficient.

The departure equation coefficients may be checked by a similar analysis, by considering the *A* angle changes as expansions, the *B* angle changes as contractions, and the *C* angle changes as rotations, clockwise or counterclockwise, and then determining whether the resulting displacements are east (+) or west (−).

TRANSFORMATION TO DIRECTIONS

Corrections to the angles *A*, *B*, and *C* are designated by the symbols v_A, v_B, and v_C. However, the direction method is generally used in reduction of a triangulation net; and, since each angle is the difference of two directions, each angle correction will be the difference between corresponding direction corrections. As is customary, direction corrections are designated by numbers within parentheses.

It will be found convenient to use the form of Tables 2 and 3 to complete the final latitude and departure equations, with a column allowed for each triangle. Since there are three angles in each triangle, three pairs of coefficients will appear in each column. For example, in triangle 123, Fig. 1, the

following relations for the latitude equation are found:

$$0.0458\, v_A = 0.0458\, [(3) - (1)] = -\,0.0458\, (1) + 0.0458\, (3) \ldots\ldots (12a)$$

$$-\,0.1093\, v_B = -\,0.1093\, [(32) - (31)] = 0.1093\, (31) - 0.1093\, (32) \ldots\ldots (12b)$$

$$-\,0.1022\, v_C = -\,0.1022\, [(6) - (5)] = 0.1022\, (5) - 0.1022\, (6) \ldots\ldots\ldots (12c)$$

The final coefficient of each direction correction is found by adding the individual coefficients opposite that direction horizontally in each table.

AZIMUTH EQUATION

If the measured (field) angles are used in the derivation of equations for the final adjustment, the *C* angles, or corresponding directions, must be used in deriving the azimuth equation. However, if a preliminary adjustment of the angles in each quadrilateral is made, as in the sample net, the angles are consistent throughout the net and any chain of directions connecting the two fixed bases may be used. Reference to Fig. 1 shows that the simplest form of the azimuth equation is given by the following combination of directions:

$$-\,(4) + (6) - (7) + (11) - (12) + (16) - (17) + (19) + 2.50 = 0 \ldots (13)$$

In Eq. 13, the constant term is found by the calculations shown in Table 4.

TABLE 4.—DETERMINATION OF CONSTANT TERM IN EQ. 13

n−7 (fixed).	132	08	04.58
$\Delta\alpha$........			+02.50

The *A* and *B* angles are used to write an equation based on the length conditions connecting the two measured bases. Both of these distance measurements should be reduced to the standard elevation governing the coordinates of the two fixed (U. S. C. and G. S.) stations. If the net is to be computed on one of the state-wide systems of coordinates, the field measurement of each base must be reduced to sea level distance, and further corrected to the scale of the standard system.

A system of local coordinates is sometimes preferable for a small area such as a county or metropolitan district. For rural counties, it is customary to reduce all measured distances to sea level datum. In a large city, however, it may be desirable to make the published results of the control survey agree as nearly as possible with values which the local surveyor would find by accurate measurement on the ground. This can be accomplished by a system of local coordinates, reducing all distances (including distances between fixed stations) to a mean elevation selected for the district.

The distance equation for the sample net under consideration is derived from the computations shown in Table 5, and has the form:

$$\begin{aligned} &-\,0.65\,(1) + 0.65\,(3) - 2.09\,(5) + 2.09\,(6) + 0.38\,(7) - 1.09\,(9) \\ &\quad + 0.71\,(11) + 1.66\,(12) - 1.66\,(13) - 2.23\,(28) + 2.23\,(29) \\ &\qquad + 1.55\,(31) - 1.55\,(32) + 8.7 = 0 \ldots\ldots\ldots\ldots\ldots (14) \end{aligned}$$

A Practical Application

The principles and methods described in the preceding section were used to advantage on a triangulation project in Logan County, Ohio, where it was decided to develop a sample area between four U. S. C. and G. S. triangulation stations to show some of the problems involved in extending geodetic control in a rural area. In addition, the completed project was intended to illustrate

some of the values of horizontal control for section, township, and other survey corners in such an area. Rolling terrain called for triangulation rather than traverse for the basic control, even considering the fact that triangulation alone does not tie in any section corners.

A reconnaissance party set out to establish a chain of quadrilaterals connecting U. S. C. and G. S. stations "Logan" and "Best" on the north with "Cavern" and "Wortman" on the south. The net shown in Fig. 4 was the result. It has several overlapping figures, a rather undesirable characteristic in a demonstration project, which should be kept as simple as possible. However, triangulation reconnaissance for daylight observation without the aid of towers is not always easy.

TABLE 6.—COORDINATES OF UNITED STATES COAST AND GEODETIC SURVEY STATIONS IN LOGAN COUNTY NET

Station	U. S. C. AND G. S. COORDINATES		LOCAL COORDINATES	
	Latitude ° ′ ″	Longitude ° ′ ″	North	East

Origin....	40 25 00.000	83 45 00.000	100,000.00	100,000.00

The net shown is well controlled by the U. S. C. and G. S. stations at each of the four extreme corners. It was therefore considered complete in itself and adjusted for final coordinates. Since the project was intended to establish a local coordinate system for the county, the local coordinates of the four known stations were computed as shown in Table 6.

The angles were observed in daylight with a direction theodolite reading to single seconds. Special signals were constructed for the purpose, including two heliotropes for use on the longer lines. Triangle closures on the seventeen triangles averaged 2.23 sec, with a maximum of 5.80 sec.

LEAST SQUARES ADJUSTMENT

The first adjustment involving nineteen equations (thirteen angle equations and six side equations) was completed by least squares methods commonly used for this type of problem. A set of preliminary adjusted angles resulted which made all triangles in the net entirely consistent, but did not require that the total net fit between fixed triangulation stations in either latitude or departure.

Starting with the fixed line Logan-Wortman and using corrected angles from the first adjustment, the lengths and azimuths of lines Logan-Bald Knob and Bald Knob-Cavern were computed with the triangles shown in Fig. 5. By use of these two lines and the known coordinates of Logan, the local coordinates of Cavern were found to be N 39,228.14 and E 121,599.38, which, when compared with the known coordinates of Cavern given in Table 6, show a closing error of +0.92 ft in latitude and −0.27 ft in departure. This discrepancy cannot be adjusted satisfactorily by any simple arbitrary method such as is commonly used for traverses, but should be eliminated by small changes in all the angles shown in Fig. 5. Corrections to other angles of the net also will be involved, since the triangle closures and side equation relations set up in the original least squares solution must not be disturbed. To accomplish this result, a complete new solution is needed using the former nineteen condition equations based on corrected angles plus two additional equations to take out the errors in latitude and departure, respectively. The coefficients for the first nineteen equations will be the same as before, but the constant term will be zero in each case since the adjusted equations are based on corrected angles. The new solution is accomplished efficiently by adding the necessary columns to the tabular form of the preliminary solution.

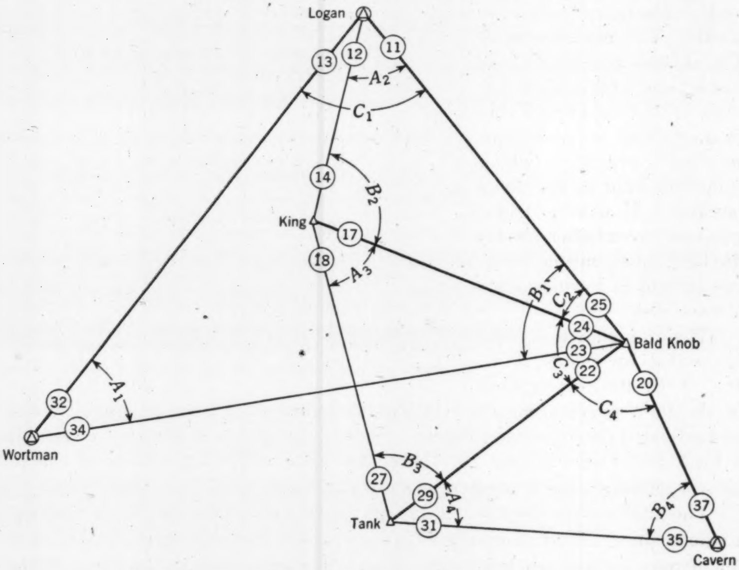

FIG. 5.—TRIANGLES FOR DERIVATION OF LATITUDE AND DEPARTURE EQUATIONS OF LOGAN COUNTY NET

FORMATION OF LATITUDE AND DEPARTURE EQUATIONS

The latitude and departure equations take the form of Eqs. 10*a* and 10*b*, in which x_n and y_n are the fixed coordinates of the end point, and x_c and y_c are the coordinates of the station at the *C* angle of each triangle used. Also, the constant terms are

$$\Delta y = y_n - y'_n \quad \text{.....................} (15a)$$

$$\Delta x = x_n - x'_n \quad \text{.....................} (15b)$$

in which x'_n and y'_n are preliminary coordinates of the end point as found from the first adjustment.

Derivation of the coefficients of the latitude and departure equations is greatly facilitated by the tabular arrangement shown in Tables 7 and 8. These tables are similar to Tables 1, 2, and 3 for the sample net of Fig. 1.

TABLE 7.—DATA FOR LATITUDE AND DEPARTURE EQUATIONS OF LOGAN COUNTY NET

[a] Coordinates of end station: N = 39,227.22; E = 121,599.65.

The latitude equation is written by inserting the coefficients in Col. 6, Table 8, using the symbols (11), (12), $\cdots$, (37) to denote the unknown corrections. The constant term represents the fixed N-coordinate of the end point (Cavern) minus the computed coordinate of that point, in this case −0.92. Multiplication of the equation by 10 for more convenient use in the solution gives

$$\begin{aligned}&-0.598\,(11) - 0.576\,(12) + 1.174\,(13) - 0.106\,(14) + 0.638\,(17)\\&-0.532\,(18) - 0.306\,(20) - 1.079\,(23) + 1.385\,(25) - 0.307\,(27)\\&+1.139\,(29) - 0.832\,(31) + 2.065\,(32) - 2.065\,(34) - 0.399\,(35)\\&\qquad + 0.399\,(37) + 9.2 = 0 \qquad \text{(16a)}\end{aligned}$$

By a corresponding procedure, the departure equation is written from coefficients in Col. 11, Table 8, as follows:

$$\begin{aligned}&-2.203\,(11)+0.245\,(12)+1.958\,(13)+0.045\,(14)-0.271\,(17)\\&+0.226\,(18)-0.719\,(20)+0.646\,(23)+0.073\,(25)+0.131\,(27)\\&-0.485\,(29)+0.354\,(31)-1.237\,(32)+1.237\,(34)+0.170\,(35)\\&\qquad-0.170\,(37)-2.7=0\;\ldots\ldots\ldots\ldots\ldots\ldots\;(16b)\end{aligned}$$

Eqs. 16, when added to the preceding nineteen equations, gave final corrections to the angles, with the result that the position closure on the final station, Cavern, was 0.02 ft in latitude and 0.01 ft in departure. In this manner, the entire supplementary net was made consistent with U. S. C. and G. S. stations in the county. If it is assumed that U. S. C. and G. S. results are acceptable without local verification—certainly a logical assumption for a rural area—this method eliminates the need of measuring a base line or of determining a geodetic azimuth.

DISCUSSION

Julius L. Speert,[5] M. ASCE.—A strong case is presented in this paper for the adjustment of local triangulation nets to the basic geodetic datum when ties are available at two or more points. The subject is particularly timely because of two parallel but independent developments in recent years. The first of these is the continued expansion and the breakdown of the basic triangulation net by the establishment of a large number of closely spaced geodetic stations. This has brought geodetic control into many regions that previously had been without it. The second important development was the introduction and acceptance of the state plane coordinate systems.

These innovations make it possible to express geodetic data in terms of simple x-coordinates and y-coordinates that are convenient for use by all local surveyors. The old excuse that geodetic data are too complicated for purely local use is no longer applicable. To conform with the trend of bringing the strength of geodetic control within the scope of the local surveyor's use, the methods of geodetic computation must be simplified in their application to small local survey nets computed on a plane coordinate grid. The paper presents a worthy contribution in that direction.

It is appropriate to stress that the method of adjustment proposed by the authors is essentially the same as that recommended and used for many years by the United States Coast and Geodetic Survey and described in detail in its publications.[6,7] The principal improvement made by the authors is the adaptation of the method to computation in plane coordinates and their demonstration of its true simplicity.

The problem of adjusting a local net to the basic geodetic datum will fall naturally into one of two cases—according to whether the local net was established before or after the ties to the basic datum became available. Each case is subject to its own particular type of treatment.

In the first case, where the local net was established first, and properly adjusted internally before the geodetic datum was extended into the area, the problem becomes one of readjustment of datum. Perhaps the simplest method of datum readjustment is by the use of "isodiffs." This method has been described in its application to geodetic triangulation,[8] but the appropriate simplifications should be readily apparent to any engineer who is interested in using it on a plane coordinate system. The method is especially advantageous when either funds or time for complete recomputation and adjustment are not readily available. If the original adjustment was made by the least squares method of condition equations, and if the original computations are available to the computers, the addition of equations for the new conditions imposed by the ties (as recommended by the authors) offers an excellent opportunity to complete the adjustment without repeating the bulk of the original computations. Both methods take full advantage of the previous computations and adjustment.

[8] "Readjustment of Triangulation Datum," by Julius L. Speert, *Transactions*, ASCE, Vol. 103, 1938, p. 1002.

In the second case, when ties to the basic geodetic datum are available at the time the local net is established, the original adjustment should, of course, be based on that datum. In this case the computer has greater latitude in his choice of method. The two basic methods of geodetic adjustment—condition equations and variation of coordinates—are both available. Both lend themselves readily to considerable simplification in their application to a small local net on a plane coordinate system.

The authors have presented an excellent description of the condition equation method. However, for this particular type of survey net the coordinate method is usually so far superior to the condition method as to economy of labor that it would appear to justify far more consideration than it has received. A detailed description of its application to a plane coordinate system was published as far back as 1935.[9] In this method there will always be just two normal equations for each new station established, regardless of the complexity of the net, or of the amount of overlapping of its component parts. Thus, the adjustment in Fig. 1 would require the solution of only eight simultaneous equations as compared to the sixteen equations of the condition method; and the adjustment in Fig. 4 would require the solution of ten equations instead of twenty one. The addition of further ties, check observations, or other complexities to the problem merely increases the advantages of the coordinate method over the condition method.

C. H. NEY,[10] ESQ.—An interesting and practicable method of adjusting a local triangulation net between two fixed points, that have been established with a higher degree of accuracy, has been outlined by the authors. As the positions of the survey stations are defined in terms of rectangular coordinates, surveyors and city engineers who have occasion to make use of this type of adjustment will be spared the necessity of familiarizing themselves with the computation of geodetic latitudes and longitudes.

With one of the fixed stations taken as the origin, the latitudes and departures of the other triangulation stations are determined. A traverse, composed of selected triangle sides joining the fixed points, is used in the formation of the condition equations of closure. For the determination of the absolute terms of these equations, the latitude and departure of the second fixed point must be computed through the traverse. The accuracy of the triangulation adjustment hinges upon the correct determination of these values, which, in reality, define the azimuth and length of the polar ray joining the two fixed points.

The authors compute the required latitude and departure of the second fixed point by plane trigonometry on the premise that the survey is of such limited extent that no error will result from neglecting spherical excess and the curvature of the earth. However, it should be kept in mind that there is a definite limit to the physical extent of the local survey beyond which the authors' methods of adjustment will not be applicable. In this discussion an attempt will be made to formulate a criterion for the determination of this limit.

[9] "Triangulation Adjustments in Plane Coordinate Systems," by R. M. Wilson, *Engineering News-Record*, October 3, 1935, p. 459.

[10] Chf., Triangulation Adjustments Div., Geodetic Survey of Canada, Dept. of Mines and Resources, Ottawa, Ont., Canada.

In 1928, W. M. Tobey, then Assistant Director of the Geodetic Survey of Canada, issued a bulletin[11] outlining a method whereby a traverse having courses of almost unlimited length may be treated in terms of latitudes and departures by an application of Legendre's theorem to the polar triangles formed by lines joining each traverse station with the origin.

Fig. 6(a) shows a traverse on the spheroid, and Fig. 6(b) shows a corresponding "Legendrian" traverse on a plane where the measured deflection angles, $\beta_2, \beta_3, \beta_4, \cdots, \beta_n$, are increased by $\frac{\epsilon_2}{3}, \frac{\epsilon_2 + \epsilon_3}{3}, \frac{\epsilon_3 + \epsilon_4}{3}, \cdots, \frac{\epsilon_{n-1} + \epsilon_n}{n - 1}$, and where the distances, $t_1, t_2, t_3, \cdots, t_n$, of the Legendrian traverse are identical with the corresponding values determined from actual measurement on the earth's surface. It is seen that the deflection angle at any point of the corresponding Legendrian traverse is greater than the corresponding deflection angle of the actual traverse by one third of the sum of the spherical excesses of the polar triangles adjacent to the polar ray.

The bearings, $b_1, b_2, b_3, \cdots, b_n$, of the courses of the Legendrian traverse are

$$b_1 = b_{1a} \dots\dots\dots\dots (17a)$$

$$b_2 = b_{2a} + \frac{\epsilon_2}{3} \dots\dots\dots\dots (17b)$$

$$b_3 = b_{3a} + \frac{2}{3}(\epsilon_2 + \epsilon_3) - \frac{\epsilon_3}{3} \dots\dots\dots\dots (17c)$$

and

$$b_n = b_{na} + \frac{2}{3}(\epsilon_2\epsilon + {}_3 + \cdots + \epsilon_n) - \frac{\epsilon_n}{3} \dots\dots\dots\dots (17d)$$

in which $b_{1a}, b_{2a}, \cdots, b_{na}$ are approximate bearings of the measured courses referred to the meridian through the origin, and computed from the north, as follows:

$$b_{1a} = \beta_1 \dots\dots\dots\dots (18a)$$

$$b_{2a} = \beta_1 + \beta_2 \dots\dots\dots\dots (18b)$$

and

$$b_{na} = \beta_1 + \beta_2 + \beta_3 + \cdots + \beta_n \dots\dots\dots\dots (18c)$$

The Legendrian latitudes and departures for the nth-station for the traverse are

$$L_n = L_{na} - [\tfrac{2}{3}(\epsilon_2 + \epsilon_3 + \epsilon_n) - \tfrac{1}{3}\epsilon_n] D_{na} \sin 1'' \dots\dots\dots\dots (19a)$$

and

$$D_n = D_{na} + [\tfrac{2}{3}(\epsilon_2 + \epsilon_3 + \epsilon_n) - \tfrac{1}{3}\epsilon_n] L_{na} \sin 1'' \dots\dots\dots\dots (19b)$$

in which L_n and D_n are the Legendrian values of the latitudes and departures, respectively, and

---

[11] "The Conversion of Latitudes and Departures of a Traverse to Geodetic Differences of Latitude and Longitude," by W. M. Tobey, *Publication No. 25*, Geodetic Survey of Canada, Ottawa, Ont., 1928.

$$L_{na} = t \cos b_{na} \ldots\ldots (20a)$$

and

$$D_{na} = t \sin b_{na} \ldots\ldots (20b)$$

are the approximate values as computed in ordinary traverse reductions. The addition of the corrective terms to the approximate latitudes and departures allows for reduction of traverses up to 120 miles in length with geodetic precision. Before the length and azimuth of a polar ray that extends from the origin to any one of the traverse stations may be determined, it is necessary to calculate the spherical excesses of the polar triangles.

(b)

FIG. 6

The spherical excesses of the polar triangles are determined from

$$\epsilon''_n = \frac{D_{na} L_{(n-1)a} - D_{(n-1)a} L_{na}}{2 R N \sin 1''} + K \ldots\ldots (21)$$

in which K is a second order term of negligible magnitude. It is seen that, in calculating the excesses, the approximate values of the latitudes and departures may be used. Attention must be given to the correct signs of the latitudes and departures—points north of the origin have a plus latitude and points east of the origin have a plus departure.

Having determined the corrected latitude and departure of the terminal station of the traverse, the azimuth and length of the polar ray from the origin to this station may be found. If ψ represents the angle on the plane between the initial meridian and the polar ray,

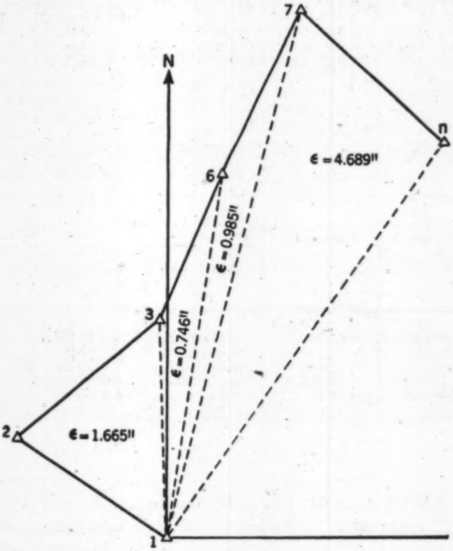

FIG. 7

$$\tan \psi = \frac{D_n}{L_n} = \frac{D_a + dD}{L_a + dL} \qquad (22)$$

The true azimuth corresponding to ψ is given by

$$\alpha_n = \psi_n + \left(\frac{\epsilon_2}{3} + \frac{\epsilon_3}{3} + \cdots + \frac{\epsilon_n}{3} \right) \qquad (23)$$

and the length of the polar ray is

$$S_n = \frac{D_n}{\sin \psi_n} = \frac{L_n}{\cos \psi_n} \qquad (24)$$

In adjusting local triangulation between widely separated fixed points by the methods suggested by the authors, the accuracy of the adjustment may be increased by taking into consideration the Legendrian corrections to the latitudes and departures.

Example 1.—Taking the length of the line 1–2 and the adjusted angles (figural adjustment only) pertaining to the authors' first numerical example,

the lines 1–2, 2–3, 3–6, 6–7, and 7–n, were worked out and treated as a traverse (Fig. 7). Computed in the usual manner, the azimuth and length of the polar ray 1–n are found to be $\alpha_{1-n} = 34° 32' 50.65''$ and $\log S_{1-n} = 4.0542039$ m. The Legendrian reduction gives, for the same line, $\alpha_{1-n} = 34° 32' 50.72''$ and $\log S_{1-n} = 4.0542039$ m. For a survey of limited extent, as typified by this example, it is evident that no increased accuracy of practical importance is obtained by the application of the Legendrian principle.

Example 2.—To show the application of the Tobey method[11] for finding the azimuth and length of a long polar ray, the traverse of the preceding example (Fig. 7) has been recomputed using the original deflection angles. The length of each course has been converted to meters, however, and multiplied by 6. As this theoretical traverse extends over an area 35 miles from north to south and 38 miles from east to west, it is sufficiently large to benefit by the Legendrian refinement in making the computations.

1–2	4.4190809
2–3	4.4175670
3–6	4.3508778
6–7	4.3974938
7–n	4.4385440

(*d*) Measured deflection angles—

$$\begin{aligned}
\beta_1 &= +\ 304^\circ\ 27'\ 16.53''\\
\beta_2 &= +\ 106^\circ\ 58'\ 15.95''\\
\beta_3 &= -\ \ 28^\circ\ 44'\ 37.70''\\
\beta_6 &= +\ \ \ 2^\circ\ 46'\ 42.55''\\
\beta_7 &= +\ 106^\circ\ 40'\ 29.75''
\end{aligned}$$

The various steps of the reduction are given in detail hereinafter.—

(*a*) The determination of the approximate bearings of the courses (reckoned clockwise from the north and referred to the meridian through Station 1) is as follows:

$$\begin{array}{lcr}
\text{Azimuth 1–2} & = & 304^\circ\ 27'\ 16.53''\\
\beta_2 & = & \underline{106^\circ\ 58'\ 15.95''}\\
b_{2a}\ \text{(approximate bearing 2–3)} & = & 51^\circ\ 25'\ 32.48''\\
\beta_3 & = & \underline{-\ 28^\circ\ 44'\ 37.70''}\\
b_{3a}\ \text{(approximate bearing 3–6)} & = & 22^\circ\ 40'\ 54.78''\\
\beta_6 & = & 2^\circ\ 46'\ 42.55''\\
b_{4a}\ \text{(approximate bearing 6–7)} & = & \underline{25^\circ\ 27'\ 37.33''}\\
\beta_7 & = & \underline{106^\circ\ 40'\ 29.75''}\\
b_{5a}\ \text{(approximate bearing 7–n)} & = & 132^\circ\ 08'\ 07.08''
\end{array}$$

Steps (*b*), (*c*), (*d*), and (*e*), are shown in Tables 9 to 12, respectively, in which all measurements are given in meters.

(*f*) Azimuth and length of polar ray 1–n—

$$\operatorname{Tan}\psi = \frac{D}{L} = \frac{38{,}548.32}{55{,}988.26}$$

$$\begin{aligned}
\operatorname{Log}\tan\psi &= 4.58600546 - 4.74809697 = 9.83790849\\
\psi &= 34^\circ\ 32'\ 51.68''\\
\Sigma(\epsilon/3) &= \underline{+\qquad\ 2.69''}\\
\alpha_{1-n}\qquad &= 34^\circ\ 32'\ 54.37''
\end{aligned}$$

$$\begin{aligned}
\operatorname{Log} L_n &= 4.74809697\\
\operatorname{Cos}\psi &= \underline{9.91574505}\\
\operatorname{Log} S &= 4.83235192\\
S &= 67{,}975.32\ \text{m}
\end{aligned}$$

Thus, for the polar ray 1–n,

$$\alpha_{1-n} = 34° \; 32' \; 54.37''$$
$$\text{Log } S_{1-n} = 4.8323519$$
$$S = 67{,}975.42 \text{ m}$$

Had the values been computed without applying the Legendrian corrections, the result would have been

$$\alpha_{1-n} = 34° \; 32' \; 50.53''$$
$$\text{Log } S_{1-n} = 4.8323549$$
$$S = 67{,}975.89 \text{ m}$$

In general, in adjusting local triangulation nets between fixed primary stations by the methods suggested by the authors, it is desirable to have a criterion indicating the extent of the survey which may be accurately reduced. From the foregoing, it is evident that the sum of the spherical excesses of the polar triangles involved in the survey provides this criterion. From the application of the Legendrian principle it can be shown that

$$\alpha_{1-n} = \beta_1 + \beta_2 + \beta_3 + \cdots + \beta_0 - 180° + \Sigma(\epsilon'') \dots\dots\dots (25)$$

in which $\Sigma(\epsilon'')$ is the sum of the spherical excesses of the polar triangles. If $\Sigma(\epsilon'') = 0$,

$$\alpha_{1-n} = \beta_1 + \beta_2 + \cdots + \beta_0 - 180° \dots\dots\dots\dots\dots (26)$$

and the azimuth and the length of the polar ray joining the origin with the terminal station may be deduced with geodetic accuracy from the approximate latitudes and departures. The approximate value of ϵ for each polar triangle may be quickly deduced by scaling the area of each triangle, converting the area to square miles, and dividing by 76.5. Remembering that the Legendrian corrections to the latitudes and departures of the traverse courses are

$$dL_{\text{Leg}} = t \sin b_a \, db \sin 1'' \dots\dots\dots\dots\dots\dots (27a)$$

and

$$dD_{\text{Leg}} = t \cos b_a \, db \sin 1'' \dots\dots\dots\dots\dots\dots (27b)$$

respectively, and that

$$\tan \psi = \frac{\Sigma(D_a + dD_{\text{Leg}})}{\Sigma(L_a + dL_{\text{Leg}})} \dots\dots\dots\dots\dots\dots (28)$$

the effect of the spherical excesses on the azimuth and length of the computed polar ray may be readily determined. A cursory examination in this manner will show whether the desired accuracy may be attained without the application of Legendre's theorem.

H. W. Hemple,[12] M. ASCE.—One of several methods which may be used in adjusting local triangulation surveys to the federal geodetic triangulation network is illustrated in this paper. As the density of coverage of the federal net of control established by the United States Coast and Geodetic Survey (U.S.C. and G.S.) increases, more general utilization of the stations established thereon will be made to control supplemental surveys. Connections of local surveys to the federal triangulation net will make certain that these will be in their correct relative position with respect to other surveys so connected; and also will give assurance that the points established on the local survey can be re-established at any time, should the original markings be lost. The method of adjustment discussed by Professors Coddington and Marshall brings to the attention of engineers and surveyors one system by which their own surveys may be adjusted to agree with the over-all federal net.

---

[12] Chf., Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

The U.S.C. and G.S. has completed in excess of 100,000 miles of first order and second order triangulation, forming a network of control spanning the entire United States. In addition to the main scheme stations, there are thousands of supplemental points located on these arcs. The positions of all points are expressed on the North American Datum of 1927. The national survey nets on Mexico and Canada are also related to this same datum, as is the triangulation extending into Alaska, to the tip of the Aleutian Islands, and to the Bering Strait. Since all triangulation stations on the national nets of North America are on a common datum, their locations are definitely established; and all such survey data are expressed in their correct relationship to one another. For any one station, the geographic position will satisfy only that particular location.

At certain intervals a measured base line is inserted into the scheme of triangulation. These base lines are measured with invar tapes, which have been standardized at the United States Bureau of Standards. Measurements are made with a definite tension, and temperature readings are taken at each tape length. At least three tapes are used, and measurements are made backward and forward. Checks are such that the distance is determined with an accuracy so that the actual error must not exceed 1/300,000 for first order triangulation.

The check on distances between base lines as carried through the triangulation must be 1/25,000 or better. In actual practice the average check is of the order of 1/80,000 for the 100,000 miles of triangulation in the United States. Azimuth control is provided by Laplace azimuths spaced at regular intervals. Observed astronomic azimuths are corrected for the effect of the deflection of the vertical through the use of precise longitude observations and are thereby reduced to true geodetic azimuths. Surveyors and engineers should have no hesitancy concerning the accuracy in connecting to the federal net.

To promote the more general use of federal control stations, the U.S.C. and G.S. has transformed the geographic positions thereof to plane coordinates (X and Y). For each state a definite system of plane coordinates has been adopted, and all federal horizontal control therein is expressed on this plane. The purpose of transforming geographic positions to plane coordinates was to facilitate the use of federal surveys by making provision for a simpler method of treating the computations involved for the local surveys when they are connected to federal triangulation schemes. These plane coordinate systems were adopted principally as a procedure by which the surveyor could connect his traverse surveys and adjust his work to fit into the federal net, utilizing only those simple computational methods which are in general use. Professors

Coddington and Marshall show how plane coordinates may also be used to adjust a local triangulation scheme.

After the arcs of triangulation are about 25 miles apart, the U.S.C. and G.S. has found it advisable to cover the entire remaining intermediate area with control, adjusting it simulataneously. In extending the area triangulation, the main scheme stations are about 8 miles apart. Supplemental stations are established at about 4-mile intervals along the main highways. Corrections necessary to fit properly the new work into the major networks surrounding it are then distributed over a relatively large number of observations and can be assimilated without causing too great a distortion in any one measurement or observation.

The authors mention urban control in Pittsburgh, Pa., and Columbus, Ohio. Other cities where geodetic control connected to the federal net has been accomplished are Rochester, N. Y.; Atlanta, Ga.; Boston, Mass.; Cleveland, Ohio; Hartford, Conn.; Minneapolis, Minn.; and Houston, Tex.; as well as many others. In June, 1947, the East Bay cities of the San Francisco (Calif.) area completed a comprehensive scheme of urban control rigidly connected to the federal net; and in December, 1947, the urban control for Cincinnati, Ohio, also rigidly connected to the federal net, was completed.

In the extension of the federal triangulation control, it is the policy of the U.S.C. and G.S. to establish base lines for length control in proximity to urban centers. These control the distance determinations in the federal net and will likewise aid in the control of the lengths for the urban triangulation whenever the cities establish a scheme of urban control. If such local control is available when the federal surveys are established in the locality, connections are made between the two schemes; and, if the bases and lengths of the urban control are of sufficient accuracy, the federal net is adjusted thereto.

The decade from 1937 to 1947 has marked a greatly augmented use of federal triangulation by engineers of state, municipal, and private organizations. It is confidently expected, that, as the ease and facility with which local survey connections may be made to the federal net become more generally known, this precise control will be used even more. Such papers as this are indicative that general interest is becoming increasingly manifest.

Lansing G. Simmons,[13] M. ASCE.—This subject has become of increasing interest in recent years, particularly to engineers and surveyors taking advantage of the rapidly expanding precise triangulation net of the United States. With the establishment of the state plane coordinate systems, the problem of adjusting triangulation directly on these plane grids, without reference to the geographic elements of position, length, and azimuth, is of concern to all involved in the establishment of high-grade horizontal control surveys. The authors have presented a solution which, although departing from correct theory in some instances, will produce excellent results for control schemes of local extent.

The writer cannot agree with the statement in the "Synopsis" to the effect that "Local triangulation nets, both urban and rural, can be precisely adjusted to large-scale geodetic triangulation with comparatively little effort * * *." Most readers will agree, particularly when it is realized that the actual solution of the nineteen simultaneous equations of the Logan County example does not appear in the paper. The importance and precision of the work should be considered before such a plan is adopted.

---

[13] Chf. Mathematician, Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

The new features brought out are the development and the use of condition equations, in terms of rectangular coordinates, necessary for the elimination of the position closure between stations previously established. This has always been a troublesome point in the adjustment of local work, and has usually been handled by simply neglecting the condition and by permitting inconsistencies to exist between new and old work.

Any triangulation net worthy of an adjustment, including the rigid conditions of position closures, is usually worthy of a completely rigid and simultaneous adjustment. The authors state that one of three possibilities for a preliminary adjustment would be to include all condition equations except those for latitude and departure closures. These would be introduced later in a final adjustment. It is believed that all conditions, including those of position, should be contained in one adjustment. This system not only gives better results in general, but can be accomplished more rapidly than any combination of successive adjustments that would yield comparable results.

Although the paper is principally confined to local triangulation nets, readers should be warned of the fact that, in strictness, the observed angles of a a triangulation scheme are not plane angles and should not be so used in working on a plane grid. The difference is infinitesimal for short lines on a local grid, but it becomes quite appreciable in carrying a precise scheme across a state with longer lines. These differences between observed (geodetic) angles and grid angles result from the fact that a straight line on the earth is not exactly a straight line on the projection, and vice versa. Their magnitude can easily approach 1 sec or 2 sec and, at times, several seconds of arc.

As an example, in carrying the computation over a considerable distance, if the necessary corrections are not applied to the observed angles to obtain grid angles, no account is made of the slowly changing scale of the projection. This difference between geodetic and grid angles can also be illustrated by the fact that a large geodetic triangle must necessarily close to 180° plus the spherical excess, whereas a triangle on the grid is closed to exactly 180° in an adjustment. Therefore, it follows that that the algebraic sum of the corrections to the three angles of a triangle must be equal to the spherical excess and negative in sign.

In conclusion, the authors of the paper have dealt with an interesting subject and have effected a nice solution. The foregoing cautions are aimed at those who propose to adapt the method to extended triangulation of high precision. It is believed that the most satisfactory solution in these cases is to compute the work geodetically, converting the position of each station to the grid individually.

E. F. CODDINGTON[14] AND O. C. J. MARSHALL,[15] Members, ASCE.—The discussions express three general opinions concerning this paper: First, the need and timeliness of a simple method to fill in the 25-mile gaps of the first order triangulation nets provided by the United States Coast and Geodetic Survey (U. S. C. and G. S.); second, an excellent description of this control net by Mr. Hemple; and, third, a questioning by some of the discussers of the accuracy of the method.

Messrs. Ney and Simmons raise the question of the accuracy of the method, especially when extending basic control nets. Mr. Ney demonstrates that the computation errors were insignificant in the case of the synthetic net used by the writers. The Logan County (Ohio) net is smaller than the synthetic net. As to the question of rigid or correct theory raised by Mr. Simmons, it may be stated that practically all geodetic theory is applied by a succession of approximations. The number of significant terms in the series of approximations increases with the length of lines or with the size of area under consideration. The writers have been successful in applying mechanical integration to find accurate lengths of elliptical arcs on the earth's surface.

The writers are convinced that local rectangular coordinates are sufficiently accurate for areas under 25 miles square, or to fill in control in any 25-mile gap in the completed first order triangulation net executed by the U. S. C. and G. S. The local rectangular coordinates of all geodetic stations of the net adjusted to the first order control may be easily transferred back to geographic coordinates (latitude and longitude) in case state-wide coordinates may be desired for mapping purposes. This method was derived to enable city engineers to use local coordinates in making cadastral surveys tied to first order geodetic control.

THE GENERAL PRINCIPLES OF HIGHWAY TRANSITION CURVE DESIGN

By John Joseph Leeming,[1] Esq.

With Discussion by Messrs. Carl F. Meyer, Ralph L. Fisher, William R. Welty, Elmer R. Haile, Jr., Charles M. Noble, and John Joseph Leeming

Synopsis

The theoretical and experimental background of the published theory of highway transition curve design is explored in this paper. The writer shows (1) that the theory is fallacious in its disregard of the superelevation, and (2) that the experimental evidence produced for it is questionable.

A modified theory, called "the lateral force theory," is outlined. Experimental evidence is produced to show that the length of the transition curve is not a matter of great importance, and the proposal is made that it should be made a fixed proportion of the total length of the curve. It is also shown that the transition need not necessarily be spiral in form.

Simplified equations for the solution of the compound curve are given, based on the radius of the arc as parameter, together with a table of spiral functions. There is also a brief description of the proposed method of curve design, illustrated by a worked example.

1. Introduction

In designing transition curves the fundamental principle of the method described by John Oran Eichler, Assoc. M. ASCE, and Howard W. Eves[2,3] is, in the words of the authors,[4]

> "* * * that the rational way to achieve this transition [from tangent to curve] is to make the rate of gain of the 'centrifugal ratio,' P/W, constant throughout the curve. This is equivalent to the demand that the driver sharpen his curve by turning his steering wheel at a constant rate."

The symbol P in this context denotes the centrifugal force. In this theory it is also postulated that the rate of change of centrifugal force, for which

[4] *Ibid.*, p. 960.

W. H. Shortt's[5] symbol C will be used, should be the same for all curves. Mr. Shortt, in England, suggested that this rate for C should be 1 ft per sec^3, claiming that this is the maximum rate that will pass unnoticed. The value has been accepted by others, although in the United States values of 2 ft per sec^3 and 3 ft per sec^3 have been proposed.

This theory gives the same length for a transition curve whether superelevation is present or not, although it is obvious that this factor must have some effect on a car.

Consideration of the foregoing from the viewpoint of first principles at once raises the question as to whether the rate of change of centrifugal force is the important effect for transition curve design. To find an answer it is necessary to consider the forces acting on a car traveling on a canted road.

2. THE LATERAL FORCE

Fig. 1 represents a car traveling on a curve of radius R, at a speed v, on a road canted at an angle α. The angle, and all forces, are considered to be positive as drawn. The centrifugal force is F_c. The reactions of the road on the car, parallel and normal to the surface, are designated by $j\,W$ and $n\,W$, respectively, and are called the lateral and normal forces. Then, resolving forces and eliminating W, the weight of the car,

$$j = \frac{v^2}{g\,R}\cos\alpha - \sin\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and

$$n = \frac{v^2}{g\,R}\sin\alpha + \cos\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which g is the acceleration due to gravity. The two quantities, j and n, are called the lateral and normal ratios, respectively. They are pure numbers, provided the units used are mutually consistent.

The normal force, $n\,W$, is very little greater than W under road conditions. Its increase due to curvature is a very small increase in an already existing force, acting in a direction that cannot affect the stability of the car or the comfort of the passengers. Therefore, it may be neglected.

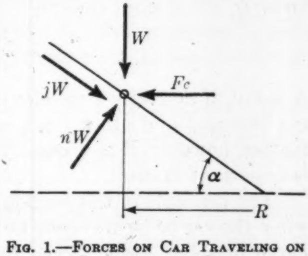

FIG. 1.—FORCES ON CAR TRAVELING ON A SUPERELEVATED CURVE

The lateral force, $j\,W$, is the key to the situation. It is the sum of the components of the centrifugal force, and of the weight of the car, along the surface of the road and is the force which tends to cause the car to skid or to overturn, or which causes the passengers discomfort by urging them sideways in their seats. It is also the force that must be applied by the driver through the steering wheel, as it is the force he must overcome in turning his wheel to make the car travel around a curve.

The full implications of the lateral force as a factor in road design were dealt with at some length in a previous paper,[6] but the most important must be mentioned in passing—namely, that a change in cant is equivalent to a change in curvature and that one change should never occur without the other.

---

[5] "A Practical Method for the Improvement of Existing Railway-Curves," by W. H. Shortt, *Proceedings*, Inst. C. E., Vol. 176, 1909, p. 97.

At a certain speed, called the "hands-off speed," the lateral ratio j is equal to zero. At this speed the car steers itself around the curve, provided the steering is properly adjusted, and the driver need not touch the wheel at all. The centripetal force is acting still, but it is applied to the car by the superelevation. If the curvature and the cant are changing together in due proportion (on a well-designed transition curve, for example), the wheel can be seen to turn itself if the proper speed is held. Alternatively, if the driver reaches the hands-off speed on a superelevated circular arc, he may then steer the car in a zigzag course by varying the speed without touching the wheel, which again will turn itself.

At any speed different from the hands-off, the driver must exert some force to follow the curve, but the direction as well as the magnitude of this force will be decided by whether the speed is more or less than the hands-off. If it is less he must steer away from, if more he must steer toward, the center of curvature. Thus, the presence of the superelevation does make a very vital difference to the driver, and also to the passengers, who are affected similarly. Therefore, it is the rate of change of lateral force that is the important result and should be kept constant on a transition curve.

A significant effect follows from this consideration. In Eq. 1, cos α approximates to unity. Then, at any constant speed, the requirement for maintaining a constant hands-off speed is that

$$\frac{k}{R} = \sin\alpha \text{........................} (3)$$

in which k equals v^2/g. For this condition a circular arc is not essential. Any curve for which it is possible to keep the curvature and superelevation proportional will do, including the conventional transition spiral.

Similarly, the condition for maintaining a constant rate of change of lateral force, Q, at constant speed is

$$Q = \frac{dj}{dt} = \frac{d}{dt}\left(\frac{k}{R} - \sin\alpha\right) \text{..................} (4)$$

A spiral, if correctly superelevated, will provide this condition, but its use is not essential and other types of curves can be used. Before discussing this matter, however, it is necessary to decide whether the rate of change of force is important in itself.

The principle of this section may be summarized in another manner. Assume the car to be traveling at a constant speed on a well-designed transition curve of spiral form. Then the rate of change of direction in plan will be proportional to C, the rate of change of centrifugal force, but the change will be made by two agencies. The first is by the rate of change of the superelevation. This is solely a function of road design, the driver has nothing whatsoever to do with it, and in most cases will be unaware of it. The second agency is the application of force by the driver at the steering wheel, and this is proportional to Q, the rate of change of lateral force. In his turn, the road engineer has nothing to do with this.

---

[6] "Road Curvature and Superelevation," by J. J. Leeming, *Road Paper No.* 7, Inst. C. E., October, 1942.

The whole essence of the theory put forward in this paper is that this latter effect must be studied and allowed for in design, because it may cause variation between theory and practice. However well designed a curve may be according to spiral principles, if the driver does not follow a constant Q proportional to the value of C on which the spiral has been designed, he is not following the design curve. It is surely logical that the curve should be laid out to conform to the driver's practice; and, if he prefers, and habitually uses, some method of turning his wheel other than the constant rate expressed by constant Q, then the type of transition should be chosen to conform with his habits—even if this curve is not of spiral form.

3. The Rate of Turning the Steering Wheel

If the rate of application of force by the driver at the steering wheel is defined as "the rate of turning the wheel," the foregoing principle raises two further questions of fact, namely:

1. Does the driver turn his wheel at a constant rate on any given transition curve?
2. Does he turn it at the same rate on all transition curves?

These two questions are not the same, although they have not hitherto been separated. The first decides the shape of the transition curve, but does not involve any condition as to its length. The assumption that this question can be answered affirmatively has formed the case for the spiral curve, although it is seen that other curves can also satisfy the condition. The second part, if answered similarly, means that all transition curves must be designed to provide the same rate of change of force, at some chosen speed. The assumption that both questions can be answered affirmatively forms the basis of the previous theory.

Examination of the literature setting forth the case for this affirmative answer to the two questions shows that it rests entirely on Mr. Shortt. All other writers have merely repeated his conclusions; but his experiments were made on uncanted railway tracks, and some doubts may be felt at once on examining the original paper. Mr. Shortt stated that he had found that a rate of change of centrifugal force of 1 ft per sec^3 was the maximum which would pass unnoticed. This statement must involve the idea of comfort, and it has been so read in the past by most people. However, it is impossible for an observer to analyze his feelings so delicately and accurately as to be able to decide beyond doubt that the rate of change of force affected his comfort, and not the force itself. Nevertheless, there must be some value of the force that will cause discomfort, and the possibility that some lower value might cause some lesser degree of discomfort obviously is present. Mr. Shortt did not even discuss this possibility, nor did he state how he arrived at his conclusions so that the reader could judge for himself.

F. G. Royal-Dawson[7] applied Mr. Shortt's principle to roads, without experimental proof of the validity of the transfer, and called the rate of $C = 1$ a "natural rate of turning." In this case the difficulty of the limit to the value of the force itself, previously referred to, was avoided by the expedient of stipulating a maximum value for the centrifugal ratio, usually 0.25. The superelevation was specified as some fraction of the centrifugal ratio, and it was then stated that the natural rate of turning should be adhered to, provided that the centrifugal ratio did not exceed this amount at some "design speed."

---

[7] "Curve Design," by F. G. Royal-Dawson, E. & F. N. Spon, Ltd., London, 1932.

This argument is not very convincing, quite apart from the fact that it contains the fundamental fallacy of using C and the centrifugal ratio, ignoring the superelevation. The theory gives the same length for a transition curve, no matter what the value of the superelevation. However, Mr. Shortt himself stated, in his original paper,[5] that "* * * a curve which cannot be given superelevation is more in need of easing at the ends than one which can be superelevated," thus implying that superelevation does affect the problem, although, mathematically, he and his followers ignored this principle.

There has also been a large school among British engineers, both railway and highway, that has not accepted the principles of Messrs. Shortt and Royal-Dawson on practical grounds. Finally, H. A. Warren[8] carried out some experiments which threw doubt on the validity of the rate of change of force as the criterion for transition curve design. These experiments were on a small scale, and there was some question as to the accuracy of the work, by which C was derived from the plotted path of the car.

Thus, it was thought that there was need for experimental work on the rate of turning the wheel. The writer, therefore, undertook this work, in collaboration with A. N. Black. A preliminary report on the results has been published,[9] but a summary is given herein, which includes later work.

4. Reasons for the Experimental Procedure

The experimental technique had to be based on the previous theory, because, despite its shortcomings, this held the field, and because it had found some measure of acceptance. Therefore, the experiments were designed to answer the two questions:

(1) How do drivers actually take curves?
(2) What is the criterion of comfort on curves?

The two questions of Section 3 are included in the first of these latter two.

Since the force the driver applies at the wheel is proportional to j, the best method of investigating these questions is to measure j as directly as possible. That part of the centripetal force applied through the superelevation (that is, $W \sin \alpha$), being independent of the driver and imposed on him by the road designer, is irrelevant to the purpose. To make the conclusions general, it is also essential that the tests be carried out under the most natural conditions possible, to avoid distractions to the driver that would tend to influence his method of driving, and also that the tests should include as many cars and drivers as possible.

---

[8] "Experimental Transition Curves," by H. A. Warren and E. R. Hazeldine, *Journal*, Inst. Municipal & County Engrs., London, March, 1939, p. 1021.

[9] "Road Curvature and Superelevation: Experiments on Comfort and Driving Practice," by J. J. Leeming and A. N. Black, *ibid.*, December, 1944, p. 137.

The method used by Mr. Warren was to trace out and survey the path of the car. This procedure, however, is open to a number of objections. In the first place it is inaccurate, because it involves some process of double differentiation of the path, to determine the centrifugal ratio, from which the superelevation must be deducted to find j. It is laborious in every way, and involves considerable apparatus as well as a technique which must infallibly distract the driver. Finally, the method can only be useful on a limited number of curves because of the labor involved—resulting from the fact that a detailed survey of the curve is necessary, since the superelevation must be known. Thus, the answer obtained would be limited to some extent, and would therefore be of less general application.

5. Experimental Procedure

From the considerations mentioned, it was decided that the ideal method would be to use a recording accelerometer. This instrument measures j directly, and Q can be determined by simply measuring the slope of the line on the record. Accordingly, such a device was designed and built, which, although simple to make with the materials available in wartime England, could fit into most cars.

The accelerometer consists of a 10-lb weight hung on springs from the baseboard of a strong wooden case. When the instrument is placed athwart the car, under the influence of the lateral force the weight shifts over against the springs, moving a stylus on the end of a long magnifying lever. This records the movement of the weight on a strip of metallic paper traveling over a drum driven by a phonograph motor. A fixed stylus provides a datum line.

This instrument was carried in cars traveling on ordinary journeys. Before starting, it was emphasized that the driver should not vary his usual driving methods in any way. When the car approached any curve thought suitable, the operator started the motor; and, for each curve, recorded its direction of curvature, the average speed of the car, and the comfort sensations of himself and the driver.

In the subsequent analysis, the individual curves were identified, and smoothed off to average straight lines if this could reasonably be done. For more than 90% of the curves it was found that the rate of change of force could be represented by sloping straight lines, and the curve as a whole by two such lines, with or without a length of straight line parallel to the datum—that is, of constant j—between them. Thus, the assumption that the driver turns his wheel at a constant rate on any given transition seems justified.

It soon appeared that there was considerable variability in a driver's practice. Records made on the same curve with the same car and driver at different times showed very marked differences even at the same speed, and Q varied between such wide limits as to make it quite obvious that there can be no natural rate of turning. In other words, the answer to question 2, Section 3, is that drivers do not always turn their wheels at the same rate. The variability also made it essential to use statistical methods, so that an extensive statistical analysis was started and a large number of records were taken in a variety of vehicles.

No conclusive evidence could be found of wide differences in practice between drivers, considering the general variability and the inevitable differences in speeds. Most of the records were taken, perforce, in the British type of light car, but a fair range of commercial vehicles was also included. Among these latter was one of the largest and heaviest rigid wheel base vehicles made—an eight wheeler—loaded with 15 tons of bricks. In England its speed is limited by law to 20 miles per hr, but allowing for this it did not seem to show any marked difference from the smaller cars, nor did the one American car it was possible to include. It was not possible to take records in an articulated vehicle, nor in a fast, heavy, passenger vehicle.

A marked tendency was found for Q to vary with the value of j reached on any curve. This tendency can be expressed by the regression equation:

$$\bar{Q} = 1.3\, e^{3.5j} \quad \text{.........................}(5)$$

in which e is the base of natural logarithms, and $\bar{Q}$ is the mean value of Q observed, in feet per second^3. This expression refers to entrance transitions, and is independent of speed. The scatter was moderately wide, and the equation represents only a trend. Another way of expressing this principle is that the driver turns his wheel faster on entering a sharp curve than on entering a flat one. Values of Q as low as 1 ft per sec^3 were comparatively rarely observed, and then only on curves in the lower ranges of j.

Another fairly marked tendency was for the driver to use a definite proportion of the curve as transition, with an over-all mean of two thirds. The use of the all-transitional curve was comparatively rare. There was also a marked tendency for the exit transition to be slightly shorter than the entrance one, although the difference is not great enough to be of practical importance. This latter effect is probably related to the caster action of the steering, which helps the driver on the exit, and opposes him on the entrance. The proportion of transition tended to vary with the value of j reached, and with the speed of the car and the length of the curve, according to the regression equation:

$$p = 0.34 + 6.3\,j - 25.5\,j^2 + 33.0\,j^3 - 0.002\,v + 0.007\,L/v \quad \text{......}(6)$$

In this expression, p is the mean proportion of transition observed (that is, the length of the two transitions combined, divided by the total length of the curve); v is the speed, in miles per hour; and L is the total length of the curve, in feet. For $j \geqq 0.1$, Eq. 6 gives values of p ranging from two thirds to one half. It should, however, be viewed with caution. Because of wartime restrictions in England, the data from which Eq. 6 was calculated do not include very large samples of curves taken at speeds higher than 50 miles per hr, although, since the completion of the regression analysis, more records at higher speeds have been made, and it appears unlikely that the conclusions will be materially altered.

The curves were also analyzed by class of road, including right-angle junctions and rotary intersections. This procedure gave a rough classification by the deviation angle of the curve, which appears to have little effect. This analysis cannot be made with any confidence by measuring the deviation angle of the curves themselves, because it is not possible to decide on the driver's angle of approach to the curve, and the records gave reason to believe that this varies fairly widely.

In recording comfort, no attempt was made to separate the sensations due to the force or to its rate of change. The observer was merely asked if a sensation of curvature was felt or not, according to the groups: (*a*) Easy, when no sensation of curvature was felt at all; (*b*) comfortable, when a sensation of curvature was felt, but not thought uncomfortable; (*c*) slightly uncomfortable; and (*d*) uncomfortable. The effects of the force and of its rate of change were separated in the statistical analysis.

As was to be expected, there was considerable variation in the assessment of comfort, but the application of statistical methods showed that comfort depends mainly on j, although high rates of Q tended to reduce the tolerable values of j slightly. Speed does not appear to affect the assessment of comfort. No uncomfortable or noticeable value of Q could be detected at low values of j.

6. Conclusions from the Experiments

The main conclusions from the experiments are:

(1) The driver does appear to turn his wheel at a constant rate on any given transition.

(2) There is no such thing as a constant rate of turning applicable to all transitions. The driver tends to turn his wheel faster when entering a sharp curve than when entering a flat one. This conclusion is in accordance with general observation, but is in contradiction to the previous theory.

(3) There is some marked tendency for drivers to use about two thirds to one half of the curve as the transition.

(4) As far as comfort is concerned, j is the important effect; and Q is unimportant.

From these conclusions it appears that there is no sound reason for using the rate of change of force as the criterion of transition curve design, and it is suggested that this theory should be abandoned. On the other hand, it may be urged that some value of C or Q in the range of 1, 2, or 3 ft per sec^3, according to opinion, is a value which is safe or comfortable, and that its use is convenient. To counter this argument it is necessary to consider the mathematics of the compound curve.

7. The Compound Curve

Mathematics.—Although the condition for constant Q can be satisfied by curves of other types than the usual spiral, this curve is not unsatisfactory provided the superelevation is properly designed to comply with the conditions of Eq. 3. It is so simple and easy to use, and so familiar, that there is little to be gained by abandoning it. At the same time, the lemniscate has its advocates, and, if preferred, there is no reason whatever against its use. Nevertheless, the spiral will be used herein. Its mathematics have been dealt with elsewhere[3] at some length and need not be repeated. However, since it has been shown that the rate of change of force is not important, it also follows that the length of the curve is relatively unimportant, and may be eliminated from the equations for the main dimensions of the curve, basing these on the

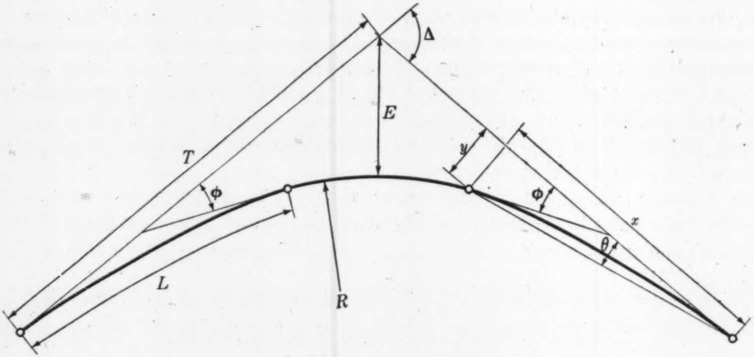

FIG. 2.—BASIC DIMENSIONS OF SYMMETRICAL CIRCULAR CURVE WITH TRANSITION SPIRAL AT BOTH ENDS

radius. These modifications were first published by I. Kursbatt[10] in a slightly different form.

Referring to Fig. 2,

$$x = N\,R \qquad (7a)$$

$$y = P\,R \qquad (7b)$$

$$T = R\left(M \tan\frac{\Delta}{2} + S\right) \qquad (8a)$$

$$E = R\left(M \sec\frac{\Delta}{2} - 1\right) = R\left[(M-1) + \left(\sec\frac{\Delta}{2} - 1\right) + (M-1)\left(\sec\frac{\Delta}{2} - 1\right)\right] \qquad (8b)$$

$$L = 2\,\phi\,R \qquad (8c)$$

$$\theta = \phi/3\text{—small correction} \qquad (8d)$$

and

$$\phi = \frac{p}{2\,(2-p)}\,\Delta \qquad (8e)$$

in which T is the total tangent distance from the point of intersection to the starting point of transition; E is the external distance from the intersection point to the nearest point of the curve; R is the radius at the point on the transition defined by the angle ϕ; x and y are the coordinates of the same point from the starting point of transition as origin:

---

[10] "Calculations for a Circular Curve with Transitions," by I. Kursbatt, *Highways, Bridges and Aerodromes*, London, February, 14, 1945, p. 226.

$$N = 2\phi\left(1 - \frac{\phi^2}{5\,(2!)} + \frac{\phi^4}{9\,(4!)} - \frac{\phi^6}{13\,(6!)} \cdots\right) \quad \text{.........} (9a)$$

$$P = 2\phi\left(\frac{\phi}{3} - \frac{\phi^3}{7\,(3!)} + \frac{\phi^5}{11\,(5!)} - \frac{\phi^7}{15\,(7!)} \cdots\right) \quad \text{........} (9b)$$

$$M = P + \cos\phi = 1 + \frac{\phi^2}{6} - \frac{\phi^4}{168} + \frac{\phi^6}{7{,}920} \cdots \quad \text{..........} (9c)$$

and

$$S = N - \sin\phi = \phi - \frac{\phi^3}{30} + \frac{\phi^5}{1{,}080} - \frac{\phi^7}{65{,}520} \cdots \quad \text{.........} (9d)$$

In these expressions, which apply whether or not a circular central arc is present, ϕ is in radians.

Table 1 gives these spiral functions to six decimal places, for angles to 25° at half degree intervals. Corrections for the polar deflection angle in Eq. 8*d* are also given, although this is usually negligible for small values of ϕ.

The second form of Eq. 8*b* will be found rather simpler for calculation purposes, in spite of its more complicated appearance.

In Eq. 8*e*, if $p = \frac{2}{3}$, $\phi = \Delta/4$, and if $p = \frac{1}{2}$, $\phi = \Delta/6$.

The Practical Problem.—Under practical road conditions the engineer will have two tangents, meeting at an angle Δ, which will have been measured on the ground. If there is unlimited room available, no complications are involved; the curve can be made as flat as desired. Frequently, however, some obstacle or other restricts either the exterior distance E (Fig. 2), or the tangent distance T. The problem is to make the best use of the room available.

Whichever of these distances is limited can be substituted in Eq. 8*a* or Eq. 8*b* to find R, provided the value of ϕ is known so that the values of the appropriate functions may be determined from Table 1. When $\phi/\Delta = \frac{1}{2}$, the curve will be all-transitional; and, as ϕ/Δ decreases, R increases, with a corresponding reduction in j, but the length of the transition decreases, thus increasing Q. Finally, when $\phi/\Delta = 0$, the curve is a circular arc without transitions and R is a minimum for the conditions, but Q will be infinite.

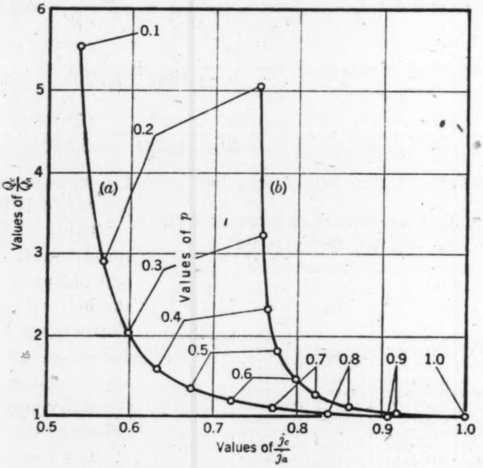

FIG. 3.—PLOT OF $\frac{Q_c}{Q_a}$ VERSUS $\frac{j_c}{j_a}$ FOR $\Delta = 60°$ AND
(*a*) Fixed T
(*b*) Fixed E

If the superelevation is assumed to be proportional to the centrifugal ratio, a quite usual practice, and if the value of j on any compound curve is denoted as j_c and that for the corresponding all-transitional curve as j_a, with the corresponding values of Q denoted as Q_c and Q_a, the following expressions can be written for the ratios between these quantities: For fixed E,

$$\frac{j_c}{j_a} = \frac{M_\phi \sec \Delta/2 - 1}{M_{\Delta/2} \sec \Delta/2 - 1} \qquad (10a)$$

and, for fixed T,

$$\frac{j_c}{j_a} = \frac{M_\phi \tan \Delta/2 + S_\phi}{M_{\Delta/2} \tan + S_{\Delta/2}} \qquad (10b)$$

For either condition,

$$\frac{Q_c}{Q_a} = \left(\frac{j_c}{j_a}\right)^2 \frac{\Delta}{2\,\phi} \qquad (11)$$

The symbols M_ϕ and S_ϕ represent the values of M and S for the value of ϕ used, and $M_{\Delta/2}$ and $S_{\Delta/2}$, those for $\Delta/2$. These expressions depend only on the relative values of the angles, and express the ratio of the value of j or Q on any compound curve on which E or T is fixed to that on the all-transitional curve for the same conditions. Fig. 3 gives curves for Q versus j for $\Delta = 60°$, although the effect of Δ is so small that they may be considered approximately general. In effect, these curves show the effects on j and Q caused by the various values of ϕ/Δ chosen by the engineer, although the latter has been expressed as a proportion of transition.

TABLE 2.—SUGGESTED RATES OF SUPERELEVATION

Radius, in feet	SUPERELEVATION	
	1 on:	Feet per foot
1,200[a]...	14½	0.069
1,400....	17	0.059
1,600....	19	0.053
1,800....	22	0.045

4,000....	38	0.026
4,500....	39	0.026
5,000....	40	0.025
7,500[b]...	48[b]	0.021[b]
>7,500....	....[c]	....[c]

[a] 1,200 ft or less. [b] 5,000 to 7,500 ft, superelevation for 1 on 40 to 1 on 48, or 0.025 ft per ft to 0.021 ft per ft, according to the nature of the material. [c] Normal camber or crossfall retained.

From Fig. 3 it is evident that the higher proportions of transition greatly increase j without reducing Q to any appreciable extent. The difference in Q between the all-transitional curve and one with 0.9 of transition is negligible, in the ratio of 1.00 to 1.03, although the difference in j is more important, in the ratio of 1.00 to 0.92. Thus, there is no justification whatever for the all-transitional curve. It merely increases j unnecessarily.

Thus, the case against a fixed rate of C or Q is clinched. No matter what rate is chosen, for a fixed E or T, and fixed speed, long transitions and eventually all-transitional curves are demanded as the room available decreases. As it decreases further, the ridiculous demand may be made that the transition be longer than the whole curve, even at low values of j. This argument is usually countered by ruling that in such cases the "design speed" must be reduced—making nonsense of the whole matter, because this theory completely ignores the driver, who cannot be expected to observe the "design speed," as he is, of course, completely unaware of its existence. It appears, in fact, that the driver slows down to reduce j and not to reduce Q and that, if a design speed is specified, it should be on the basis of j and not of Q. It is therefore suggested that the rate of change of force should be abandoned as a method of transition curve design.

8. ALTERNATIVE METHOD OF TRANSITION CURVE DESIGN

Although this paper only purports to deal with general principles, some new procedure must be suggested, since the effect of the argument is that the previous theory should be abandoned.

For the moment, the "proportion rule" first proposed elsewhere[9] is favored. This rule states that curves should be designed to have about two thirds of their length transitional, although the writer now inclines to the belief that one half is a better proportion. The exact length of the transition is not, however, a matter of extreme importance, so that ϕ may be taken to the nearest half degree.

The proposed procedure is illustrated by the following example, which is, however, only intended to demonstrate the method. The values used are not put forward as recommendations, nor is the example intended to show that the rule is sound. The required information includes:

a. The maximum speed for which the road is intended, say (for purpose of example only), 80 miles per hr;

b. The maximum value of j considered safe at that speed, say, 0.15;

c. The rates of superelevation[11] to be used, say, as shown in Table 2; and

d. The proportion of transition, say, two thirds, so that $\phi = \Delta/4$, taken to the nearest half degree.

By substituting the foregoing known values in Eq. 1, the minimum permissible radius of curve will be found, in this example, to be 2,300 ft.

Next, the deviation angle, Δ, and the greatest lengths of T and E allowed by the topography are measured on the site. For the example, let $\Delta = 22° 38'$, and let the maximum possible $E = 55$ ft. Then $\phi = 5° 30'$; and, from Eq. 8*b*, using Table 1 to obtain the values of the spiral functions, $R = \dfrac{55.00}{0.001535 + 0.019828 + 0.000030} = 2{,}570.93$ ft. This value is permissible, resulting in $j = 0.13$, and a superelevation rate of 0.04 ft per ft. If not permissible, some reconsideration of the alinement is necessary.

From Eq. 8*a*, $T = 2{,}570.93\ (1.0015\ 5 \times 0.200122 + 0.095964) = 762.01$ ft, and $L = 2{,}570.93 \times 0.191986 = 493.58$ ft. The spirals may be set out in any convenient manner, the ten-chord method being especially suitable. The method has the merit of extreme simplicity.

9. CONCLUSION

The whole argument of this paper runs counter to established practice. It is submitted, nevertheless, that the rejection of the current theory is based on sound reasoning supported by experimental analysis, and that the new concept is far more in accord with common sense and with everyday observation. The objection will no doubt be raised that it takes the whole problem back to rule-of-thumb days, and that it is vague and unscientific. However, it does appear that vagueness is inherent to the subject, and that past theoretical and mathematical treatment is not justified by facts.

Far from the length of a transition curve being "a theoretically determinable quantity," as one of the enthusiasts for the previous theory has claimed, it varies widely at the driver's whim. Therefore, there seems to be little object in going to great lengths to find it. The principal aim is to arrive at some reasonable compromise. This, it is claimed, the proportion rule accomplishes.

10. ACKNOWLEDGMENTS

The author's most grateful thanks are due to Mr. Black and to Mr. Kursbatt.

DISCUSSION

Carl F. Meyer,[12] **M. ASCE.**—Because they lead to a suggestion for a new method of transition curve design, Mr. Leeming's experiments appear to throw some light on a perplexing problem. The author's statement (under the heading, "9. Conclusion,") that "The whole argument of this paper runs counter to established practice" should, in itself, be enough to stimulate discussion. However, the phrase "established practice" may be misleading; considering all the interrelated factors, there is hardly any established practice, at least in the United States. This fact may be noted by examining the recommendations of such bodies as the United States Public Roads Administration and the various state highway departments in the United States, wherein marked variations will be found in the length of transition and in the superelevation rate for identical conditions of radius and design speed.

It is true, however, that most attempts at rationalizing this problem have been based on the use of some constant rate of turning, C; but no conclusive evidence exists as to whether C should be 1, 2, or some other value. Therein lies an important reason for the great variation in transition lengths that are found.

The principal objection which the author has to the previous theory (see "Synopsis"), is its "disregard of the superelevation." Mention is made (under the heading, "3. The Rate of Turning the Steering Wheel"), for example, of F. G. Royal-Dawson's method which

> "* * * contains the fundamental fallacy of using C and the centrifugal ratio, ignoring the superelevation. The theory gives the same length for a transition curve, no matter what the value of the superelevation."

Although there may be a fallacy, it should be emphasized that in the previous theory superelevation is not completely ignored or disregarded. Present practice bases superelevation on R, according to some variable allowance for side friction and up to some practicable maximum. The length of transition is then based on R, design speed, and some value of C. Joseph Barnett,[13] M. ASCE, for example, suggests $C = 2$, giving $L = 1.6 \frac{v^3}{R}$. Thus, L is dependent on the superelevation, although possibly not in accordance with correct dynamic theory.

There is little doubt that the crux of the problem lies in conclusive answers to the two questions posed by the author in Section 3. He is to be commended for his ingenious efforts to answer them. After studying Mr. Leeming's paper, describing his experiments and the resultant conclusions, the writer suggests that answers to the following might aid in forming a better understanding of the experimental procedure and in judging the validity of the conclusions:

---

[12] Prof. of Civ. Eng., Worcester Polytechnic Inst., Worcester, Mass.

[13] "Transition Curves for Highways," by Joseph Barnett, U. S. Bureau of Public Roads, U. S. Govt. Printing Office, Washington, D. C., 1938.

(1) Can the author supply a sketch of the accelerometer setup and a copy of a typical (Q–j)-graph?

(2) What were the ranges of values of Q and j corresponding to the four groups of comfort experienced by the observer? It would be interesting to compare values of j with the side friction factors found by R. A. Moyer,[14] Assoc. M. ASCE, and Mr. Barnett.[15]

(3) Were the comfort sensations those of the same driver and observer, or were different pairs of individuals used?

(4) Did the test curves traversed include those with transitions as well as those without; and, if so, did this difference affect the results?

(5) If, as stated (under the heading, "5. Experimental Procedure"), "* * * no attempt was made to separate the sensations due to the force or to its rate of change," how was it possible to arrive at the conclusion (under the heading, "6. Conclusions from the Experiments") that "(4) As far as comfort is concerned, j is the important effect; and Q is unimportant?"

The author was frank in mentioning the limited scope of his experiments imposed by wartime restrictions on speeds. The availability of only one American car was unfortunate, notwithstanding the author's finding that the type and the weight of vehicle seemed to have little effect on the results.

The finding (under the heading, "5. Experimental Procedure"), stating, "Another fairly marked tendency was for the driver to use a definite proportion of the curve as transition, * * *" seems quite significant provided that many different drivers were involved. This tendency, taken in connection with the mathematical analysis represented by Fig. 3, is substantial argument against large values of p, and is especially devastating to the all-transitional curve favored by some engineers. Assuming that these and later extensive experiments justify the author's conclusions, the practical application still remains to be developed. In doing this the author seems to favor the "proportion rule" (Section 8), but apparently only "for the moment." Is his reticence due to the feeling that something better will be found, or is he doubtful as to the proper value of p to use?

Although the proportion rule is easy to apply, a moderate variation in the proportion of transition results in a rather large change in transition length. For instance, in the example worked by the author in Section 8, using $p = \frac{2}{3}$, the resulting values of R and L were about 2,570 ft and 494 ft, respectively. A similar computation with all data unchanged except $p = \frac{1}{2}$ will give approximate values for R and L of 2,670 ft and 350 ft. The degree of curve remains about the same, but the transition length is reduced about 30%. As the author noted (under the heading, "8. Alternative Method of Transition Curve Design"), "The exact length of the transition is not, however, a matter of extreme im-

UNIVERSITY OF MICHIGAN LIBRARIES

portance * * *." Apparently flexibility in the matter of transition length is obtained in the proportion rule method by varying the value of p.

In the practical application of the proportion rule, the values of R and L found by using a particular value of p would be slightly altered for convenience in staking (at least by most engineers in the United States). In the example given in Section 8, for instance, the computed values were $R = 2{,}570.93$ ft (or $D = 2°13' +$) and $L = 493.58$ ft. Probably 500-ft spirals joining a 2°10′ or 2°15′ curve would be used. Of course, E would not then be exactly 55 ft, but a rigid requirement permitting no deviation from a fixed E is rarely met.

The tables of spiral functions (Table 1), for which the equations use the radius as parameter, are very useful for the special cases involving a maximum value of E or T. Since these situations happen frequently, it is to be hoped that engineers will not reject the author's proportion rule solely because of the absence of such special tables in route surveying textbooks, or among the tables issued by the American Railway Engineering Association (AREA). This omission is not a stumbling block, for the usual AREA ten-chord tables and formulas may be used with only slight added effort. A quick slide rule solution of the example in Section 8 demonstrates this fact.

First, solve Eq. 8*e* for $\phi = 5.7°$ and round off to 5°30′ as in the given example. (Incidentally, it should be realized that Eqs. 8*c* and 8*e* apply also to the AREA spiral, and may be derived by using the basic relation $\phi = \frac{L\,D}{200}$.)

Then, in the AREA formula—

$$E = (R + o) \operatorname{exsec} \frac{\Delta}{2} + o \dots\dots\dots\dots\dots\dots (12a)$$

—there are two unknowns (R and o); but since the length o is always small by comparison with R it may be neglected temporarily and R solved for (approximately $\frac{E}{\operatorname{exsec}\frac{\Delta}{2}} = \frac{55}{0.01983} = 2{,}770$ ft). Thus (from AREA tables), $D =$ approximately 2°04′ and $o = 4.25$ ft. Next, recompute a closer value of R from

$$R + o = \frac{E - o}{\operatorname{exsec}\frac{\Delta}{2}} \dots\dots\dots\dots\dots\dots (12b)$$

giving $R = 2{,}555$ ft. Then $D = 2°14'$ (or 2°15′). Finally, L (from Eq. 8*c*) $= 492$ ft. In practice this would probably be rounded to 500 ft, using ten 50-ft chords.

Despite the author's objections to the current theory, certain of the methods that contain the several objections he has raised give results surprisingly close to the method he now proposes, as may be illustrated by simple computations using the Barnett tables.[13] In the Barnett method full superelevation is computed for 75% of the design speed up to a maximum rate of 0.10 ft per ft. The length of transition approximates that obtained from—

$$L = 1.6\,\frac{v^3}{R} \dots\dots\dots\dots\dots\dots\dots\dots (13)$$

—which is derived by using $C = 2$. The Barnett tables are built for values of degree of curve varying by 30′ or 1° increments, and transition lengths varying by 50-ft or 100-ft increments. In Table 3 several combinations of D and L are given which fit closely the conditions of the author's example, namely, design speed = 80 miles per hr, $\Delta = 22°38'$, and $E = 55$ ft (approximately). Values of D, L, T, and E were obtained quickly by simple interpolation from the Barnett tables; the values of ϕ, p, e (superelevation rate), and j have been computed for comparison with the author's values in Section 8. It will be observed that the combinations using 350-ft and 500-ft transitions compare closely with the values obtained by the "proportion rule" using $p = \frac{1}{2}$ and $p = \frac{2}{3}$, respectively. The largest difference seems to be in the matter of superelevation rate, the values of which could be scaled downward toward the author's recommendations (with consequent increase in j) without changing the values of the other quantities in Table 3.

TABLE 3.—SUITABLE TRANSITIONS FOR EXAMPLE OF SECTION 8

D	L	T	E	ϕ	p	e	j
2°00′	300	723.6	48.2	3.0	0.42	0.084	0.065
2°00′	350	748.7	58.6	3.5	0.47	0.084	0.065
2°30′	400	659.2	48.4	5.0	0.61	0.10	0.086
2°30′	500	709.5	51.1	6.25	0.71	0.10	0.086
2°30′	600	759.8	52.1	7.5	0.80	0.10	0.086

It was not the writer's intention to show the preceding comparison for the purpose of discounting the author's alternative method of transition design. On the contrary, it is felt that the author has made a genuine contribution to this interesting problem. As for the proposed method (under the heading, "9. Conclusion"), taking "* * * the whole problem back to rule-of-thumb days * * *," there appears to be no more, if as much, rule of thumb than exists in the present theory. Even though the author feels that his method may meet resistance because it runs counter to present theory, the writer is encouraged to feel that engineers are willing to reject anything found unsound (as stated in the "Conclusion") in favor of "* * * sound reasoning supported by experimental analysis * * *." The modern engineer does not prefer old-established error to novel truth.

RALPH L. FISHER,[16] ASSOC. M. ASCE.—A realistic approach to the problem of the transition curve has been presented by the author, who states that "vagueness is inherent to the subject" and cumbersome "mathematical treatment is not justified by the facts."

The basic function of a spiral curve is to enable a driver to develop the necessary steering angles (and friction values) with "safety and comfort" within the limits of his lane. On a tangent or on a circular curve a driver is subject to constant, known conditions and it is only on the spiral that he must make adjustments. It is awkward to drive on curves that are transitional throughout. Even when traveling on a tangent, a driver is constantly moving the steering wheel in order to keep on his path. On a curve of constant radius these adjustments in steering are also necessary. If the radius of the curve is constantly changing, the driver's task is made more difficult.

---

[16] Engr. of Design, State Highway Dept., Trenton, N. J.

UNIVERSITY OF MICHIGAN LIBRARIES

Mr. Leeming suggests that curves have from one half to two thirds of their length transitional. Except for the rare case of equal length curves, this would make every spiral different, even those having the same radius of circular curve. If spirals replace a large part of the circular curve, they must perform a function for which they are not suited, that is, change in direction. For this latter function, the circular curve, with its constant conditions, is best fitted. It would be better design practice to confine the spirals to each end and thereby be able to use a larger radius for the circular curve, thus creating more uniformity of operating conditions.

The alinement, grades, superelevation, and spirals should be designed as a unit. Too often the spirals are added more or less as an afterthought, with the result that the spirals or the superelevation runouts are at bridges, vertical curves, minimum grades, or other unfortunate locations—thus creating problems that need never have occurred. Any transition curve should provide a path conforming to driver behavior. Observation indicates that most drivers tend to "cut corners" and to use more throw than is provided by the cubic spiral. The designers of the Pennsylvania Turnpike developed a 2.5 power spiral, which gives more throw than the cubic spiral. It was not used because of lack of time to make the necessary field tests and because of lack of tables for the field forces.

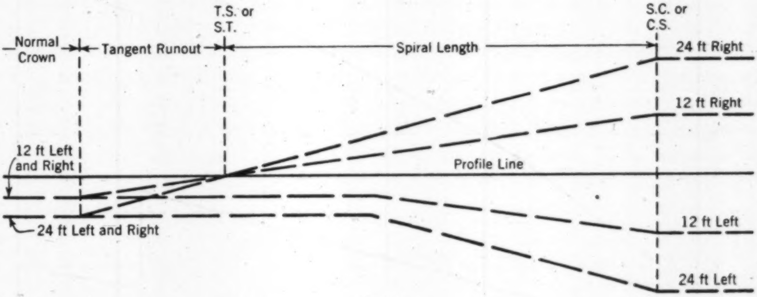

FIG. 4

The writer agrees with Mr. Leeming that (within limits) the length of the transition is not a matter of great importance. As he states, there is considerable variation in a driver's practice, even on the same curve and at the same speed. For the same conditions, a driver does not develop the steering angles at the same rate. It is believed that the amount of throw is of more importance than the rate of curvature of the transition spiral.

Before decision as to the lengths of the spirals can be made, the method of obtaining the superelevation must be determined. This requires careful study for multilane roads or divided roadways with narrow islands. In the colder regions consideration must be given as to where snow can be ploughed on the superelevated sections. The cross section should be designed so that during periods of thawing and freezing, water from the melting snow will not run on the pavement and freeze, thus becoming a hazard. At sags, care should be taken that the low side does not go below certain minimum elevations for surface drainage or water table conditions. Detailed studies may have to be made at bridges where vertical clearance is limited.

For the foregoing reasons, the length of spiral is rarely governed by the distance necessary for change in centrifugal acceleration, as distances given by this method are generally too short. With the flat grades used on most highways today, the length of spiral is generally governed by the minimum gutter grades. If the lengths of the spirals and tangent runouts are selected to fit these flat grades, they can be used throughout, and there will not be the necessity of using one length for the steeper grades and having "special cases" for the flatter grades.

Fig. 4 shows the usual method of obtaining superelevation with spirals. In cases of 5% superelevation, a spiral 400 ft long is required if the relative slope of the outer edges of the pavement with respect to the center line is held to a change of 0.3%. With a center line grade of 0.5% this means that one edge of the pavement would have a grade of 0.2%. However, the shoulder can be warped to give minimum gutter grades of 0.3%.

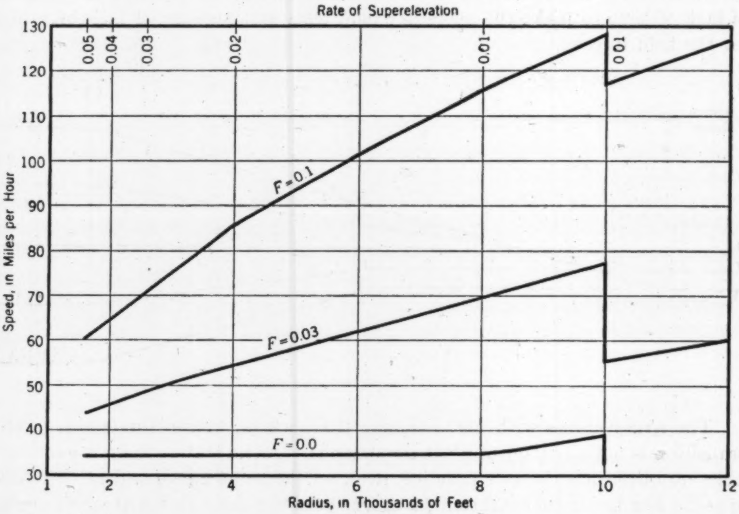

FIG. 5

Uniformity of operating conditions is the keynote of modern highway design. In practice, the design speed is usually selected first and then the other elements, including transition curves, are designed to be consistent with this design speed. As an example, with an assumed design speed of 60 miles per hr and a minimum radius of 1,600 ft, for a friction factor of 0.1, E would equal 0.05 from

$$V^2 = \frac{R\,E'}{0.067} \qquad (14)$$

UNIVERSITY OF MICHIGAN LIBRARIES

For other radii, the superelevation varies inversely as the radius.

Fig. 5 shows the loci for $F = 0.0$ (balanced forces), $F = 0.03$ (assumed icy surfaces), and $F = 0.1$. The locus for balanced forces indicates uniform and consistent operating conditions and the speed is low enough for most trucking units. The break in the curves at the 10,000-ft radius point is due to the change from a superelevated section to a normal crowned section.

TABLE 4.—RATE OF SUPERELEVATION FOR 400-FT CUBIC SPIRAL TO CURVE OF 1,600-FT RADIUS HAVING 5% SUPERELEVATION

Distance from T.S. (ft) (1)	Rate of superelevation (%) (2)	Radius (ft) (3)	Distance from T.S. (ft) (1)	Rate of superelevation (%) (2)	Radius (ft) (3)
0	0	∞	250	3.12	2,560
50	0.62	12,900	300	3.75	2,130
100	1.25	6,400	350	4.37	1.830
150	1.87	4,280	400	5.0	1,600
200	2.50	3,200			

For the cubic spiral, the degree of curve and the superelevation varies directly with the length from the point of tangency (T.S.). Table 4 shows this relationship for a 400-ft spiral to a curve of 1,600-ft radius with 5% superelevation. The curvature of this spiral varies from infinity to 1,600 ft, and this curvature is fixed. It seems apparent that, if this rate of curvature is suitable for a transition to the minimum radius, it would also be suitable for curves of larger radius if the proper length of the sharper end were deleted. In other words, by selecting a proper segment of this spiral to meet a given radius, it would be suitable for all curves of 1,600-ft, or greater, radius. This seems to be more logical than having a spiral with a different rate of curvature for each radius.

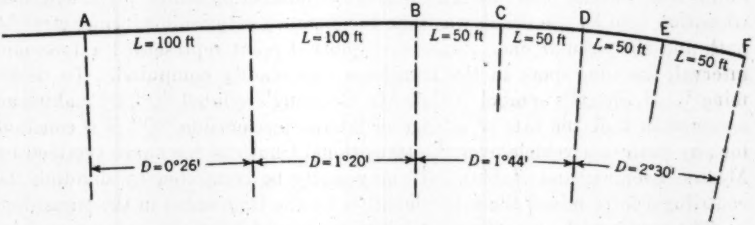

FIG. 6

Fig. 6 was prepared from Table 4. This series of curves gives a throw of 6.40 ft for the 1,600-ft radius, compared with a throw of 4.17 ft for the cubic spiral. This additional throw is believed to conform more nearly to driver behavior. However, if desired, by changing the radii slightly, these curves could approximate the cubic spiral very closely. The transitions from point A to point B would be used for curves of 3,500-ft radius to 3,200-ft radius; from A to C, for 3,200 ft to 2,500 ft; from A to D, for 2,500 ft to 2,100 ft; from A to

E, for 2,100 ft to 1,800 ft; and, from A to F, for 1,800 ft to 1,600 ft. In actual practice, it would probably be necessary to develop two series of transition curves, one for general conditions and another of minimum length for cases where the middle ordinate or tangent lengths are restricted. All elements of these curves as required by local surveying practice could be easily computed, thus doing away with the necessity for any tables or computations by the field parties. This is a factor to be considered, particularly during periods when most highway departments are experiencing a shortage of trained personnel.

William R. Welty,[17] Assoc. M. ASCE.—It is gratifying that the research of the English engineering profession in this hereto virtually unexplored subject is made available to the American engineer in this fine paper. The fact that transition curves in the past have been designed on fallacious assumptions does not require that the same procedure continue in the future.

The writer had the opportunity to examine the spiral experimentally, using the photographic method developed by Bruce D. Greenshields,[18,19] Assoc. M. ASCE. This study [20] of the transition curve was instituted by the writer due to recurring doubts as to the validity of the conventional spiral transition theory. The work of Kenneth A. Stonex and Charles M. Noble,[21] M. ASCE, H. A. Warren,[8] and Mr. Leeming and A. N. Black,[9] certainly casts doubt on the preconceived theories, if it does not entirely shatter them. In the study using the photographic method, a specially arranged motion picture camera and timer were set up at a high vantage point (for example, on a skycraper or in a blimp) above and close to the curve to be studied. The camera was arranged so as to take one picture every eighty eighth of a minute. Thus, the motion of the vehicle in feet between successive frames gives the vehicle's velocity in miles per hour. For examination of the vehicle's path, its position was plotted to scale for each 1/88-min interval. The points at the approximate center of the curved path were fitted graphically with a circular arc of the smallest radius which would pass through the greatest number of points. The length of transition used by the driver was then the distance between his former straight path and the circular one. Since each plotted point represented a 1/88-min interval, the time spent in the transition was readily computed. To determine W. H. Shortt's symbol "*C*" or Mr. Leeming's symbol "*Q*", by making an assumption that the rate of change of lateral acceleration "*Q*" is a constant for any path of a vehicle over the transitional length of the curve (verified by Messrs. Leeming and Noble), "*Q*" may easily be computed by dividing the centrifugal force minus the superelevation by the time spent in the transition.

The study, although of very limited scope and by no means comprehensive, did seem to bear out Mr. Leeming's conclusion that the value "*Q*" is by

UNIVERSITY OF MICHIGAN LIBRARIES

no means a constant. A direct relationship seems to exist between "j" and Q; Q seemed to have a value between $31.4\,j$ and $47.2\,j$. Measurements were not made of high speed operation, but some values measured with an accelerometer on the Pennsylvania Turnpike by Messrs. Stonex and Noble approximately fitted the graphical relationship.

According to the Shortt theory of a constant C or Q, the length of transition will vary with the cube of the velocity. It was found in the photographic study that for the same curve the faster drivers used the shortest transitions, which is in opposition to the former theory. The writer believes that the reason the faster drivers use a shorter transition than do the slower drivers may be explained in the following manner:

1. Fast drivers expect on entering a curve to develop considerable side thrust.
2. Since the side thrust is uncomfortable to the driver (and he expects that it will be), he develops the maximum side thrust quickly, continues it only as long as is necessary, and gets out of the curve as soon as possible.
3. On the other hand, the slow driver, since motorists are humanly lazy, turns the steering wheel at a minimum rate to save work, thus using a long transition. A long transition does not, in this case, prolong the discomfort of a high value of side thrust, since at slow speeds a high value of side thrust is not reached.

The accelerometer method of measurement possesses certain advantages: First, the rate of change of lateral acceleration may readily be determined; and, second, the transitional and circular lengths of the path are easily secured. On the other hand, it is believed, as recognized by Mr. Leeming, to be quite possible that the fact the driver knows his actions are being recorded, in the case of the accelerometer method, may cause significant changes from his normal behavior. By use of the photographic method, measurements may be made without the driver's knowledge.

ELMER R. HAILE, JR.,[22] Assoc. M. ASCE.—Although his argument may, as the author states, run counter to established practice, it is in general agreement with observations made by the writer several years ago. At that time the writer measured the rate of turning of the steering wheel on entrance to a curve, and concluded that no definite trend could be discerned because of wide variations in the rate observed during several test runs. Mr. Leeming is to be commended for carrying his experimentation and analysis through to logical conclusions.

The writer agrees with the author's four conclusions (under the heading, "6. Conclusions from the Experiments"). He does not agree, however, that the proportion rule is applicable in all cases, and this discussion is intended to point out certain limitations in its use. With reference to the third conclusion, the writer believes that the tendency for drivers to use from two thirds to one half of the curve as the transition is due to an inherent characteristic of motoring that is not generally recognized. This might be called the characteristic of "smoothing" the path of the vehicle.

---

[22] Highway Engr., U. S. Public Roads Administration, Arlington, Va.

Accepted design theory is based on the assumption that the vehicle behaves like a locomotive fixed on rails, whereas, in reality, each driver selects the path for his vehicle, and constantly tends to smooth out any "kinks" in the road. This action is usually subconscious and, in fact, unavoidable, stemming from the fact that the driver guides his vehicle by the appearance of the road many car lengths ahead. In contrast, the railroad locomotive is guided solely by the rails through the pony wheels. The inability of the driver to see the road at the front wheels is occasionally embarrassing—for example, when attempting to drive up a ramp or onto a hydraulic lift at a service station. However, in high speed driving on the highway, this inability to see the front wheels is comfortable rather than uncomfortable.

Some examples of this tendency of drivers to smooth the courses of their vehicles are as follows:

(1) In making a right turn at a street intersection, drivers tend to swerve left before turning right, and also to swing wide into the cross street in order to obtain a longer radius of curvature. This behavior is often observed, and persists in spite of many collisions and near collisions that result from it.

(2) A circular curve, when viewed from a distance, appears to break sharply from the tangent. There is a tendency to smooth out this break in the same manner as described in item (1). This smoothing is better known as the transition.

(3) An all-transitional curve, say, with a length of 300 ft and a central radius of 250 ft, appears to bend sharply in the middle. Drivers invariably traverse the middle of such a curve with a radius longer than the design radius, and, if traffic permits, they fail to confine their vehicles to the proper traffic lane.

(4) A short curve with a small deviation angle appears to be a bad break when it is located between two long tangents. Drivers invariably "cut the corner," particularly at high speeds.

In the foregoing examples, the underlying motivating force is the aim of the driver to select a smooth path between the location of the vehicle at any instant and some point ahead that appears in the field of vision. In slow city driving, the driver may gage his path to a point less than 100 ft ahead, but in fast rural driving he may keep his eyes on the road several hundred feet ahead.

The properties of two curves computed by conventional methods are compared with curves computed by the proportion rule, as follows:

Conventional Method.—

Curve 1.—Assume that $v = 40$ miles per hr; $\Delta = 35°$; and that the tangents are limited. Then the minimum allowable $R = 409$ ft and $L = 250$ ft, using a maximum superelevation of 0.10 ft per ft.[23] Then $\phi = 17° 30'$; $T = 256$ ft; and $E = 27$ ft.

Curve 2.—Assume that $v = 60$ miles per hr; $\Delta = 21°$; and the tangents are limited. Then the minimum allowable R = 955 ft and $L = 350$ ft, using a maximum superelevation of 0.10 ft per ft.[23] Then $\phi = 10° 30'$; $T = 353$ ft; and $E = 22$ ft.

---

[23] "Transition Curves for Highways," by Joseph Barnett, U. S. Bureau of Public Roads, U. S. Govt. Printing Office, Washington, D. C., 1938, p. 55.

UNIVERSITY OF MICHIGAN LIBRARIES

Each of the curves given is transitional throughout because $\phi = \Delta/2$.

Proportion Method.—Applying the proportion rule, with p equal to, say, one half ($\phi = \Delta/6$):

Curve 1.—$\Delta = 35°$; $\phi = \Delta/6 = 5°50'$; and $L = 250/2 = 125$ ft. Then $R = 614$ ft; $T = 256$ ft; and $E = 31$ ft. Using[24] $j = 0.16$ and superelevation $= 0.10$, allowable $v = 49$ miles per hr, an increase of 9 miles per hr over the conventional curve.

Curve 2.—$\Delta = 21°$; $\phi = \Delta/6 = 3°30'$; and $L = 350/2 = 175$ ft. Then $R = 1{,}432$ ft; $T = 353$ ft; and $E = 25$ ft. Using[25] $j = 0.14$ and superelevation $= 0.10$, allowable $v = 72$ miles per hr, an increase of 12 miles per hr over the conventional curve.

To substantiate the fact that it is possible to permit speeds higher than those permitted by conventional theory, the following paragraph is quoted from an unpublished report by E. W. Allfather, dated July 20, 1940, describing the results of using an aeroplane bank indicator to determine the safe speeds to be painted on curve signs on the Blue Ridge Parkway in Virginia and North Carolina:

> "It was demonstrated that, for short double spiral curves, signs may safely show speeds fifteen miles per hour in excess of the theoretical speed obtained at the point of maximum curvature. However, it is doubtful if this rule could be applied to long double spirals as too much distance would be covered while traveling through degrees of curvature more nearly approaching the maximum degree obtained at the S.C.S. [spiral-curve-spiral]."

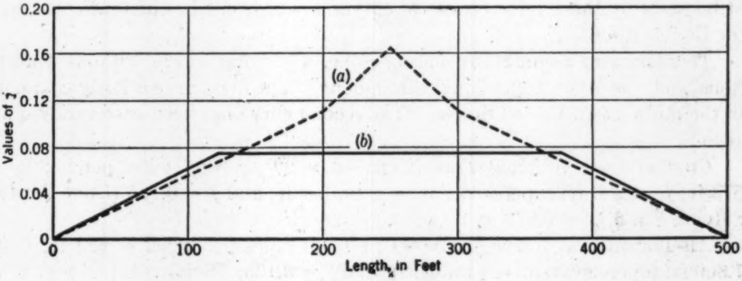

Fig. 7.—Comparison of Values of j at $v = 40$ Miles per Hr and 0.10 Superelevation for

(a) Double Spiral; $p = 1$, $R = 409$ ft

(b) Circular Curve with Spirals; $p = \frac{1}{2}$, $R = 614$ ft

Fig. 3 proves the case against all-transitional curves so well that further proof seems unnecessary. However, for the record, Fig. 7 was plotted to show the theoretical values of j that would be obtained if a vehicle travels at 40 miles per hr over the conventional double spiral, compared to those for the circular curve with spirals for which p equals one half. On the conventional double spiral, maximum superelevation was attained before the midpoint on the curve, as recommended.[26]

---

[24] "Transition Curves for Highways," by Joseph Barnett, U. S. Bureau of Public Roads, U. S. Govt. Printing Office, Washington, D. C., 1938, p. 5.

[25] *Ibid.*, p. 6.

[26] *Ibid.*, p. 9.

Although it is perhaps irrelevant to the present paper, the writer would like to know the values of j and Q which the observers described as "uncomfortable" and "slightly uncomfortable." It is presumed that correction was made for body roll in measuring j with the accelerometer.

In Section 1, the author noted that the formulas generally used for determining the length of required transition do not take superelevation into account. In 1936 the writer proposed a formula which allowed for the effect of superelevation[27] but recommended that it not be used because the lengths of transition computed with the formula were much too short for values of j near zero. This advice is in line with Mr. Leeming's observation that Q is unimportant. However, one should not overlook the fact that the minimum length of transition may be fixed by the distance required for changing from a crown section to a fully superelevated section, especially on multiple-lane roads.

In making a statistical analysis it is of paramount importance that cognizance be taken of all variables and special conditions. The author noted that his experiments were made principally with the British type of light car, at speeds seldom exceeding 50 miles per hr. Some of his tests were made on right-angle junctions and rotary intersections. It would be helpful if Mr. Leeming could describe the curves most frequently used in his tests. Very possibly, few, if any, of the curves he tested were comparable with the curves on the Pennsylvania Turnpike which have radii varying from 38,197 ft to 955 ft and an average length of about 1,400 ft.[21] It would be interesting to know what proportions of his tests were run on (*a*) curves without transitions, (*b*) curves with transitions, and (*c*) all-transitional curves. It seems likely that analyses of his tests by these three classes of curves would result in different constants for Eqs. 5 and 6.

To illustrate, assume two curves—one, a circular curve without transitions, and, the other, transitional throughout. The first curve is fairly common in the midwestern United States. The second curve has been used rarely if at all.

Circular Curve Without Transitions.—$\Delta = 90°$; $v = 40$ miles per hr; $R = 573$ ft; $L = 900$ ft; superelevation = $\frac{3}{4}$ in. per ft; and $j = 0.125$ (from Eq. 1). Solving Eq. 6, $p = 0.87$.

All-Transitional Curve.—$\Delta = 90°$; $v = 40$ miles per hr; $R = 573$ ft; $L = 1{,}800$ ft; superelevation = $\frac{3}{4}$ in. per ft; and $j = 0.125$. Solving Eq. 6, $p = 1.03$ (an impossible solution, as p cannot exceed 1).

In neither of the foregoing illustrations does p approximate values between two thirds and one half which the author states is the case for $j \overset{=}{>} 0.1$. Perhaps the inference to be drawn is that the curves tested did not include many curves similar to those illustrated herein.

If driving tests to measure p should be made on the foregoing circular curve, the length of transition employed by the driver of the car could hardly exceed 300 ft because the offset required for inserting a spiral transition of that length is 6.5 ft. This means that, in order to stay on the road, the driver would probably make his transitions somewhat shorter than 300 ft. If he used 200 ft, the length of circular curve remaining would be 700 ft and the value of p would be $\frac{400}{400 + 700} = 0.36$. It is apparent, therefore, that the measured value of p would range from around 0.3 to 0.4 for a circular curve similar to the curve considered.

---

[27] *Transactions*, ASCE, Vol. 102, 1937, p. 1096.

If driving tests should be made on the foregoing all-transitional curve, using the same line of reasoning, it appears that the value of p would range from about 0.8 to 1.0. This discussion should emphasize the desirability of qualifying statistical analyses such as those represented by Eqs. 5 and 6 by setting forth the limits of all variables.

In conclusion, it is believed that the author's proportion rule is applicable to all short curves, particularly those for which customary design methods result in values of p greater than two thirds. At other curves, especially those of great length, the value of p has little significance. Indeed, when the radius is greater than about 4,000 ft, there are no noticeable consequences if p is allowed to become zero, which is to say that the curve need not have transitions.

There is need for a comprehensive study to determine the length of transition required to satisfy the behavior of the average driver, but, until it can be determined for various radii and lengths of curves, and for a logical range of speeds, there seems to be insufficient justification for changing current practice.

Charles M. Noble,[28] M. ASCE.—In this refreshing paper the author questions the rather complacent attitude toward the subject of highway transition curve design.

Originally the cubic equation, generally utilized in the United States, was developed for railway practice and has been perfected by the railroads to suit actual operating equipment and speeds in the light of many years of practical experience. Safety and passenger comfort are the criteria. Fixed rails guarantee an accurate adherence to the designed path of the spiral so that the human equation in steering the vehicle is entirely absent. No real and searching investigation has been made to develop a transition curve suited entirely to highway vehicles and drivers.

As pointed out by the author and the writer,[29] the use of superelevation cancels out part of or all the centrifugal acceleration (depending on the speed of the vehicle), and this changes the fundamental assumptions in present spiral theory. Primarily, the transition curve enables the vehicle to attain superelevation safely within the lane path by avoiding the introduction of premature lateral forces, which are present if the superelevation is "run out" on the tangent ahead of the curve. If the spiral is long enough to attain this objective, there is some evidence to indicate that it will also be long enough to absorb safely the application of residual (after deducting the effect of superelevation) centrifugal forces.

These matters are clearly perceived by the author, and in the "Synopsis" he succinctly states:

---

[28] State Highway Engr., New Jersey State Highway Dept., Trenton, N. J.

[29] "Thoughts on Highway Design Research as Related to Safety of Vehicle Operation," by Charles M. Noble, *Proceedings*, Highway Research Board, National Research Council, Washington, D. C., Vol. 17, 1937, p. 247.

> "* * * (1) that the theory is fallacious in its disregard of the superelevation, and (2) that the experimental evidence produced for it is questionable."

The writer wishes to support these statements and urges the implementation of an adequate, scientifically instrumented research program so that the real and practical facts relating to highway transition curve design may become known.

In 1937 E. R. Haile, Jr.,[30] Assoc. M. ASCE, and T. T. Wiley,[31] Assoc. M. ASCE, proposed that spiral lengths be proportioned on the basis of rotational change in attaining the curve superelevation. The latter stated the railroads had determined that superelevation should not be introduced in track (4 ft 8½-in. gage) at a rate greater than 1¼ in. per sec of time at the design speed. This is equivalent to slightly more than 2% of cross slope, from which he concluded that:

> "Superelevation on a highway should not be introduced at a rate exceeding 0.02 ft per ft per sec, and the length of spiral on a curve with a superelevation of 1 in. per ft should approximate the distance traveled in 4 sec at the design speed."

It is worthy of note that this principle and the precise maximum value recommended by Mr. Wiley—namely, 2% cross gradient per sec of time—were utilized in designing the spiral lengths on the Pennsylvania Turnpike.

Apparently the author is not familiar with the high speed curve tests conducted on the Pennsylvania Turnpike, which were fully reported.[21] These tests were extended to the top speeds (105 miles per hr) of the stock car models used. A fifth wheel and electrical recording on flags spaced at measured intervals were utilized to obtain accurate speed measurements. Actual path measurements for both the front and rear of the car were taken and recorded. It is believed that a careful study of these test results by the author will be interesting and may suggest additional methods of approach to this problem.

The writer believes that in so far as possible all roadway features should be designed to conform with the requirements of both vehicle and driver,[32] and therefore wishes to support and emphasize the following quotation from the paper (under the heading, "3. The Rate of Turning the Steering Wheel"):

> "It is surely logical that the curve should be laid out to conform to the driver's practice; and, if he prefers, and habitually uses, some method of turning his wheel other than the constant rate expressed by constant *Q*, then the type of transition should be chosen to conform with his habits—even if this curve is not of spiral form."

This policy of matching road design with the characteristics of both driver and vehicle has received impetus in recent years and is now regarded as accepted procedure by American engineers.

As suggested by the author, it is entirely conceivable that driver-vehicle requirements may dictate another form of curve than that represented by the cubic equation. Experience in driving on the Pennsylvania Turnpike indicates that cubic equation spirals are faster than the simple curve they connect and may have a tendency to lure the driver into the curve too fast. This is not serious, but it indicates that the cubic equation may not be the ideal sought.

[31] *Ibid.*, p. 1105.

[32] "Engineering Design of Superhighways," by Charles M. Noble, *Proceedings*, Am. Road Builders' Assn., 1941, p. 183.

There is some indication that it may be desirable to treat sharp curves and flat curves differently. It is believed that there has been confusion in dealing with the subject of transition curves as between sharp and flat curves. Some proponents advocate making the curve transitional throughout, and even Mr. Leeming proposes that the transitions should be a fixed proportion of the entire curve. To most practical American highway engineers it appears preposterous to transform a simple curve 3,000 ft or 4,000 ft long into transitional curves throughout, or to have a fixed proportion of their length transitional. The tendency of drivers to "cut corners" on entering a curve should also be considered as one of the factors in the problem.

To develop further the sharp-flat curve idea, it may be illustrative to divide curves arbitrarily into two groups: Those sharper than 1,000-ft radius and those flatter than 1,000 ft. There is a possibility that the cubic equation may be suited to curves sharper than 1,000-ft radius, whereas another form of transition may be required for easier curves. There is also some evidence that curves flatter than a 3,500-ft radius do not require spirals at all for design speeds up to 70 miles per hr.

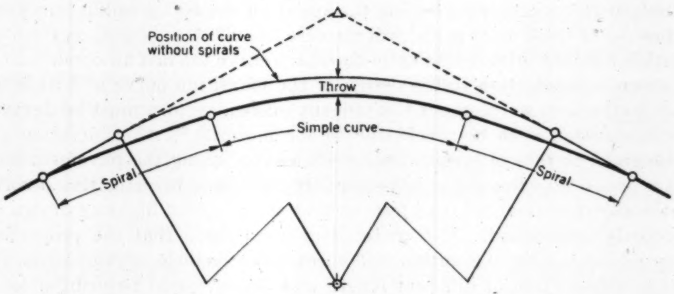

FIG. 8

For example, assume a curve with 3,000-ft radius, a superelevation of 0.03 ft per ft, and a design speed of 70 miles per hr. (On modern American main trunk highways a curve of this radius may vary from 500 ft to 5,000 ft in length.) If the rotational theory for determining spiral length is applied, a 154-ft spiral is required. (For simplicity, it is assumed that the roadway surface is level at the beginning of the transition.) This will result in a "throw" of 0.34± ft (Fig. 8). This offset or throw is so small that it does not appear to meet the requirements of drivers who cut corners on entering curves. If Mr. Leeming's proportional rule is applied, and assuming that the 3,000-ft radius curve is 1,260 ft long, then a 420-ft spiral is required, which will result in a throw of 2.5± ft. This throw or offset may more nearly meet the corner cutting tendency of the driver, but if a cubic equation is utilized much of its length will be of such slight curvature that it is meaningless in practical driving. To be specific, a driver will traverse 211 ft of the spiral before the curve sharpens to a 6,000-ft radius, and 360 ft, before reaching a 3,500-ft radius. Thus, it appears that the throw may meet the requirements of the driver, but that the curve is too flat on the end and should be shortened 210 ft, indicating a transition curve length of 210 ft. However, such a curve must have different characteristics from a cubic equation in order to obtain the desired throw within a length of 210 ft.

On the other extreme, assume a curve with 500-ft radius, a superelevation of 0.10 ft per ft, and a design speed of 43 miles per hr. If the rotational theory is applied, a 315-ft spiral is required, which will yield a throw of 8.24± ft. This offset may be entirely sufficient to meet the corner cutting tendency of the driver, whereas the offset of 0.34 ft for the cubic equation spiral on a 3,000-ft radius curve appears insufficient. Furthermore, it is necessary for the driver to traverse only 45 ft of the 315-ft spiral before reaching a radius of 3,500 ft. If the author's proportional rule is applied, assuming the curve is 700 ft long, a 230-ft spiral is required, which will result in a throw of 4.4± ft. It is believed that this transition is too short for a 500-ft radius curve.

In considering the operating possibilities on the 3,000-ft and 500-ft curves, it is interesting to note that increasing the speed on the 3,000-ft curve from 70 miles per hr to 80 miles per hr will increase the unbalanced centrifugal ratio, f, to only 0.113, whereas increasing the speed on the 500-ft radius curve from 43 miles per hr to 53 miles per hr will increase f to 0.275. Therefore, the longer transition will give drivers who enter the sharp curve too fast an opportunity to slow down. In addition to the design of the transition curve and its length, proper methods of warping out the tangent roadway crown must be devised if the entire design is to be acceptable to the motorist.[33] Consideration must also be given to rate of longitudinal grade change along the pavement edges.

It is hoped that this paper will stimulate additional investigation involving scientifically instrumented road tests so that this phase of highway design may be properly established. The writer does not believe that the proportional theory advocated by the author will meet driver-vehicle requirements, inasmuch as a transition of different length and throw would be utilized for the same radius curve whenever it varied in length. Until new forms are proved superior in meeting driver-vehicle requirements, use of the cubic equation will undoubtedly continue in the United States. The author is to be congratulated for the presentation of material on an important subject, and it is hoped that he will continue his study and investigation.

John Joseph Leeming,[34] Esq.—It is gratifying to find so much agreement with the principles proposed in the paper, in spite of the fact that the proportion rule does not find general acceptance. Indeed, the writer must admit that he is not fully satisfied with the rule in its present form. It is probably too rigid, and tends to give excessively long transitions on the longer curves. Since the paper was written, the work of the experiments has been concluded and the statistical analysis is in progress, although it will be some time before the latter will be complete. It seems possible that some sliding scale of reduced proportion of transition for longer curves may result, although this is only conjecture. For the moment, the writer is inclined to agree with Mr. Haile that the rule should only apply to short curves. In spite of its shortcomings, however, the rule has some experimental background, and does represent some attempt to relate transition curve design to facts. The writer cannot agree with Mr. Haile that there is "insufficient justification for changing current practice," since the latter has no theoretical or experimental justification at all.

[33] "Developments in Curve Design, Speed and Sight Distance," by Charles M. Noble, *Roads and Streets*, January, 1942, p. 25.

[34] County Surveyor, Dorsetshire, England.

Messrs. Noble and Fisher both object to the proportion rule on the ground that it involves spirals with different rates of curvature for different radii of curves. Nevertheless, it appears from the experiments that drivers do vary the scale of the transitions they use. This is the meaning of the observed variable Q, since Q is a measure of the scale of the spiral. To demand a constant shape of spiral, as Mr. Fisher does, is to return to the principle of the constant C, which the writer has shown to be unsound.

Professor Meyer and others desire further particulars of the experimental technique. Present space hardly permits this; but the original paper has been deposited in the Engineering Societies' Library. In reply to Mr. Noble, however, the writer did read the report on the high speed tests on the Pennsylvania Turnpike,[21] and his study of the report influenced his own experiments somewhat. The latter, however, were intended to deal with ordinary touring conditions and with the ordinary driver, whereas the Pennsylvania tests were designedly carried out at extreme speeds with highly skilled drivers, and were mainly directed toward finding the maximum safe value of j at high speeds.

It is not possible to state what proportion of the curves analyzed had transitions. In the first stage of the work the mean proportions of transition, for various classes of roads worked out as follows:

Type of road	Average value of P	Number of curves
First class	0.64	507
Second class	0.67	379
Unclassified	0.67	370
Rotary intersections	0.64	43
Right-angle junctions	0.67	38
Total		1,337

Values are not available for the total number of curves analyzed. The first class roads included a fair proportion of curves with transitions (although some of these were of compound circular arcs) and superelevation; the second class, a few; and the remainder, probably none at all. The experimental results give no reason to believe that the presence of a transition either makes for any greater consistency on the part of the driver, or prevents him from cutting corners. As a result of his observations, the writer is convinced that the latter process is due to the principle stated by Mr. Haile (and with which the writer is in complete agreement) that "* * * the driver guides his vehicle by the appearance of the road many car lengths ahead," combined with the geometrical properties of the compound curve as shown in Fig. 3. Ordinarily, the driver does not begin to turn before he reaches the start of the curve. Whenever the records could be compared with the road conditions, the length of the curve on the record was not appreciably greater than the corresponding length of the curve on the ground, and often, it was shorter. If, then, the driver begins to turn at about the start of the spiral, the quicker he turns his wheel, the flatter will be the curve he follows and the less will be the value of j (that is, the force he has to apply at the wheel), although the throw or cut will be greater. Since he has no objection to a high value of Q, and since he is, in Mr. Welty's words, "humanly lazy," the driver takes the line of least resistance and cuts the curve if its general appearance leads him to believe that it would be feasible. This will usually be the case if a sharp curve has unduly long transitions. On the other hand, short transitions anticipate the cut, as it were, and lead to as flat a curve as the conditions allow. A high value of Q does not increase the driver's work.

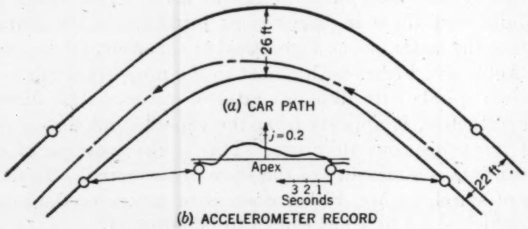

FIG. 9.—TYPICAL RECORD OF CAR ACTION ON ALL-TRANSITIONAL CURVE AT 39 MILES PER HR

The foregoing, however, is not a complete explanation, as the following example shows. A careful analysis was made of an all-transitional curve, laid out and constructed with great care early in World War II. A diagram of the curve is shown in Fig. 9 and the design data for the lemniscate curves of the inner and outer edges are given in Table 5. The deviation angle, I, of the entire curve is 39° 26′; the hands-off speed, 22.5 miles per hr; and the superelevation at the apex, 0.07. The curve is admittedly sharp, especially so, as it was on an important road which carried much traffic. It was located at the start of a diversion of an originally straight road, built for the construction

TABLE 5.—DESIGN DATA FOR LEMNISCATE CURVES IN FIG. 9

Description	Outer curve (ft)	Inner curve (ft)
External distance, E	32.2	35.0
Tangent distance, T	297.6	323.5
Half length of curve, $\frac{L}{2}$	290.2	315.7
Minimum radius, R	456.5	496.0

of an aerodrome, but owing to wartime conditions there was only a minimum of construction. Recordings were made with the accelerometer, tied in with the tangent points of the curve, and checked by timing. Other traffic was observed and timed. A typical record, taken at 39 miles per hr, is shown in Fig. 9, in which it can be seen that the record is markedly unsymmetrical. The car's probable path is shown, and the observations are confirmed that most of the faster traffic followed a similar line. (The English left-hand rule of the road must be remembered in interpreting Fig. 9.) In this case, the most probable explanation is that the driver follows the first half of the curve fairly closely, although some slight tendency to cut the apex is possible. When he reaches the apex, the sharpening of the curve passes unnoticed until the swerve at the three-quarters point becomes obvious, and a sharp exit is made. It was also noticed that traffic in the opposite direction cut the curve very noticeably, yet in this case the recordings were of a more normal type.

In reply to the questions raised by Mr. Haile, the analysis of comfort is not yet complete, as it involves a statistical analysis of great complexity. Provisionally, it may be stated that about half the observers found the value of $j = 0.13$ combined with the value of $Q = 4$ ft per sec^3 to be imperceptible. A similar number of observers thought $j = 0.22$ in combination with $Q = 5$ ft per sec^3 to be uncomfortable. In the later work, no distinction was made between the two classes of discomfort. So far, it has been impossible to state whether speed has any effect on the estimation of comfort. Body roll is included in these values of j, and, since it is one of the sensations of the driver, it should be included in analyzing comfort. Mr. Noble[33] found that this effect would amount to about 10% of the real value of j. British cars tend to be more stiffly sprung than American cars, and their body roll might be less than this.

Mr. Welty's experiments were unknown to the writer, and are of interest in that they agree so well with his own conclusions, even though the value of Q found was higher than that of the writer and Mr. Black. Derivation of Q by the analysis of the car path by any graphical method is probably less accurate than by the direct accelerometer method. The writer does not think that the accelerometer unduly influenced the drivers. He himself was one of them, and he found that he soon became accustomed to the presence of the instrument and paid no further attention to it. Some deliberate swerves were made for study, and recorded, but the results were not used in the analysis.

With reference to Mr. Fisher's contribution, the use of the term "friction factor" was deliberately avoided although the writer was aware that it had been used in the United States. The term "lateral ratio" was adopted after careful thought, because he found a frequent tendency for confusion, both in the literature on the subject and in discussions with his colleagues, between the friction factor and the coefficient of friction as understood in dynamics.

If the writer understands Mr. Noble correctly, the method of transition design, mentioned by him as proposed by Mr. Haile,[30] and by T. T. Wiley,[31] Assoc. M. ASCE, which determines the length of the curve "* * * on the basis of rotational change in attaining the curve superelevation," is open to the same theoretical objection as the method of W. H. Shortt. Referring to Eq. 1, Mr. Shortt based the length of transition on C, which is proportional to $\frac{d}{dt}\left(\frac{v^2}{R}\right)$, disregarding the superelevation. Those of Messrs. Haile and Wiley, on the other hand, are apparently based on $\frac{d}{dt}$ ($\sin \alpha$), neglecting C. Both should be considered, if the rate of change of force is a criterion. In his early work the writer derived a formula for the length of transition based on Q, and was faced by the difficulty, mentioned by Mr. Haile, that, when j is zero (that is, at the hands-off speed), the length of transition becomes zero. This result is nonsense, yet it is logically demanded by the theory. The fallacy was suspected to lay in the use of the rate of change of force, and the experiments confirmed the suspicion. It is true that very short transitions may produce a sharp rise in the superelevation, but this rise does not effect the rate of change of force. Any unpleasant effect from the rise is very possibly due to the psychological effect of a sudden rotation of the horizon. There is also the question of the unsightliness of a sharp rise in the curb or in the edge of the roadway.

The writer must dispute Professor Meyer's claim that the Shortt formula $\left(L = 1.6 \frac{v^3}{R} \text{ if } C = 2\right)$ makes L dependent on superelevation. Mr. Shortt defined C as the rate of change of centrifugal force. The only other terms are v and R, and there is no term which could be said to include, in any way, superelevation. The fact that the latter may be based in some way on R does not affect the formula, which gives the same length of curve whatever the relation between superelevation and R.

In conclusion, the writer strongly supports Mr. Noble's plea for adequate research, and hopes that this paper will help in achieving that end.

CLASSIFICATION AND IDENTIFICATION OF SOILS

By ARTHUR CASAGRANDE,[1] M. ASCE

WITH DISCUSSION BY MESSRS. RALPH E. FADUM; JAMES H. STRATTON; DONALD J. BELCHER; J. A. HAINE AND J. W. HILF; JACOB FELD; KENNETH S. LANE; GEORGE F. SOWERS; RENÉ S. PULIDO Y MORALES; RAYMOND F. DAWSON; D. F. GLYNN; L. F. COOLING; A. W. SKEMPTON, AND R. GLOSSOP; MILTON VARGAS; DONALD M. BURMISTER; M. G. SPANGLER; E. W. LANE; B. K. HOUGH, JR.; AND ARTHUR CASAGRANDE.

SYNOPSIS

The purpose of this paper is threefold: (1) To review and compare existing soil classifications used in civil engineering, with emphasis on their limitations; (2) to present a new soil grouping tentatively adopted by the United States Engineer Department in 1942 for use on airfield projects; and (3) to outline field identification procedures, requiring no apparatus. In abbreviated form, this paper was presented at the Annual Meeting of the Society in New York, N. Y., in January, 1943.

1. INTRODUCTION

The two most controversial chapters in the study of soils for civil engineering purposes are: (*a*) Soil classification, the most confused chapter; and (*b*) the shear strength of soils, the most difficult chapter. If the art of soil classification is far from satisfactory, the confusion is often made worse in that users are unaware of its limitations and apply it for purposes other than that originally intended.

Thorough knowledge of not only one but all classification systems important in civil engineering is the best protection against pitfalls and is the best assurance of an intelligent application of an individual classification. In addition, it provides tools with which the engineer can fashion, if necessary, a new classification to fit his needs in applying soil mechanics to a particular problem. It also frees him from the danger of becoming narrow-minded in this field. Those who really understand soils can, and often do, apply soil mechanics without any formally accepted soil classification.

NOTE.—Published in June, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Prof. of Soil Mechanics and Foundation Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

Limitations of Soil Classification Systems.—It is not possible to classify all soils into a relatively small number of groups such that the relation of each soil to the many divergent problems of applied soil mechanics will be adequately presented. Some systems require detailed tests to permit proper grouping of soils; others are specifically designed so that classification is possible on the basis of field identification without quantitative test results. Some classifications were created principally to facilitate making soil surveys, whereas others are chiefly to aid in digesting and correlating empirical knowledge in a specific engineering problem.

FIG. 1.—METHODS OF

Development of Systems.—To some extent, soil classifications used in civil engineering reflect in their chronological order the development of soil mechanics. In its beginnings this leaned heavily on the soil testing methods developed by agricultural soil science. Since this science originally stressed classification by grain size, the first soil classifications used by civil engineers were textural classifications. Most of these were based on the relative contents of three grain-size fractions called sand, silt, and clay. Later classifications used the entire grain-size curve.

Probably the first departure from the grain-size analysis as the exclusive basis for classification was proposed in 1908 by A. Atterberg in Sweden for agricultural purposes. Later, the Swedish Geotechnical Commission devised and used a similar classification in its extensive research. Still later, the United States Bureau of Public Roads classification was created, with identification and classification of fine-grained soils based almost exclusively on tests other than the grain-size analysis. Finally, new soil classifications have been developed to fill the needs in design and construction of airfields for heavy airplanes.

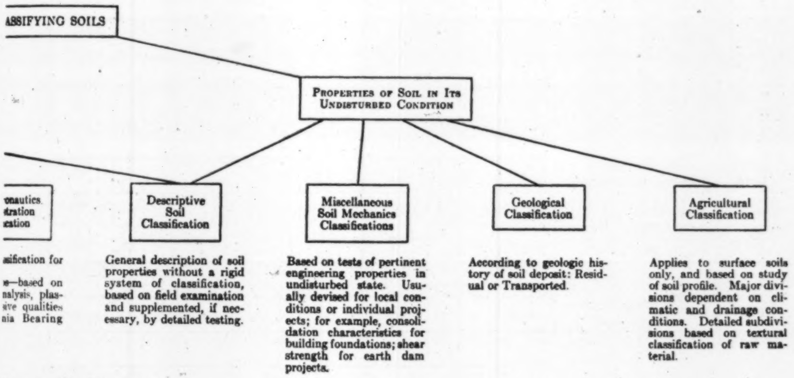
The essential elements of all classifications described in this paper are summarized in Fig. 1.

2. GRAIN-SIZE SCALES

The division of grain sizes into fractions with arbitrarily standardized boundaries is usually called grain-size classification. It is not really a soil classification but rather a grain-size scale, and will be so termed in this paper, to prevent confusion. Its purpose is to form the basis of grain-size classifications of soils, usually termed textural soil classifications.

The most important grain-size scales, summarized in Fig. 2, will be discussed.

United States Bureau of Soils Grain-Size Scale.—This scale is the one most commonly used in the United States. For practical purposes, and particularly for the textural soil classification as developed by the Bureau, the fraction between 1 mm and 2 mm has always been grouped together with the sand fraction (1).[2]



ASSIFYING SOILS
Properties of Soil in Its Undisturbed Condition
nautics

cation
sification for
e—based on
nalysis, plas-
sive qualities
nia Bearing
Descriptive Soil Classification
General description of soil properties without a rigid system of classification, based on field examination and supplemented, if necessary, by detailed testing.
Miscellaneous Soil Mechanics Classifications
Based on tests of pertinent engineering properties in undisturbed state. Usually devised for local conditions or individual projects; for example, consolidation characteristics for building foundations; shear strength for earth dam projects.
Geological Classification
According to geologic history of soil deposit: Residual or Transported.
Agricultural Classification
Applies to surface soils only, and based on study of soil profile. Major divisions dependent on climatic and drainage conditions. Detailed subdivisions based on textural classification of raw material.

CLASSIFYING SOILS

International Grain-Size Scale.—A. Atterberg's (2) scale was proposed as international standard in 1913 when the International Society of Soil Science (3) stated:

> "It was decided to accept the group division of soil grains recommended by Dr. Atterberg. For the time being the following nomenclature shall be used in the German language [English terms added by the author]:

Grains larger than 20 mm	Stein und Geröll	[stones]
Grains from 20 mm to 2 mm	Kies	[gravel]
Grains from 2 mm to 0.2 mm	Grobsand	[coarse sand]
Grains from 0.2 mm to 0.02 mm	Feinsand	[fine sand]
Grains from 0.02 mm to 0.002 mm	Schluff	[silt]
Grains finer than 0.002 mm	Kolloidale Teilchen oder Rohton	[colloidal particles or raw clay]"

A noteworthy exception to this proposal was taken in 1914 by J. Kopecky (4), who recommended a modification based on the following divisions: 0.2, 0.06, 0.02, 0.006, and 0.002 mm. It is of interest that the scale adopted by the Massachusetts Institute of Technology (M.I.T.), Cambridge, Mass. (Fig. 2), has essentially the same numerical values.

M.I.T. Grain-Size Scale.—The advantages of the M.I.T. scale are (*a*) that the 0.002-mm limit for the clay fraction has been adopted to correspond to the international grain-size scale; and (*b*) that it, like that of the Bureau of Soils, possesses the simplicity of division into three major fractions, and permits the plotting of results on a triangular chart, as discussed in Section 3, textural soil classifications.

---

[2] **Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).**

United States Department of Agriculture (U.S.D.A.) Grain-Size Scale.—The U.S.D.A. modified the original Bureau of Soils scale by (1) lowering the upper boundary for the clay fraction from 0.005 mm to 0.002 mm, to bring this scale in line with the international standard and (2) designating the entire range from 2.0 mm to 0.05 mm as sand.

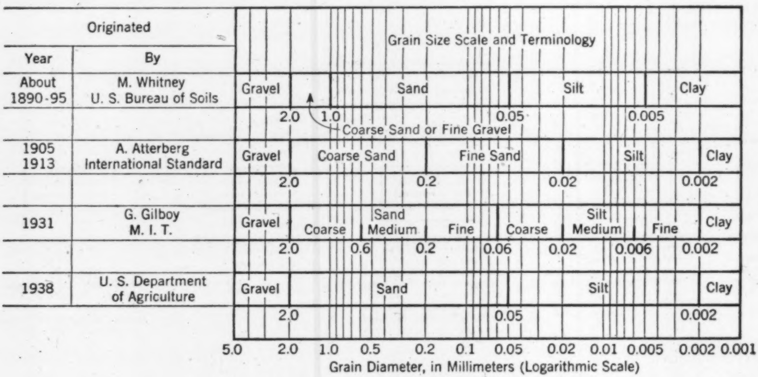

FIG. 2.—COMPARISON OF PRINCIPAL GRAIN-SIZE SCALES

Comparison of the M.I.T. and the new U.S.D.A. scales (Fig. 2) shows that their major divisions are practically identical. The various subdivisions are of no consequence since, in fact, they are never used in practical applications.

Limitations of Grain-Size Scales.—Below the range of the sieve analysis, all preceding grain-size scales represent merely two points of the grain-size curve. This is a very incomplete presentation as compared with the complete curve, which can be obtained readily by modern methods of wet-mechanical analysis.

The use of the terms "silt" and "clay" for arbitrary grain-size fractions is misleading. Such terms should be reserved exclusively for the description of soils having the corresponding physical characteristics. To designate the size fractions, one should either use the terms "sand sizes," "silt sizes," "clay sizes," together with the name of the classification used, or state the size without a name. For example, "30% clay sizes according to the Bureau of Soils Classification" would mean "30% < 0.005 mm." Obviously, designation of the grain size itself is much more brief and leaves less doubt as to its meaning. If a publication merely refers to 12% clay, the reader must usually guess what particular grain-size fraction is meant, or whether perhaps 12% of the total material consists of a plastic soil.

Because of the limited usefulness of the grain-size scales, the lack of a uniform standard is less serious than would be expected. Since the new U.S.D.A. scale is almost identical with the M.I.T. scale, either would probably cause less confusion if adopted as a United States standard. In the absence of such a uniform standard, it is desirable to adhere to the designation of the numerical limits of the grain-size fraction, omitting any names for the individual fractions.

In 1945, R. Glossop and A. W. Skempton (5) proposed the M.I.T. grain-size scale as a standard in their valuable contribution on this subject.

3. Textural Soil Classifications

Basis and Types.—The principle of classifying soils purely on the basis of their grain-size distribution dates back to the time when it was not yet realized that the physical properties of fine-grained soils, having the same grain-size distribution, can be widely different. The simplicity of textural soil classifications, and the fact that they can be applied with little experience, are the main reasons why they are still widely used.

In the United States the original textural classifications are based on the relative percentages of the sand, silt, and clay size fractions. They are facilitated by plotting these three fractions on a triangular chart. Therefore, they will be referred to as triangle textural classifications.

For individual engineering projects, textural classifications have been devised which are based on a comparison of the entire grain-size curves of soils with a set of master curves. These classifications will be called master curve textural classifications.

Triangle Textural Classifications.—The most widely used triangle textural classification is the U. S. Bureau of Soils classification (6) shown in Fig. 3. Soils are divided into the ten groups whose names appear inside the triangle. This classification is applied only to that part of a soil smaller than 2 mm in size, with the sand fraction extending from 2.0 mm to 0.05 mm.

The principle of the triangular plot is that any point represents a number on each of the three scales, and these three numbers always add up to 100. Therefore, to classify a soil, it is only necessary to determine the sand and silt fractions in per cent, and to find the corresponding point in the triangle. For example, if the fraction of a soil smaller than 2 mm in size contains 26% of sand sizes, and 32% of silt sizes (automatically making the contents of clay sizes 42%), then the position of this soil on the chart is found by the intersection of the 26% line on the sand scale with the 32% line on the silt scale. It can be seen that this point P (Fig. 3(*a*)) is to be classified as a "clay." If particles larger than 2 mm in size were present in quantities sufficient to be especially noticeable, this would be indicated by adding the term "gravelly" to the name of the soil.

Engineers who have used this classification have often noticed serious discrepancies between the names as derived from the triangle and the actual physical characteristics of the soils. Therefore, they have introduced other subdivisions and, in some cases, other names. For example, Fig. 3(*b*), used by the Lower Mississippi Valley Division of the U. S. Engineer Department, represents an attempt to adjust this method of classification to the soils of the lower Mississippi Valley. It should be noted that "loam," which is really an agricultural term, is not used in Fig. 3(*b*).

The difficulty of all triangle classifications lies in the fact that those physical characteristics of fine-grained soils which are of interest to the civil engineer often are not reflected by the three grain-size fractions. Point P in Fig. 3(*a*) may represent a highly plastic soil in one part of the United States and a slightly plastic silt in another locality.

FIG. 3.—COMPARISON OF SOILS CLASSIFICATION TRIANGLES (SIZES IN MILLIMETERS: SAND FRACTION, 2 TO 0.05; SILT FRACTION, 0.05 TO 0.005; AND CLAY FRACTION, LESS THAN 0.005)

The more successful use of the classification in Fig. 3(*a*) in agricultural soil studies may be because in well-developed surface soils certain fine-grained materials such as uniform, nonplastic, rock flour do not exist. It would seem as if the weathering due to the mechanical, chemical, and biological forces, which are responsible for the development of the surface soils, tends to reduce the range of physical properties which a soil with a given grain-size distribution may possess; or, in other words, the grain-size distribution is more likely to reflect the physical properties of a weathered surface soil than of the underlying unweathered materials.

Master Curve Textural Classifications.—The development of modern methods of wet-mechanical analysis which yield the entire grain-size curve as readily as the three fractions used in the triangle classification has led to utilizing the entire grain-size curve for soil classification. This can be accomplished by plotting a set of typical grain-size curves, called master curves, covering the desired range of soils.

Examples of master curve textural classifications are the classifications developed by the Boston Metropolitan District Water Supply Commission (7), by the U. S. Engineer Office in Providence, R. I. (8), and by Donald M. Burmister, Assoc. M. ASCE (8*a*). In the Providence classification, the necessity for further differentiation of fine-grained soils into nonplastic and plastic soils is also recognized.

Textural soil classifications by means of master curves have been reasonably successful for noncohesive soils of the same general geologic origin. However, for most fine-grained soils the same objections apply as for the triangle classification.

TABLE 1.—COMPARISON OF GRAIN-SIZE DISTRIBUTION AND PHYSICAL CHARACTERISTICS OF SOME FINE-GRAINED SOILS

No.	Location (1)	Material (2)
1	Winnipeg, Canada	Very tough, highly plastic clay
2	Massena, N. Y.	Soft, medium plastic, Laurentian clay
3	Massena, N. Y.	Soft, somewhat organic, silty Laurentian clay of low plasticity
4	Vera, Wash.	Kaolin-type clay, with typical lack of toughness
5	California	Diatomaceous earth with characteristics of clayey rock flour
6	Wayland, Mass.	Diatomaceous earth with characteristics of nonplastic rock flour
7	Missouri	Lean, silty clay
8	Hartwick, N. Y.	Typical rock flour

[a] Airfield Classification System symbols; see Table 4. [b] The new KH-group.

Limitations of Textural Soil Classifications.—Table 1 shows the large range of soils covered by almost identical grain-size curves. Soils Nos. 1 to 5 range from a highly plastic, very tough clay having high dry strength, through kaolin-type clays lacking toughness and having only low dry strength, to diatomaceous soils with very low plasticity and only slight dry strength.

It is also instructive to compare the grain-size distribution of soils Nos. 6 to 8 (Table 1) with their other characteristics. The highest percentage of grains smaller than 0.005 mm is shown by the diatomaceous earth which is practically noncohesive and nonplastic. The clay (No. 7) with only 26% material smaller than 0.005 mm actually shows more plasticity and greater dry strength than soil No. 5 containing three times as much material smaller than 0.005 mm.

Many similar discrepancies between grain-size distribution and physical characteristics of fine-grained soils could be cited. Nevertheless, the grain-size curves of fine-grained soils are still extensively used as the exclusive basis for soil classification. In contrast to the misleading impressions which these curves may convey, the pertinent physical properties of such soils can easily be distinguished on the basis of simple field identification procedures.

4. Agricultural Soil Classification

A classification of surface soils for agricultural purposes, called pedological classification, is a complicated system in which the classification of the physical properties of an individual soil layer represents merely one element. Since surface soils have "grown" under the influence of climate, vegetation, type of underlying parent material, topographic features, and age, all these factors, and particularly their influence on the chemistry of the surface soils, play a major role in a pedological soil classification.

Of main interest to the civil engineer is that part of such a classification which describes the physical properties and composition of the surface soils and of the underlying parent materials. In the United States, such description is confined to a textural classification.

Because in a textural classification soils with different physical characteristics would be classified the same, A. Atterberg in Sweden suggested the classification (3) of the physical properties of soils for agricultural purposes shown in Table 2. Further subdivisions are made to distinguish between soils rich in humus or lime, and soils containing gravel, stones, and diatoms. To assist in identification, Atterberg proposed the use of his plasticity tests as well as a dry strength number based on the dry strength of the soil. Thus, his classification emphasizes pertinent physical characteristics whose differentiation is not possible by using grain-size analysis alone.

TABLE 2.—Atterberg Soil Classification

Major divisions	Secondary divisions	Description
A.—Clays (Plastic Soils)		
	I.—Sticky Clays (Highly Plastic)	This group contains only the heaviest clays
	II.—Loamy Clays (Not Sticky)	Subdivided into medium heavy and fairly heavy clays
B.—Loams (Nonplastic, More or Less Cohesive Soils)		
	I.—Fairly Heavy Loams	Clayey loams
	II.—Light Loams	Sandy loams and loess soils
C.—Sand, *Mo*, and Silt Soils (Noncohesive Soils)		
	I.—Capillarity Greater Than 34 Cm	Fine-grained sandy soils; dust loess; subdivided by mechanical analysis
	II.—Capillarity Less Than 34 Cm	Coarse, dry sandy soils, useful only for forestry

Use of Agricultural Soil Maps in Civil Engineering.—The surface soils of large areas of the United States and other countries have been surveyed and mapped from an agricultural standpoint. Often it is possible to correlate, by means of field observations and tests, the classifications used on such maps with the pertinent engineering properties of these soils so as to save much time in soil surveys for roads and airfields, and in finding sources of satisfactory material for fill construction. Also, with sufficient experience, or advice from agricultural soil experts, the engineer can derive information on the subdrainage characteristics of a given area.

A systematic correlation between agricultural soil classifications, as found on the soil maps, and the engineering properties, has been published for the State of Indiana (9).

5. Geologic Soil Classifications

Every comprehensive soil investigation should also include a geologic classification. In most cases differentiation between the two major subdivisions, that is, residual and transported soils, will be possible on the basis of a general field examination. Further subdivisions of the transported soils, such as glacial, fluvial, lacustrine, marine, aeolian, and volcanic, are a useful and sometimes necessary part of a comprehensive soil classification which, however, may require the assistance of a geologist. When geologic maps are available, they should be utilized in connection with foundation investigations for important civil engineering projects.

6. United States Bureau of Public Roads Classification System

Development and Limitations.—The Public Roads (PR) Classification (10) was developed in the years 1927 to 1929 from extensive research that the U. S. Bureau of Public Roads had directed particularly toward the use of soils in secondary road construction. The original definition of its groups is based on the stability characteristics of soils when directly acted upon by wheel loads. This classification, therefore, is essentially a grouping applicable to the use of soil in a road surface or as a base beneath a thin bituminous wearing surface. Unfortunately, it has been termed "subgrade classification." Attempts to use it for judging the characteristics of subgrades beneath a substantial thickness of pavement and base have frequently led to disqualification of excellent subgrade and subbase materials. The susceptibility of soils to frost action is also not properly recognized in this classification because at the time it was developed, knowledge of frost action was still limited.

A simplified presentation of the PR classification system is shown in Table 3. It differs from the usual presentation (10) to place more emphasis on those characteristics which aid in field identification. To understand the use of the letter A in the group designations, it is noted that the original PR classification also provided for three additional groups designated B–1, B–2, and B–3. These soon fell into disuse and need not be considered here.

Classification Procedure.—The original publication (10) contains recommendations for classifying soils based on grain-size distribution, plasticity, and shrinkage characteristics, as well as on other tests which are not so commonly used. The numerical limits of the test results, which determine the group classification of a particular soil, have undergone many revisions, the latest (11) being dated February, 1942.

Modifications of PR System.—Some of the shortcomings of the PR system were recognized by soils engineers in various highway departments, who tried either to adapt it to their local soil conditions and problems, or to develop new classifications. In New Hampshire, where frost action is the most destructive agent, engineers have eliminated the A–1 group entirely, since soils in this group (such as some well-graded glacial tills) were found to be just as subject to frost heaving as soils in the A–2 group. Therefore, all sandy and gravelly soils of the A–1 and A–2 groups were classified as A–2 materials, and the new A–2 group was subdivided into three subgroups, depending on their frost-heaving characteristics. The definition of the A–3 group was not changed; all soils in this group are considered better subgrades than the soils in the combined A–1 and A–2 groups (12).

TABLE 3.—SIMPLIFIED CHART OF PUBLIC ROADS CLASSIFICATION SYSTEM

Major divisions		Group	General description	Examples
Coarse-Grained Soils		A–1	Coarse with fines—well graded; considerable dry strength and practically no swelling and shrinkage.	Sand-clays in Southern States; some types of glacial till.
		A–2	Coarse with fines—compared with A–1 either deficient in dry strength or subject to volume change.	Many types of glacial deposits and of residual soil.
		A–3	Coarse-grained soils containing less than 10% passing No. 200 mesh and having no dry strength.	Clean, well graded glacial gravel; beach and dune sands.
Fine-Grained Soils	Silts	A–4	Silts and clays of low plasticity	Rock flour; many sandy and silty clays; loess.
		A–5	Elastic silts	Highly micaceous silt; diatomaceous earth.
	Clays	A–6	Highly colloidal types of inorganic clays; medium to high plasticity.	Some inorganic clays from southern and tropical regions.
		A–7	The great majority of inorganic clays and some types of organic clays; medium to high plasticity.	Glacial clays; some types of gumbo; kaolin-type clays; some organic clays.
Peat and Muck		A–8	Materials having very high compressibility.	Peat and organic clays.

Realizing that the PR system is seriously deficient for classifying subgrades, highway engineers have given consideration to a radical revision of this system without changing the designations A–1, A–2, etc. Under a tentative proposal, all gravelly and coarse sandy soils of the A–3 group, which are excellent subgrades, would be classified as A–1 materials, together with those originally defined as A–1. Equally radical changes are proposed for the fine-grained soils. If this is adopted, it would not be possible to gain a clear idea of the type of soil from the PR designation, except by noting the "edition" of the classification. Such confusion could easily be avoided by giving this radical modification an entirely new designation not mistakable for the original, as by using a prefix letter other than A.

7. TEXAS HIGHWAY DEPARTMENT SOIL CLASSIFICATION SYSTEM

About 1939, the Texas Highway Department developed a classification of Texas soils for writing specifications such that natural materials would be used to best advantage in road construction (13). The ten soil types are based essentially on gradation and plasticity characteristics. Type 1, which is typical, is defined as follows:

> Type 1 soil is a material which will retain high stability under the direct impact of traffic loads. Soils of this type are the only materials permitted in the upper six inches of the finished roadway. This type of material can also be used for the roadbed below six inches, if economically available. Type 1 soil includes caliche, rock, shell, iron ore, or gravel with good grading, and excellent soil binder. The detailed requirements vary depending upon whether the aggregate is angular or rounded by nature.

The other soil types are classified in the order of decreasing value in road construction. Types 7 to 9 represent clays of increasing plasticity and type 10 represents a highly compressible material, usually of organic character, having a liquid limit greater than 90.

8. CIVIL AERONAUTICS ADMINISTRATION (CAA) SOIL CLASSIFICATION SYSTEM

The CAA system, established in 1944 for classifying soils in the order of their value as subgrade of airport pavements, is based on the mechanical analysis, plasticity characteristics, expansive qualities, and California Bearing Ratio (CBR).

Soils are divided into groups designated by the symbols E–1 to E–10. Their characteristics are briefly described by A. H. Hadfield (14):

> "* * * there are two groups: the E–1 to E–4 'granular soils,' containing 50% or more of sand and the E–5 to E–10 'non-granular soils,' containing less than 55% sand (the E–5 has 65% or less sand).
>
> "The granular soils are further divided into non-frostheave soils, groups E–1 and E–2, and soils subject to frost heave, groups E–3 and E–4. The E–1 soil is a free draining, non-plastic sand corresponding to the PRA classification A–3. The E–2 soil is a sand containing slightly more silt and clay than the E–1. The E–3 corresponds to a non-plastic and moderately plastic PRA A–2 type, and the E–4 is equivalent to the PRA A–2 plastic type.
>
> "In the non-granular group the E–5 soil corresponds to the non-plastic or moderately plastic A–4 silt, and the E–6 to the more plastic A–4 silts, the A–4 and A–6 silty clays, and the A–6 or A–7 clays of low plasticity. The E–7, E–8 and E–9 groups include clay soils of average plasticity, high plasticity and very high plasticity, respectively, covered by PRA's A–6 and A–7 soils groups. The E–10 is the highly elastic soil classed as A–5 by PR."

9. AIRFIELD CLASSIFICATION SYSTEM FOR U. S. ENGINEER DEPARTMENT

Development.—As a result of difficulties in the use of other classifications for the design and construction of military airfields, the Office of the Chief of Engineers tentatively adopted in 1942 a new soil classification which will be referred to as the Airfield Classification (AC) System. It was originally developed by the writer for instruction in Army courses on "Control of Soils in Military Construction" offered at the Graduate School of Engineering, Harvard University, Cambridge, Mass., from 1942 to 1944.

TABLE 4.—AIRFIELD CLASSIFICATION SYSTEM—PHYSICAL CHARACTERISTICS OF SOIL GROUPS AS AFFECTING CONSTRUCTION OF FOUNDATIONS FOR AIRFIELD PAVEMENTS[a]

[a] Table 4 represents the third revision since it was first prepared by the author in 1942. [b] For binder = fraction passing No. 40 U. S. standard mesh. [c] These characteristics do not apply to undisturbed materials having fissures and root holes, such as most surface soils. [d] These weights apply only to soils having specific gravities from 2.65 to 2.75.

In the AC system, it is recognized that a clean gravelly soil, which would be classified A–3 in the PR system, is a better foundation material for pavements than a gravelly soil of the A–1 or A–2 groups, because it is not subject to frost action and is free draining. The AC system also recognizes that a gravelly soil is generally a better foundation material for heavy wheel loads than a sand.

The fifteen groups of the AC system represent a considerably greater number than are used in the other systems. However, the grouping is specifically so devised that soils can readily be classified by an experienced soils engineer on the basis of visual and manual examination.

10. Soil Groups and Group Symbols of AC System

Table 4, representing the third revision by the writer, summarizes the essential information on the AC system including the group symbols. Each symbol consists of two letters which may be considered as initials of the name of the most typical soil of that group. Their meaning will be understood from the following outline:

Coarse-grained soils are subdivided into:

(1) Gravel and gravelly soils; symbol G.
(2) Sands and sandy soils; symbol S.

The gravels and the sands are each divided into four groups:

(*a*) Well-graded, fairly clean material; symbol W, in combinations GW and SW.
(*b*) Well-graded material with excellent clay binder (corresponding to PR A–1 group); symbol C, in combinations GC and SC.
(*c*) Poorly graded, fairly clean material; symbol P, in combinations GP and SP.
(*d*) Coarse materials containing fines, not covered by preceding groups; symbol F, in combinations GF and SF.

Fine-grained soils are subdivided into three types:

(1) The inorganic silty and very fine sandy soils; symbol M, which stands for the Swedish terms *mo* and *mjala* (flour), used for fine-grained nonplastic, or slightly plastic, soils and, in the international grain-size scale, designating the fractions from 0.2 mm to 0.02 mm and from 0.02 mm to 0.002 mm, respectively.
(2) The inorganic clays; symbol C.
(3) The organic silts and clays; symbol O.

Each of these three types of fine-grained soils is grouped according to its liquid limit into:

(*a*) Fine-grained soils having liquid limits less than 50; that is, of low to medium compressibility; symbol L, in combinations ML, CL, and OL.
(*b*) Fine-grained soils having liquid limits greater than 50; that is, of high compressibility; symbol H, in combinations MH, CH, and OH.

Important Note.—In classifying fine-grained soils the term compressibility refers to the slope of the virgin pressure-void ratio curve and not to the actual condition of the undisturbed soil which may be partly dried or otherwise preconsolidated. Experience has proved that the liquid limit is a good measure of relative compressibility.

Highly organic soils, usually fibrous, such as peat and swamp soils having very high compressibility, are not subdivided and are placed in one group; symbol Pt.

Use of Group Symbols.—The sequence of the group symbols need not be memorized, but the meaning of the symbols and the sequence of the major divisions, that is, G–S–L–H should be learned.

When a material does not clearly fall into one group, boundary classifications such as GW–SW or ML–CL should be used.

A study of the soil names in Col. 2, Table 4, will show that these represent no new soil terminology, but are those that experienced soils engineers use when describing a soil on the basis of visual and manual examination.

Emphatically the group symbols are not intended to be substituted for detailed descriptions. However, the use of these symbols is proper when comparing physical characteristics of different soil groups, as in Table 4, references (15)(16).

11. Coarse-Grained Soil Groups of AC System

GW–SW Groups.—These soils are well graded. They comprise gravelly and sandy soils having little or no fines. The presence of the fines must not noticeably change the strength characteristics of the coarse-grained fraction and must not interfere with its free-draining characteristics. In areas subject to frost action, the material should not contain more than about 3% of soil grains smaller than 0.02 mm in diameter. Where frost action is not a factor, contents of the order of 10% passing No. 200 mesh may not be objectionable. The GW and SW soils would be classified in the PR system as A–3 materials.

GC–SC Groups.—These soils also are well graded. They comprise gravel-sand mixtures and sands with an excellent clay binder, or other natural cementing agent, so proportioned that the mixture shows negligible swelling and shrinkage. Thus, dry strength of GC and SC materials is usually provided by a small amount of highly colloidal clay, and in some cases by the cementation of calcareous material (as in coral), or iron oxides (as in iron ore gravels). The letter C in these group symbols conveys the meaning of both "clay" and "cementation."

Materials in the GC and SC groups correspond to the A–1 group in the PR system. They may be used as road surfacing material because they are stable under wheel loads both in wet and dry condition. However, they are usually subject to frost action.

GP–SP Groups.—These soils are poorly graded. They comprise gravels and sands, containing little or no fines, as stated for the GW and SW groups. Materials in the GP and SP groups can be subdivided into:

(*a*) Uniform gravels, such as the clean, round-grained gravel deposited in gravel banks along the middle courses of rivers;

(*b*) Uniform sands, such as beach sand and dune sand; and

(c) Nonuniform mixtures of very coarse material with fine sand, with intermediate sizes lacking, as often results during excavation from mixing of gravel and sand layers.

These groups would be classified A-3 in the PR system.

GF-SF Groups.—Any coarse-grained material which contains detrimental fines (either silty or clayey) and which does not qualify for the GC-SC groups is classified in the GF-SF groups. Silty gravels, silty sands, poorly graded gravel-sand-clay mixtures, and sand-clay mixtures are typical examples. In the PR system they would be classified as A-2 materials.

Identification of Coarse-Grained Soils.—In field identification of coarse-grained materials, the gradation, grain size, shape, and the mineral composition are examined by spreading a dry sample on a flat surface.

The division between gravelly sands and sandy gravels has not been standardized. Many highway engineers classify gravelly sands containing only 20% to 30% of gravel sizes (retained on No. 10 mesh) as gravelly soils. An exact point of division is unimportant, except for specifications, and boundary cases may be classified as GW-SW, and so forth.

Considerable experience is required to differentiate, on the basis of a visual examination, between some well-graded soils and poorly graded soils. When in doubt, a mechanical analysis should be made and the grain-size curve plotted, from which the gradation characteristics can be judged.

Examination of fines is confined to the fraction passing No. 40 mesh (United States Standard), which fraction is usually called the "binder." In the absence of a sieve, this separation can be performed tolerably well by hand. The binder is mixed with water, and its plasticity characteristics and dry strength are examined. The dry strengths are listed in Col. 4, Table 4. For more accurate identification, quantitative determination of the liquid and plastic limit of the binder, and the grain-size curve of the entire material are required.

Identification of active cementing agents other than clay is usually not possible by visual and manual examination, since such agents require a curing period of days, and even weeks. It is on the basis of the actual use of such soils that they are classified into the GC-SC groups. In the absence of such experience, they may be classified tentatively into other groups, neglecting any possible development of strength due to cementation.

Depending on the use to which a coarse-grained soil is put, the durability of its grains may require careful examination. Pebbles and sand grains consisting of sound, igneous rock are easily identified. Weathered material is recognized from its discolorations and the relative ease with which the grains can be crushed. Pebbles consisting of weathered granitic rocks and quartzite are not necessarily objectionable when used for the foundations of pavements. In the process of compaction, some round-grained quartzite gravels, found in southeastern United States, will break up into much smaller, but angular and quite durable, quartz fragments which will form a well-graded stable base. Disintegrated granite in California is extensively used in highway construction. On the other hand, coarse-grained soils containing fragments of shaley rock may be dangerous because alternate wetting and drying may result in partial or complete disintegration. This tendency can be identified by a slaking test. The particles are first thoroughly oven-dried, or sun-dried, then submerged in water for at least 24 hours; finally, their strength is examined and compared with their original strength. Some types of shales will completely disintegrate when subjected to such a slaking test.

The properties of coarse-grained soils in the undisturbed state (natural deposite or man-made fill) require examination if they are to be used in that condition. Depending on the problem, several of the observations and tests listed in Col. 5, Table 4, will be required.

12. Fine-Grained Soil Groups of AC System

In the transition between coarse-grained and fine-grained soils, usually those soils containing more than 50% of material smaller than 0.1 mm in size (passing No. 150 mesh) are classified as fine-grained soils (ML or CL); and soils containing less than 50% smaller than 0.1 mm in size are classified as coarse grained (SF or SC). A non-plastic, silty, fine sand with 40% to 60% passing a No. 150 mesh would be classified as an SF–ML soil.

Of basic importance in the classification of fine-grained soils is the plasticity as measured by the Atterberg liquid and plastic limit tests, or estimated by manual examination (17)(18)(19)(20)(21).

The Plasticity Chart.—The writer's method of using the liquid and plastic limit values for soil identification is illustrated in the plasticity chart, Fig. 4.

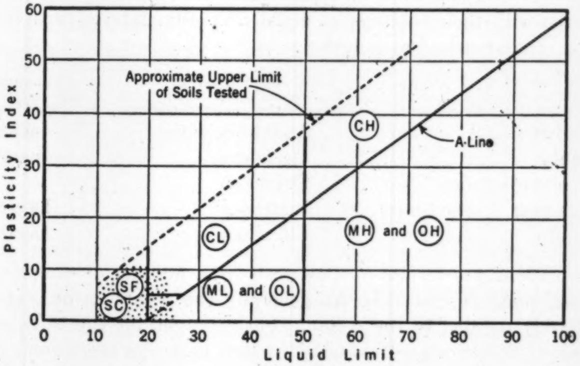

Fig. 4.—Plasticity Chart for AC System

The inclined A-line represents an important empirical boundary. It goes through the point on the base line having a liquid limit of 20, and through the point with a liquid limit of 50 and a plasticity index of 22.0. Therefore, its equation is: Plasticity index = 0.73 × (liquid limit − 20).

The A-line represents the empirical boundary between typical inorganic clays (CL–CH groups) which are generally above the A-line, and plastic soils containing organic colloids (OL–OH groups) which are below it. Also located below the A-line are typical inorganic silts and silty clays (ML and MH groups), except for liquid limits less than 30, for which values inorganic silts may range slightly above the A-line.

For soils having liquid limits less than 25, there is considerable overlapping of several soil groups as shown by the dotted area in Fig. 4. For example, a soil with a liquid limit of 20 and a plasticity index of 8 could be classified according to its grain-size composition and physical characteristics either as a sandy clay (CL), or a very clayey sand (SF), or it may be such a well-graded mixture of sand and clay as to fall into the SC group. Frequently, such soils will be classified as boundary cases CL–SC or CL–SF; or SF–SC. A soil with a liquid limit of 20, and a plasticity index of 0 to 2, may be either a typical rock flour (ML), or a very silty sand with a trace of plasticity (SF), or a boundary case designated SF–ML. In spite of this overlapping, an experienced soils engineer will be able to differentiate between these soil groups purely on the basis of field identification.

Relation Between Position on Plasticity Chart and the Physical Properties.—Experience has shown that the compressibility, when compared at equal preconsolidation load, is approximately proportional to the liquid limit, and that materials having the same liquid limit possess approximately equal compressibility. In comparing the physical characteristics of soils having the same liquid limit, it will be found that, with increasing plasticity index, the cohesive characteristics (toughness and dry strength) increase, whereas permeability decreases.

The behavior of soils at equal liquid limit, with plasticity index increasing, as compared with their behavior at equal plasticity indexes, with liquid limit increasing, is summarized as follows:

Characteristic	Comparing soils at equal liquid limit with plasticity index increasing	Comparing soils at equal plasticity index with liquid limit increasing
Compressibility	About the same	Increases
Permeability	Decreases	Increases
Rate of volume change	Decreases	....
Toughness near plastic limit	Increases	Decreases
Dry strength	Increases	Decreases

After plotting the results of limit tests on a number of samples from the same fine-grained deposit (Fig. 5), generally the points lie on a straight line approximately parallel to the A-line. For example, for the thick stratum of the so-called "Soft Boston Blue Clay," which underlies large areas of Greater Boston, the liquid limit ranges from 30 to more than 70 along a line corresponding approximately to the lower boundary of the area marked "Glacial Clays." Of hundreds of limit determinations on this clay, the average liquid limit is 47 and the average plastic limit is 23.

Position of Typical Inorganic Clays.—The belt of glacial clays in Fig. 5 seems to cover most inorganic clays from Boston, Detroit, Chicago, and northeastern Canada. Much tougher clays are represented by the line showing test results on clays from one locality in Venezuela and by the belt which covers gumbo clays from several southern states.

Kaolin-Type Clays.—Interesting types of fine-grained soils are the kaolin-type clays, usually derived from feldspar in granitic rocks. On the plasticity chart, they plot below the A-line. Although they are generally referred to as clays, they possess some of the characteristics of inorganic silts. They have relatively low dry strength; and in the wet state show some reaction to the shaking test, which is characteristic of the ML–MH groups. However, they are extremely fine grained and smooth, and often contain as great a clay-size fraction as many tough clays located well above the A-line, as shown by soil No. 4 in Table 1. In Fig. 5 the kaolin-type clays in a belt slightly below the A-line are from widely separate deposits. They may be classified as boundary cases, ML–CL, and MH–CH. Test results on a different type of kaolin (from Mica, Wash.) are located along a line which lies in the MH area well below the A-line.

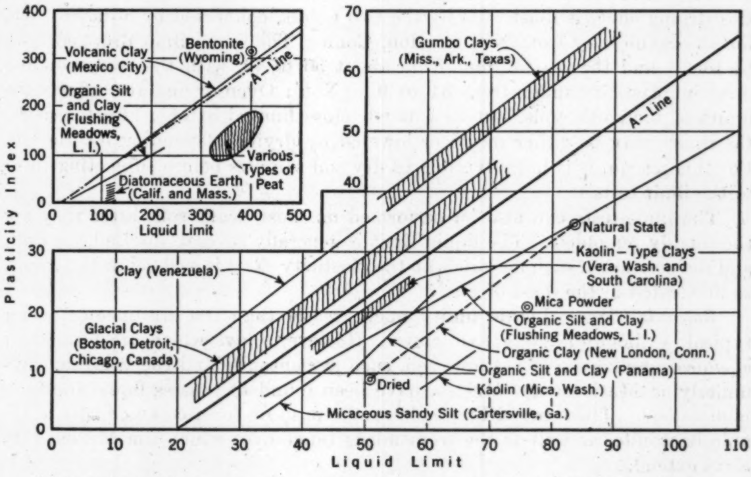

Fig. 5.—Relation Between Liquid Limit and Plasticity Index for Typical Soils

Inorganic Silts, Rock Flour, Micaceous, and Diatomaceous Soils.—The common types of inorganic silts and rock flour have liquid limits less than 30 and are located in the ML area, Fig. 4. A typical rock flour, such as is found in glaciated areas, is usually nonplastic.

Eolian deposits of the loess-type have liquid limits ranging usually between 25 and 35 and vary from nonplastic (that is, the base line) to the A-line, and in exceptional cases also into the CL group slightly above the A-line.

Micaceous soils have a substantially greater liquid limit than a similar soil without the admixture of mica, as illustrated in Fig. 5 by the micaceous, sandy silt from Cartersville, Ga.

Fairly pure diatomaceous earth is generally nonplastic, with liquid limits above 100. With other fine-grained admixtures, diatomaceous soils were found to range throughout the ML and MH groups. The locations on the plasticity chart of two types of fairly pure diatomaceous earth are shown by the small shaded area in the inset of Fig. 5.

Organic Soils.—Even a very small admixture of organic colloidal matter will cause an inorganic clay to increase its liquid limit, without an appreciable change in the plasticity index, thus causing a relative shift to a position below the A-line. In Fig. 5 are shown the positions of several organic silts and clays. Most of the organic silts, silt clays, and clays deposited by the rivers along their lower reaches near the Atlantic seaboard (for example, Hudson River silt, and Potomac River silt) range in liquid limit between 40 and more than 100 and are located on the plasticity chart from 5 units to 15 units below the A-line.

An important property of all fine-grained, organic soils is the radical drop in plasticity due to oven-drying. This is due to the fact that organic colloids are very sensitive and undergo irreversible changes upon drying. In Fig. 5 this drying effect is illustrated by the two points, connected by a dashed line, for an organic clay from New London, Conn. The liquid limit dropped from 84 to 51, and the plastic limit from about 50 to 42, with the corresponding drop in plasticity index from 34 to 9. (Note: Oven-drying also affects the limits of inorganic soils, but to a much more limited extent. Furthermore, the limits may be either raised or lowered by drying, depending on the soil. For this reason, it is not advisable to dry soil samples before subjecting them to the limit tests.)

The limit tests can also be performed on most peaty soils after they are thoroughly remolded. The liquid limit is generally several hundred per cent, and the position of such materials on the plasticity chart is well below the A-line, as illustrated in the inset of Fig. 5.

Volcanic Clays.—Liquid limits much greater than 100 are uncommon for typical, sedimentary, inorganic clays. However, clays which are formed by chemical breakdown of volcanic ash, such as bentonite and the volcanic clays underlying Mexico City, Mexico, have been found to possess liquid limits as high as 500. The inset in Fig. 5 shows the position for a commercially available bentonite, as well as the tremendous range over which the Mexico City clays extend.

13. Field Identification of Fine-Grained Soils

Basis of Field Identification.—It has been shown how the limit tests, supplemented if necessary by other tests, are used to classify fine-grained soils. However, the AC system is so devised that it is possible, with experience, to classify most soils correctly on the basis of field identification procedures alone. The easiest way of learning field identification is under the guidance of an experienced man. To learn without such assistance, one should compare systematically the numerical test results for typical soils in each group with the "feel" of the material while performing the field identification procedures.

The distinguishing characteristics between coarse-grained soils and fine-grained soils have already been described. The principal procedures for field identification of fine-grained soils are (*a*) the shaking test, (*b*) the examination of plasticity characteristics, and (*c*) the examination of dry strength. In addition, observation of color and odor is of value, particularly for organic soils.

Shaking Test.—In this method a wet pat of soil is alternately shaken in the palm of the hand and then squeezed between the fingers. A nonplastic, fine-grained soil will become "livery" and show free water on the surface while being shaken. Squeezing will cause the water to disappear from the surface and the sample to stiffen and finally crumble under increasing finger pressure, like a brittle material. If the water content is just right, shaking the broken pieces will cause them to liquefy again and flow together. The speed with which the pat changes its consistency and the water on the surface appears or disappears, is distinguished as (1) rapid, (2) sluggish or slow, and (3) no reaction. Rapid reaction to the shaking test is typical for nonplastic, uniform, fine sand (SP, SF) and inorganic silts (ML), particularly of the rock flour type; also for diatomaceous earths (MH). With decreasing uniformity the reaction becomes more sluggish. Even a slight content of colloidal clay will impart some plasticity and slow up materially the reaction to the shaking test; this is true, for example, of slightly plastic, inorganic, and organic silts (ML, OL); very silty clays (CL–ML); and many kaolin-type clays (ML, ML–CL, MH, and MH–CH). Extremely slow or no reaction to the shaking test is typical for all clays above the A-line (CL, CH), as well as for highly plastic organic clays (OH).

Plasticity Characteristics.—Examining of the plasticity characteristics should start with a small sample having a soft, but not too sticky, consistency. This sample is alternately rolled into a thread and folded into a lump, and the increase in stiffness of the thread is observed as the plastic limit is approached. After the water content has dropped below the plastic limit, the pieces of the threads should be lumped together, and a slight kneading action on the lump continued until it crumbles.

The higher the position of a soil above the A-line on the plasticity chart (CL, CH), the stiffer are the threads near the plastic limit, and the tougher are the lumps below the plastic limit. Examples for such tough clays are the gumbo clays (CH) shown in Fig. 5. For soils slightly above the A-line (as the glacial clays (CL, CH)), the threads at the plastic limit are medium stiff and the lumps soon start crumbling when the water content drops. Soils below the A-line (ML, MH, OL, and OH) show, with very few exceptions, weak threads near the plastic limit. For organic soils and micaceous inorganic soils, located considerably below the A-line, the threads are very weak and spongy. All soils below the A-line, except OH soils near the A-line, lack cohesiveness when the water content drops below the plastic limit, and the lumps will readily crumble.

When working in a locality where the air humidity is fairly constant, the length of time to reach the plastic limit furnishes a rough indication of the magnitude of the plasticity index. For example, for a gumbo clay with a liquid limit of 70 and a plasticity index of 50 (CH), or a highly plastic organic clay with a liquid limit of 100 and a plasticity index of 50 (OH), a very much longer time will elapse before the plastic limit is reached, as compared with a glacial clay of the CL group. For a slightly plastic silt (ML) the plastic limit will be reached very quickly. To prevent a misleading conclusion it is important that the examination of the plasticity characteristics be started for all soils at about the same consistency.

Dry Strength.—The resistance of a piece of dried soil to crushing by finger pressure is an indication of the character of the colloidal fraction of a soil.

Almost no dry strength characterizes nonplastic ML and MH soils. The dried lumps will fall apart under the slightest finger pressure. Typical rock flour and fairly pure diatomaceous earth are examples.

Low dry strength is representative of all soils of low plasticity, located below the A-line, and of very silty, inorganic clays in the CL group, slightly above the A-line.

Medium dry strength is typical of most clays of the CL group, and of those clays of the CH, MH (kaolin-type clays), and OH groups which are located near the A-line.

High dry strength is indicative of most CH clays, also of those CL clays located high above the A-line, as well as some organic clays of the OH group having very high liquid limits and located near the A-line.

Very high dry strength is developed only by those clays of the CH group located high above the A-line, as the gumbo clays shown in Fig. 5.

Color.—In field soil surveys color is often helpful in distinguishing between various soil strata, and, with sufficient preliminary experience with the local soils, also in identifying the individual soils. To the experienced eye certain dark or drab shades of gray and brown, including almost black colors, are indicative of fine-grained soils containing organic-colloidal matter (OL, OH). In contrast, clean and bright-looking colors, including medium and light gray, olive green, brown, red, yellow, and white, are generally associated with inorganic soils.

Odor.—Organic soils of the OL and OH groups usually have a distinctive odor which, with experience, can be used as an aid in identification. This odor is especially apparent in fresh samples. It is gradually reduced by exposure to air, but can again be brought out by heating a wet sample.

Observations and Tests Relating to Material in Place.—For foundations, the properties of soils in the undisturbed state require special examination. Most important are the denseness of coarse-grained soils and the consistency of fine-grained soils. Also, the consistency of the same soil remolded with its natural water content should be observed. For example, a clay may be described as "stiff and brittle in undisturbed state and very soft and sticky in remolded state." Where the drainage characteristics are of importance, one should observe stratification, root holes, and fissures. Depending on the problem, other tests, such as those listed in Col. 5, Table 4, may be required.

14. Possible Expansion of AC System

General.—Numerous suggestions have been received for the expansion of the airfield classification system. Some have recommended the use of subscripts or letters and numbers added in parentheses, to supply more detailed information. Such additional symbols are useful abbreviations but have the disadvantage that they can be read only by those who have taken the trouble to acquire a working knowledge of such a "shorthand" system. In general, readers of reports and publications should not be burdened with more than a minimum number of symbols; full description in words is preferred.

For soil specialists it may be desirable to arrive at an agreement on the use of possible symbols for describing soils more in detail or on the addition of soil groups. For this purpose the most practical of the suggestions received are summarized below, including the writer's ideas, based on experience accumulated since the new system was formulated.

Coarse-Grained Soils.—Simple field identification methods permit differentiation within the GP and SP groups between uniform soils (such as beach sand) and those materials covering a wide range of sizes but of poor gradation (as a mixture of gravel and fine sand which is deficient in intermediate sizes). By adding the new groups GU and SU for uniform gravels and sands, respectively, and restricting the use of the GP and SP symbols to those materials which have a wide but poor gradation, it is easy to provide for this differentiation.

To distinguish between those soils in the GF and SF groups which possess a silt binder and those having a plastic (clay) binder, the subscripts m and c, respectively, can be used, for example, GF_c, SF_m. The gradation of the coarse fraction could also be described by subscripts, such as, S_uF_m, S_pF_c, and S_wF_m.

Fine-Grained Soils.—The entire range of plasticity is at present divided into the two main groups designated with the letters L and H. Experience has indicated that the L group covers too large a range and that with practice one can distinguish by field identification between soils having a liquid limit ranging well below 35 and those from 35 to 50. The soils in such an intermediate group could be identified with the letter I. Thus, CL would designate a very lean clay having a liquid limit below 35, and located in the plasticity chart above the A-line; CI would be a clay with a liquid limit between 35 and 50, above the A-line; and CH would be a fat clay with a liquid limit larger than 50, above the A-line.

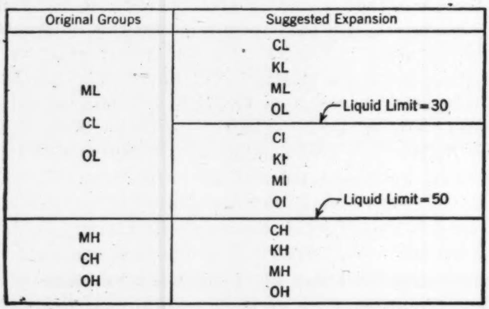
In localities where kaolin-type clays require attention, it would be desirable to add such clays as separate groups for which the symbols KL, KI, and KH suggest themselves. This illustrates the flexibility of this classification, which permits adding new groups without affecting the main framework. It should be kept in mind, however, that any expansion should not be beyond the possibilities of field identification. From that viewpoint there is no objection to introducing the kaolin-type clays as a separate group, because anyone who has handled such clays and learned their "feel" will be able to recognize them readily.

A comparison of the original groups of fine-grained soils with this possible expansion is illustrated in Fig. 6. It will be noted that the order has also been changed to conform better to the order of usefulness of soils in foundation and earthwork engineering.

15. DESCRIPTIVE SOIL CLASSIFICATION

Describing a soil in detail on the basis of a careful visual and manual inspection, utilizing more or less generally accepted nomenclature, classifies this soil, although no rigid system is used. This approach will be designated as a "descriptive soil classification." As such, it may be considered the oldest and most widely used classification. Not only field engineers and boring foremen, but also soil mechanics experts use this extensively, often in preference to a more rigid system.

The disadvantage of the descriptive classification lies in a lack of uniformity of soil terminology. The abuse of classifications by giving only the group number of a soil without any further information, has perhaps been the greatest obstacle to the development of a more uniform soil nomenclature. Therefore, the application of any system of classification as an excuse to reduce the description to a minimum or to eliminate it entirely must be strongly condemned. Instead, the main emphasis should always be on a complete verbal description of every pertinent characteristic of a soil, in its undisturbed state as well as after it is reworked.



Liquid Limit = 30
Liquid Limit = 50

Original Groups	Suggested Expansion
ML CL OL	CL KL ML OL
	CI KI MI OI
MH CH OH	CH KH MH OH

FIG. 6.—SUGGESTED EXPANSION OF AC GROUPS FOR FINE-GRAINED SOILS

For example, a soil might be described as "olive green, homogeneous, medium-plastic, silty clay, medium stiff and brittle in the undisturbed state, very soft when remolded." This descriptive classification will convey to the reader, familiar with this terminology, a fairly clear picture of this soil. In contrast, if it is designated as an A–4 or A–7 soil, the information is entirely inadequate for any engineering use.

If a soil surveyor is forced to describe each soil in detail, he will develop the habit of examining it with greater thoroughness than if he is asked merely to give the group number or symbol. He can, for convenience, use his own abbreviations for frequently recurring characteristics thereby creating a more detailed classification than is afforded by any existing rigid classification. Such abbreviations may be in the form of numerous subdivisions of certain classes within an existing system.

For some purposes the descriptive classification should emphasize specific soil characteristics. Regarding compaction, it was often found useful to group soils into (*a*) noncohesive, coarse-grained soils (that is, soils having no dry strength); (*b*) typical cohesive soils (soils having considerable dry strength); and (*c*) those fine-grained soils having little or almost no dry strength.

Descriptive Adjectives.—The most common adjectives used in describing soils are:

Grain Size

(1) Very coarse
(2) Coarse
(3) Medium coarse
(4) Medium fine
(5) Fine
(6) Very fine

Grain Shape

(1) Angular
(2) Subangular
(3) Subrounded
(4) Rounded
(5) Well rounded

Gradation

(1) Very uniform
(2) Uniform
(3) Poorly graded
(4) Fairly well graded
(5) Well graded
(6) Very well graded

Compactness

(1) Very loose
(2) Loose
(3) Medium dense
(4) Dense, firm, compact
(5) Very dense, well compacted

Consistency

a. Consistency Grading—
  (1) Very soft
  (2) Soft
  (3) Medium stiff
  (4) Stiff
  (5) Hard

b. Other Consistency Characteristics—
  (1) Brittle
  (2) Friable
  (3) Elastic
  (4) Spongy
  (5) Sticky

Plasticity

a. Plasticity Grading—
  (1) Nonplastic
  (2) Trace of plasticity
  (3) Medium plastic
  (4) Highly plastic

b. Cohesiveness Near Plastic Limit—
  (1) Very weak
  (2) Weak
  (3) Firm
  (4) Medium tough
  (5) Tough
  (6) Very tough

Dry Strength

(1) Very slight
(2) Slight
(3) Medium
(4) High
(5) Very high

Examples of Descriptive Soil Classification.—Examples of descriptive soil classification will indicate how the adjectives can be combined into a detailed description:

(1) Uniform, fine, clean sand with rounded grains. Equivalent to A–3; SP (or SU in expanded AC system).

(2) Well-graded, gravelly silty sand; angular gravel particles, ½-in. maximum size; rounded and subangular sand grains; a very silty binder of low dry strength with no plasticity; well compacted and moist in undisturbed state. Equivalent to A–2–3; GW–GF.

(3) Organic silt; medium stiff and brittle in undisturbed state and very soft and sticky in remolded state; medium dry strength; weak and spongy at plastic limit; crumbles readily below plastic limit. Equivalent to A–7, OL–OH.

(4) Highly plastic (fat) clay; stiff at the plastic limit; forms a tough lump when drying is continued considerably below the plastic limit; medium stiff in undisturbed state, soft and sticky when remolded. Equivalent to A–6–7; CH.

Acknowledgment.—The writer wishes to express his appreciation to S. D. Wilson for stimulating assistance.

DISCUSSION

Ralph E. Fadum,[3] Assoc. M. ASCE.—The critical review of the soil classification systems used in civil engineering, as presented by the author, is a worthy contribution to the literature of soil mechanics. The author is to be commended for directing attention to the inadequacies of the much used textural classification systems according to which all soils are distinguished on the basis of grain-size composition. He has submitted ample evidence to support his thesis that the grain-size composition does not, by itself, reflect the significant physical properties of fine-grained soils.

In the proposed Airfield Classification (AC) System the author distinguishes between two primary soil groups—the so-called coarse-grained group and the fine-grained group. Sands and gravels comprise the first group and silts and clays the latter group. Soils of the coarse-grained group are distinguished primarily on the basis of grain-size composition. In general, a visual examination will suffice to differentiate the eight soil types included in this group. The six soil types included in the fine-grained group, on the other hand, are distinguished primarily by the degree of plasticity that they exhibit as measured by the simple, manual tests described by the author. It is noteworthy that in accordance with this system fourteen soil types, which have significantly different physical properties, can, with experience, be recognized by simple visual and manual tests that can be made without the aid of laboratory facilities.

The proposed system is flexible and, accordingly, suitable for classifying soils with respect to performance characteristics under a wide variety of conditions. The author has referred to the AC system as the Airfield Classification System. This name connotes a restrictive meaning that does not do justice to its general applicability.

The author recommends (see heading, "12. Fine-Grained Soil Groups of AC System") that 0.1 mm be used as the boundary size between the coarse-grained and fine-grained groups—

> "* * * usually those soils containing more than 50% of material smaller than 0.1 mm in size (passing No. 150 mesh) are classified as fine-grained soils (ML or CL); and soils containing less than 50% smaller than 0.1 mm in size are classified as coarse grained (SF or SC)."

This arbitrary limit provides a convenient method of separating a soil into its component fractions for detailed laboratory analysis. If a soil is dispersed in water, the particles larger than approximately 0.1 mm will settle out very quickly; those smaller than this size will remain in suspension. Thus, the coarse-grained and fine-grained fractions can be separated conveniently by a process of successive washing and decanting. After drying, the coarse fraction s suitably prepared for a dry sieve analysis. The wash water containing the fines can be used for hydrometer analysis (if the gradation of this fraction is considered significant), or the fines can be recovered from the wash water and subjected to other tests that may be prescribed for the so-called binder fraction.

---

[3] Prof. of Soil Mechanics, School of Civ. Eng. and Eng. Mechanics, Purdue Univ., Lafayette, Ind.

The binder fraction is usually defined (22) as that fraction of a soil the constituents of which pass a standard No. 40 sieve. The writer is of the opinion that the results of the physical tests such as the Atterberg limit tests as determined from the binder fraction, consisting of the fraction of a soil smaller in size than 0.1 mm, would be more significant than the results obtained from the same tests performed on a binder fraction consisting of all material passing the No. 40 sieve.

In his discussion of the various methods of classifying soils the author includes one that he refers to as descriptive soil classification (see heading, "15. Descriptive Soil Classification"). This method, which is used extensively, consists in "Describing a soil in detail on the basis of a careful visual and manual inspection, utilizing more or less generally accepted nomenclature * * *." The author states (see heading, "15. Descripture Soil Classification") that: "The disadvantage of the descriptive classification lies in a lack of uniformity of soil terminology." The following remarks are directed particularly toward the soil terminology used in a descriptive soil classification system.

Confusion in terminology has arisen from the practice of differentiating soil types quantitatively on the basis of grain size composition, from the use of provincial names such as Boston Blue Clay, Chicago Blue Clay, etc., and from the use of terms such as marl and loam that do not convey sufficiently specific meanings. To be acceptable and useful, terminology used in a descriptive soil classification system should:

1. Consist of terms with which a boring foreman, an earthwork engineer, and a soil mechanician are equally conversant;
2. Describe the significant characteristics that can be determined quickly without the aid of laboratory facilities;
3. Be discriminating; and
4. Convey a well-defined meaning.

For purposes of soil identification and descriptive classification it is suggested that the following three size fractions be recognized as significant in describing the grain-size composition of a soil—the gravel fraction, the sand fraction, and the fine-grained fraction (composed of particles smaller than 0.1 mm in size). The composition in terms of these fractions can be expressed conveniently by a number system, as follows: 50–10–40 designates a soil composed 50% by weight of gravel, 10% by weight of sand, and 40% by weight of fines; and 0–20–80 designates 20% by weight of sand and 80% by weight of fines. If graphical representation is preferred, a triangular chart similar to those shown in Fig. 3 could be used. Reasonable estimates of composition according to these fractions suitable for identification purposes can be made without the aid of laboratory facilities.

As stated, sands and gravels are distinguished solely on the basis of the size of their constituent particles. Factors other than grain size, however, must be considered in distinguishing between silts and clays. The author has directed attention to the fact that the grain-size composition of two fine-grained soils may be identical; yet, the physical properties can be significantly different. The effect of mineralogical composition, which is reflected by the shape of the soil particles, dominates the effect of grain size on the properties of a fine-grained soil. Soils composed essentially of "clay-size" minerals, as defined by the various classification scales in current use, may exhibit either silt-like or clay-like properties. According to engineering concepts a fine-grained soil or fraction is identified on the basis of the degree of plasticity and dry strength that it exhibits. A clay-like soil can be made to exhibit plastic properties by an adjustment of its water content and it has considerable strength when air-dried. (The term plastic is used, herein, to describe that property of a material which enables it to be deformed quickly without exhibiting a noticeable elastic rebound or volume change and without cracking or crumbling.) A silt-like soil cannot be made plastic and it exhibits little or no strength when air-dried. There are no simple, direct methods suitable for routine identification and classification purposes by which the clay-like constituents of the fine-grained fraction can be separated quantitatively from the silt-like constituents. It is suggested, therefore, that the terms silt and clay be used in a qualitative rather than in a quantitative sense.

In light of the foregoing remarks and in the interest of promoting agreement on soil terminology to be used in a descriptive soil classification system, the following summarized recommendations are proposed:

1. The terms "gravel," "sand," "silt," and "clay," used singly or in combination, shall form the basic elements of a soil name. The name shall be qualified by the use of carefully selected adjectives so as to make the description of a soil complete and discriminating.
2. Distinction between silts and clays shall not be based upon the size of the constituent particles.
3. The terms "silt" and "clay" shall be used in a qualitative rather than in a quantitative sense.
4. The gravel fraction, the sand fraction, and the fine-grained fraction shall be recognized as the significant fractions in describing the grain-size composition of a soil.
5. The fine-grained fraction (or binder fraction) shall be defined as that fraction of a soil the constituents of which are smaller than 0.1 mm in size.
6. The fine-grained fraction shall be designated "silt" if it cannot be made plastic and if it exhibits little or no strength when air-dried. (Careful distinction must be made between inorganic and organic silts (23).)
7. The fine-grained fraction shall be designated "clay" if it can be made plastic by an adjustment of its water content and if it exhibits considerable strength when air-dried.

The foregoing recommendations were submitted by the writer to the American Society for Engineering Education for use in formulating a set of standard definitions (24).

JAMES H. STRATTON,[4] M. ASCE.—The very nature of military operations in active theaters of war precludes other than "rule of thumb" methods in the design of airfields and roads, and the fluidity of the military situation generally requires that their construction and improvement be undertaken by stages. Improvements in bearing capacities must generally be accomplished in the face of enemy activity and increasing severity of use by the engineer's own forces.

---

[4] Col., U. S. Army, Superv. Engr., The Panama Canal, Diablo Heights, Canal Zone.

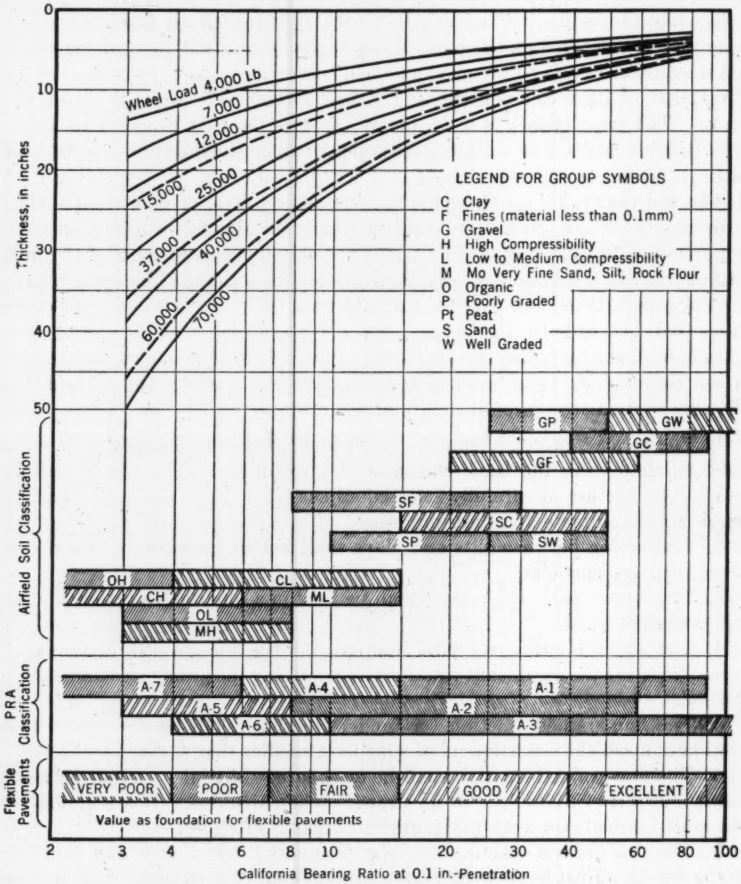

Fig. 7.—Tentative Recommendations for Combined Thickness of Pavement and Base Having Satisfactory Bearing Ratio

The military engineer must know, at all times, the capacities of his roads and airfields in terms of both traffic volume and loading intensities. This calls for rapid interpretations or analyses, and therefore some standardization of the "rule of thumb" design method is required to insure against faulty designs or interpretations of the strengths of roads and airfields which would adversely affect the plans of the military commander.

In the spring of 1942, the Corps of Engineers, United States Army, adopted the California highway method of evaluating the bearing values of road subgrades and extended the design curves developed by O. J. Porter, M. ASCE (25),[4a] to the higher loadings later required for airfields (see Fig. 7). An attempt was made to correlate the Public Roads Administration soils classification with the bearing-value curves in order to provide a design method for military road and airfield construction in the zone of operations through simple soil classification tests. As a result of the inability of the Corps of Engineers satisfactorily to correlate the Public Roads Administration soils classification with design procedures, Professor Casagrande was requested to study methods of soils classification. The material for the paper was taken from the resulting study.

Prior to adopting the Casagrande classification, a canvass was made of all district and division engineers with the interesting result that, of the forty-four offices canvassed, thirty nine were in favor of the adoption and only five raised objections. The objections were largely concerned with the confusion that would result in the adoption of revised soils classification when construction was at a peak. However, in the light of the favoring majority opinion, it appeared that a change at that time would actually facilitate the transition by giving a wide opportunity for correlation with the Public Roads Administration system of classification that would aid in later revisions and improvements of the Casagrande classification. Accordingly, the Casagrande classification was adopted as standard for the Corps of Engineers.

Objections to the soil classification method were interposed by some of the most experienced soil technicians, who condemn all soils classification methods on the ground that their use encourages casual design conclusions whereas exhaustive investigations and study are required. In weighing this objection it must be noted that "symbols" identified with soils classification are a form of "engineering shorthand" which will always be popular in the profession despite the concern of those who recognize the complexity of soils and the difficulties in predicting their behavior. The Corps of Engineers does not propose to substitute a soil classification method for needed investigations and tests and orderly design procedures except where circumstances preclude other than rough or rudimentary methods of design.

It was the conclusion of the Corps of Engineers that the correlation of the soil classification methods proposed by Professor Casagrande with the bearing values of subgrades and base courses would be helpful in developing a "rule of thumb" method of design that could be employed where extensive investigations, tests, and deliberate design methods were infeasible.

The virtues ascribed by districts and divisions of the United States Engineer Department (U.S.E.D.) to the Casagrande method of classification may be summarized by stating that the improved classification is in consonance with general progress in soils engineering. One division of the U.S.E.D. commented favorably on the method because of its mnemonic characteristics.

The Lower Mississippi Valley Division, U.S.E.D., noted that a soil derivative of loess, frequently encountered in the Mississippi Valley, consisted of from 40% to 60% of silt and partakes of the nature of both an A-4 and an A-5 soil, and thus is not classifiable by the Public Roads Administration method. This division found that this soil also was not classifiable by the Casagrande method and that further study with a view to cataloging this soil is required. The same division also pointed out that soils classification correlation with the California Bearing Ratio (CBR) values must be predicated on standard methods of soil compaction and testing for the bearing values. The United States Waterways Experiment Station at Vicksburg, Miss., investigated a wide variety of soils and reported that the bearing values correlated very well with its interpretation of the Casagrande classification with one exception, which fell 3% outside the estimated range of CBR values as specified by Professor Casagrande for the particular soil type.

One district suggested that the percentage of soil binder and its plasticity index be indicated by numerical values in the classification of gravels and sands; for example, GW-3,1 would indicate a well-graded gravel with approximately 30% soil binder and a plasticity index of approximately 10%; likewise, SP-0 would indicate a poorly graded sand with no fines. If this plan were adopted, the GC, GF, SC, and SF groups would be eliminated. For the fine-graded soils, this district proposed correlating the plasticity index and moisture condition with the classification letters. For example, C5-3 would represent a "fat" clay with a plasticity index of 50% and a moisture content of 30%. There are certain virtues in this suggestion which may be realized indirectly by adopting the suggestion of the Upper Mississippi Valley Division, U.S.E.D., that the CBR number be added after the letter symbols; thus, for example, SF-25 would indicate a soil to be a sand with an excess of fines and would give a picture of its internal structure. This suggestion is of value since the CBR is indicative of behavior under load. It is probable that this form of identification will be used when bearing tests have been made.

The North Atlantic Division, U.S.E.D., stated that the suggested soil groups are satisfactory with the exception of the gravels and sands in the fine groups—that is, GF and SF, respectively. These could be subdivided advantageously into additional groups reducing the wide latitude now covered by them. It was suggested by this division that an additional gravel and sand group, designated GL and SL, respectively, be added to the Casagrande classification, to include gravels and sands with excess of fines.

The Casagrande classification is not expected to supplant local names entirely for special soils, such as loess, buckshot, gumbo, etc. These names have special meaning in the localities of occurrence and it is expected that they will be used to supplement the Casagrande classification.

The foregoing discussion was prepared for delivery at the Annual Meeting of the Society in January, 1943. Subsequently, the discusser's duties deprived him of opportunity to participate in engineering activities where he might have noted the results of use of the Casagrande soils classification system. It would be of interest to learn if the method of classification found favor and if it assisted military engineers in the construction of roads and airfields in the theater of operations.

Donald J. Belcher,[5] Assoc., M. ASCE.—Professor Casagrande's review of the present status of soil classification and identification provides a well-organized framework that is necessary to a perspective of the current situation in this field. The trial and error process, plus native ingenuity, has produced a "system" for each large organization dealing with soil in the engineering sense. This review organizes soil classifications and identification and places them in juxtaposition so that they may be evaluated and their relationships noted. All too often various methods are treated with an intolerance that indicates a lack of scientific maturity or perspective. Much of this intolerance appears when something "fails"—that is, the system is wrong. The same people throw golf clubs and tennis rackets because their game is poor.

Perhaps there have been many instances where each system has been applied too broadly—used beyond the limitations originally perscribed. Professor Casagrande points this out with respect to the Public Roads (PR) system. It is true of other systems as well and cannot be considered as a fundamental fault. In this respect a highly desirable development of Fig. 1 would be to introduce a vertical distribution based on grain size. The author indicates this particularly under the heading, "3. Textural Soil Classifications," where it is to be noted that such a method is inadequate for fine-grained soils. Similar limitations can be placed on several of the others, particularly those in Fig. 1 under the division dealing with "Properties of Soil in its Undisturbed Condition."

In the detailed discussions of the various classifications, especially those under the heading, "4. Agricultural Soil Classification," and "5. Geologic Soil Classification," some additional attention will add to the perspective that can be gained from the over-all treatment of the subject. Primarily, it is erroneous to describe the first method as an "Agricultural Soil Classification." Engineers are in fact unintentionally perpetuating a careless description of a science; this is the proper place to correct this concept in the minds of civil engineers. To tell an engineer that this is an agricultural method (as has been done for so long) is to send him elsewhere looking for an engineering method. Unfortunately, to describe it as a pedological soil classification is a dubious improvement. It is, more simply, the science of soil formation; the classification is based on all the properties of the soils. Therein lies an advantage not found in other methods.

First, and for the record as it stands in the original paper, it would be more complete to state that it is a classification for the purpose of describing a soil and the conditions under which that soil exists. On that basis there is no fundamental leaning toward any one field of application, but any field of interest may interpret the data for its own particular use. If there is a technical predilection toward agriculture on the part of some pedologists, it is attributable to the fact that agriculture supports their programs by the allotment of funds.

It is to be regretted that an influential paper such as this should label the pedological system as a complicated one. On the contrary, its principles are simple and logical, particularly when the method is interpreted for engineering use. It also possesses simplicity of another order: With this system a soil is classified in three dimensions, length, width, and depth. With one well chosen auger boring a soil area can be classified, whereas in other methods the area shrinks to the size of the auger hole and a sample has little significance beyond the hole from which it was obtained.

---

[5] Associate Prof., Civ. Eng., Cornell Univ., Ithaca, N. Y.

It has been commonplace to find the pedological classification described in the literature as a classification of surface soils for agricultural purposes. Although Professor Casagrande described it in this way, he also states that the underlying parent materials are included. The term "surface soils" is a relative one. When it is used in conjunction with "agricultural purposes," "surface soil" is immediately interpreted as meaning 6, 8, or at most 10 in. of depth below the surface. For the sake of clarification this point should be examined in some detail and emphasis added to Professor Casagrande's inclusion of the parent material, which may extend to considerable depths. Actually, there is no arbitrary boundary or basement beyond which lies the realm of the geologist, and there is no particular need for such a limitation.

No one will advocate this method for material existing at depths common to deep foundations. Therefore, at depths of from 80 ft to 100 ft it will never be of value. Depths of from 60 ft to 80 ft are still much too great for any general use of this method, but sand dunes of that depth are found in some areas that are or can be classified on the pedological basis. Also, there are extensive areas of deep wind-blown silt that reach these and even greater depths (from 100 ft to 200 ft). These may be called Aeolian (geologic classification) or loess deposits but they also coincide with pedologic units. Along the Lower Mississippi Valley these are classified as the Memphis soil; to the north, especially in Iowa, Illinois, and Missouri, they are described as Clinton soils; and in the State of Washington as Palouse.

As the surface is approached, in the 40-ft to 60-ft depth range, the application of pedology becomes somewhat greater although only geologic deposits that form the parent materials are as yet under consideration. In this range are included much rock and drift in the glaciated areas. In those soils weathered from rock there are valid relationships in many areas between the soil mantle and the character of the rock at such depths. In the drift areas the character of the mass of of material below the surface is sufficiently well described, so that general compaction and several other requirements (26) can be anticipated on the basis of the series name of a soil (a unit of pedological classification).

Each 10-ft increment, as the surface is approached, emphasizes two trends: First, that the application of the pedological principles increases to its greatest value in the 10-ft zone immediately below the surface; and, secondly, that the dollar volume of highway and airport construction increases to its greatest volume within the same general zone.

This somewhat brief illustration is intended to show that, on a national basis, a sliding scale of applicability is necessary. In smaller units, such as within a state or district, the scale becomes more fixed. It will be found that the significance of the pedological method, as it applies to soils in the depth, is a function of the type of deposit or formation. In areas where bare rock is exposed, or, where very shallow soils exist on rough terrain, the value of the method vanishes.

Climate is also important. Within the United States climatic differences are sufficiently great that they strongly influence soil development. In the humid regions much water percolates downward through the soil, constantly leaching the soil and rock, and in general building up accumulations of clay at depths of several feet below the surface. In this process soluble materials are removed. In the west, however, the situation is often reversed. There, rainfall and melting snows in the mountains are a contrast to the desert climate prevailing in the intervening valleys a few thousand feet below. Much of the water proceeds as ground water to the valley area, where it is largely dissipated by evaporation from the surface. This reversed process precipitates salts near the surface to form the alkali and caliche soils. These are also areas where the clays may easily become saturated with exchangeable ions and thus take on characteristics of abnormally high volume change and plasticity. Such soils occur as far east as western Minnesota, where small areas of alkaline soil are associated with the Fargo (clay) series.

At present relatively little correlation has been accomplished in this way, but it is known that pavement performance, base thickness requirements, and many construction details are related to the individual soil series. The alkali attack on concrete slabs, head walls, culverts, and steel pipe is a severe action in many of these areas (27).

If this method is adaptable to engineering use, then who is using it, where is it being used, and how? An examination of this field reveals the following:

The Portland Cement Association in its work on soil-cement stabilization uses and recommends the use of the pedological method as a basis for obtaining soil data (28).

> "Missouri [(26)] uses the pedological system as used by the U. S. Bureau of Chemistry and Soils, in making soil surveys for highway purposes. Missouri takes an attitude similar to that of Michigan, in that, of the three best known methods of classifying soils, the pedological system seems best to suit their needs. The other two methods seem to be limited in their scope because the classification by texture, as in the triaxial chart takes into account no other soil properties and the classification as developed by the Public Roads Administration is more an index of the behavior of disturbed soils and so does not take into account field conditions. The pedological system is essentially a reflection of drainage, topography, parent material, weathering agencies, as well as textural class. Missouri, however, does require that samples of each horizon of each soil type be taken and submitted to the testing laboratory for analysis. Field density tests are also made of each horizon in order that the theoretical soil shrinkage can be calculated for each horizon.
>
> "The Michigan State Highway Department [(26)] has found that the pedological scheme of soil classification provides an excellent means of studying soils for general highway purposes, and that it serves as a foundation for all other soil studies in the department. The soil type, in addition to serving as a unit in mapping, also serves as a unit to which laboratory test results, road behavior observations, construction problems, and maintenance experiences are related. In other words, the soil type serves as a means for classifying and coordinating the accumulated soil experience of the entire highway department personnel."

The Nebraska Department of Roads and Irrigation (29) states:

> "The pedological system of soil classification which has international recognition, was selected.
>
> "By adopting this method of classifying and indentifying soils, it was possible to make use of a wealth of available scientific information on soils,

including the published county soil maps and reports, and to supplement such knowledge with the test data and information obtained by observation on this survey as well as that which may be obtained through future investigations."

Tennessee and Nebraska have established (30)(31) a correlation between the soil series name and the texture of the material, as well as a further correlation between these and pavement performance.

The writer has observed a distinct positive correlation between the pumping of rigid pavements and the occurrence of the Superior clay series near Superior, Wis.; the Sharkey clay series near New Orleans, La.; and the Susquehanna clay series in Texas (partially reported in (32)).

There is a fair but incomplete correlation between the California Bearing Ratio (CBR) value and the soil series. This is indicated in the results of United States Engineer Department tests on the Clermont and Brookston soil series in Indiana; and by inference in the reported CBR experiments at Stockton, Calif. (33).

The North Carolina Department of Highways reports (32) "Pumping was not encountered on soils of the Norfolk or Ruston series. Pumping occurred on the Portsmouth and Plummer series * * *." It occurred also on the Lufkin, Elkton, and Coxville series.

In 1935, H. F. Janda (34) reported that excessive longitudinal cracks in a particular concrete pavement were confined to an area of Colby silt loam. W. S. Housel, M. ASCE (35), and F. V. Reagel (36) have related soil-cement construction to the soil series and L. D. Hicks (37) has established the relationship between the principal horizons of several soil series and the cement required for proper stabilization. Public Roads Administration (PRA) studies (38) show results of typical soils of the coastal plain (Norfolk, Portsmouth, and Ruston) and their relationship to base course performance in North Carolina.

Professor Casagrande's description of "5. Geologic Soil Classifications" is significant. It would be of considerable value if the method could be evaluated in greater detail, or perhaps less subtly; for truly "it is damned by faint praise."

The weakness of the method seems to be lodged in the broad basis of the classification and in the recognition of age and general origin as the most important factors. For those reasons it can seldom be used in engineering without considerable modification. An evaluation of this situation was concisely expressed by Karl Terzaghi, M. ASCE (39), in summing up the results of an investigation in this field:

> "There are no definite relations [between geologic classifications and engineering properties], because for a given geologic origin and petrographic character of a stratum the strength of the material, rock, or soil depends on conditions that are not, and cannot be, recognized by a purely geological investigation. For almost every geologically well-defined stratum the possible scattering of its physical properties from the statistical average is so important, that one cannot even make an acceptable guess based on precedent."

Essentially the pedological classification includes a refined geological classification and the parent material of a soil is directly related to materials that are mapped and described by geologists. F. R. Olmstead (40) and others have shown this in various sections of the United States.

J. A. HAINE,[6] ESQ., AND J. W. HILF,[7] ESQ.—A development of soils classification for engineering purposes is presented to the profession by the author's excellent Airfield Classification (AC) System, which one of the writers studied under him at Harvard University in Cambridge, Mass., in 1943. From personal observation in the Southwest Pacific theater of operations, the AC system proved definitely valuable to United States Army engineer officers who were required to design airdromes rapidly in the field. The AC system was found to have two advantages over other current classification systems:

(1) The symbols used by Professor Casagrande are descriptive and easy to associate with actual soils, and experience in teaching this system to military personnel, who had no previous soils training, showed that it could be learned more quickly than systems depending solely on memory.

(2) The ability to assign definite engineering properties and even numerical values of design criteria, within reasonable limits, to the soil groups (such as the California Bearing Ratio) greatly facilitated the design of foundations for flexible pavements.

Although the AC system was devised for military roads and airdromes, it can be used profitably in foundation explorations and in prospecting for materials for rolled earth dams. In adapting this system to earth dams, it becomes necessary to expand two of the soil groups, and to specify certain limits of particle size and percentages that the author has not definitely stated in the paper.

Two of the fifteen soil groups, GF and SF, should be subdivided in order to distinguish the character of the fines in these soils which may be critical in high embankments because of the phenomenon of pore fluid pressures. This modification is easily accomplished without affecting the definitions of the original soil groups, by substituting GF (silty), GF (clayey), SF (silty), and SF (clayey), for GF and SF, respectively—mentioned by the author as a possible expansion of the AC system.

Specifications for rolled earth dams usually limit the maximum size of gravel in the rolled fill to 5 in. for a 6-in. compacted layer. In the investigation of sources of borrow materials for such structures, it follows that sizes larger than 5 in. should be excluded from the soil classification, although the importance of reporting oversize rock in exploration logs is recognized. With a range of coarse grains, from 0.1 mm to 5 in., the lower limit of gravel size (defined as 1 mm or 2 mm by the various grain-size classifications) should be raised to $\frac{1}{4}$ in. in order to simplify field identification, and to make the sand and gravel ranges more nearly equal on the grain-size curve. This definition more nearly corresponds with the coarse aggregate of concrete (No. 4 sieve), and was used by the Army (41).

A question often asked by those studying the AC system is, "How much gravel must be present in order to classify a coarse-grained soil as gravel, rather than as sand?" Professor Casagrande does not list quantitative limits for the soil groups in Table 4. Undoubtedly, such limits could be provided, but

			No reaction	High dry strength	Very tough thread	In moist state, can be kneaded for a considerable period without cracking	CH	Inorganic clays of high plasticity; fat clays	Impervious	10	10	—	—
			No reaction	Medium to high dry strength	Soft weak to medium thread	Odor of decay which can be intensified by heating	OH	Organic clays of medium to high plasticity	Impervious	12	12	—	—
Fibrous organic soils of high compressibility		Fibrous, decayed, organic vegetable matter; noticeably compressible					PT	Peat and other highly organic swamp soils	Entirely unsuitable				

[a] 0.1 mm is the smallest visual size. [b] Subdivisions of the GF-groups and SF-groups of the AC system. [c] Zone 1 is inner, impervious zone; Zone 2 is intermediate, semipervious zone; Zone 3 is outer, free-draining zone. [d] If gravelly.

the percentages by weight would be different for each soil group, making it necessary to memorize additional information. Also, these percentages would be inappropriate in field classification, because of the difficulty of estimating weights of materials in various states of compactness by visual inspection. To avoid these objections and still provide a basis for dividing coarse-grained soils into sands and gravels, the writers have rearranged Table 4 for field use. As shown in Table 5, identification of coarse-grained soils (ten of the seventeen groups) may be accomplished by a step by step procedure without requiring the estimation of any fraction other than one half.

Col. 1, Table 4, lists fine-grained soils as "containing little or no coarse-grained material," but (under the heading, "12. Fine-Grained Soil Groups of AC System") the author states:

> "In the transition between coarse-grained and fine-grained soils, usually those soils containing more than 50% of material smaller than 0.1 mm in size (passing No. 150 mesh) are classified as fine-grained soils (ML or CL); and soils containing less than 50% smaller than 0.1 mm in size are classified as coarse grained (SF or SC)."

The writers agree with the latter division between the major soil groups and have used it in Table 5. The same reasoning is used in dividing coarse-grained soils into the gravel (G) and sand (S) groups. Regardless of the amount of fine-grained material present in coarse-grained soil, the latter is classified as gravel or sand, depending on the size of the coarse grains (whether more than 50% of them are larger or smaller than ¼ in.).

Persons who have not had the benefit of considerable laboratory experience in sieve analysis often find it difficult to estimate even the simple fraction, one half. They are inclined to judge quantity by volume, rather than by weight; for example, since the percentage by volume of particles larger than ¼ in. in a soil mass depends on whether the soil is in a loose state or a dense state, accuracy cannot be expected. However, the AC system boundary classifications, suggested by the author, such as GW-SW, or SF (silty)-ML, can be used in all cases where there is any doubt about the percentages.

Table 5 was devised to enable a relatively inexperienced investigator, or one unfamiliar with the AC system, to classify a soil—first, into the coarse-grained division or the fine-grained division, and then, if coarse-grained, into the gravel or sand groups when the soil is typical. For a boundary case in the coarse-grained division, the procedure is to assume that the soil is a gravel and then continue in the chart until the final soil group, say, GC, is reached, using the indicated criteria of gradation, and the amount and character of the fines. Since it could have been assumed that the doubtful coarse-grained soil was a sand, the correct field classification is GC-SC, which follows from the duplicate criteria for the gravel and sand subgroups. Similarly, if there is doubt as to whether a soil should be classified as coarse-grained or fine-grained, the assumption of first one type, and then the other, will result in the proper boundary classification. For fine-grained soils, Professor Casagrande's simple field tests, plus other identification aids, are used to determine the proper soil group. Here, the fraction to be tested is stated in Table 5 as material smaller than $\frac{1}{16}$ in., rather than No. 40 mesh. This is merely a field expedient for separation by hand, which will not affect the resulting classification in the large majority of cases, it is believed.

Together with instructions for performing the shaking, breaking, and thread tests, Table 5 should be sufficient to enable a proper classification in the field without any laboratory equipment. If it is desired, a representative sample can be classified in the laboratory, using the criteria in Table 5 and the Atterberg limits criteria proposed by Professor Casagrande; but it must be recognized that only a very small percentage of the soils examined in the field ever reach a laboratory, and that proper field classification is the primary objective in soils surveys. The writers heartily agree with the author that a complete description of the material is necessary in reporting a soil in a log. However, the facility in identification and classification of soils that must be developed by the use of such a chart as Table 5, is a necessary first step toward that goal.

After a soil is properly classified, as Professor Casagrande has shown, it is possible to indicate the engineering properties typical of the various soil groups and their use in engineering structures. For rolled earth dams, the permeability of a material is of outstanding importance and this property is listed for each group in Table 5. Also, the prospector for embankment materials often desires to know how the soil he has classified compares with other kinds of borrow material that may be available for a homogeneous dam, or for various zones of a zoned dam. To aid in evaluating possible sources of material, the writers have attempted to rate the various soil groups according to their experience, for use in rolled earth dams, considering the permeability, workability, shear strength, and resistance to piping of typical materials. In Table 5, Zone 1 represents the impervious zone, Zone 2, the semipervious zone adjacent to Zone 1 in the dam, and Zone 3, the free-draining outer zone of a rolled earth dam. It is recognized that the numerical ratings are not rigid, but in a qualitative way they will enable the investigator to judge the suitability of a material for rolled earth dam construction.

For final design of a dam, a soil classification alone is entirely insufficient. Laboratory tests must be made on representative samples of the foundation, on the required excavation, and on the proposed borrow areas to determine, among other properties, the permeability, cohesion, angle of internal friction, and compressibility characteristics of the materials. Nevertheless, when adequate soil classifications and descriptions are available in the logs of exploration, the designer has at his disposal timely information which he can use in making preliminary estimates, in determining the extent of additional field investigations needed for final design, and in planning an economical laboratory testing program.

It would be desirable if there were a sufficiently large number of experienced soil engineers to personally perform all the identifications and classifications of soils which are required for earth dam projects, but the fact is that often the investigation is performed by personnel relatively inexperienced in soil mechanics. Under these conditions, the simplest possible descriptive classification system, consistent with adequate utility, appears to be desirable.

The AC system without undue additional refinements is admirably suited for this purpose.

JACOB FELD,[8] M. ASCE.—This authoritative and complete program of soil classification is most timely. An extrapolation of reported experience to engineering problems is required to make the subject of soil mechanics usable in actual practice. To permit such procedure, the soil type must be known, when such experience is a report of someone else's work. A universal adoption of the author's system of classification and, at the same time, a recording of the soil type encountered in each problem reported in the technical literature will make a true wealth of data available in contrast to the present volume of contributions in soil mechanics; most contributions are useless because the authors employ secret codes or untranslatable language in describing the soils encountered and controlled.

The author clearly develops the thesis that soil classification must proceed on the basis of soil action and reaction, and not on the basis of component materials. The former method corresponds to the classification of human beings by their expected reactions, rather than by their height or weight. Textural or geometric soil classifications of granular or noncohesive soils have been reasonably successful, because the interaction of grains, in most cases, is not affected by the gas or liquid occlusions on the grain surfaces. In cohesive soils, there is a great variety of possible soil reactions, with identical textural make-up, depending on the mechanical and colloidal extent of the surface coatings. In addition, textural or sieving classifications do not distinguish between grains of unlike shape.

By magnifying the problem of soil classification, the difficulty of true classification by geometric methods can be easily understood. If a grouping of humans by size (let us say, equivalent volume) is made at a shore resort, and an identical size grouping is made at a winter resort, the two groups are geometrically identical; but they cannot be expected to react alike, because the factor of their clothing has been disregarded. Similarly, as the author described, the kaolin-type clays derived from a single type of feldspar may have particle sizes equivalent to many tough clays, but they react more nearly like a silt than a clay. The particles may be of the same size and, therefore, of equal gravitational adhesion; yet the chemical nature of the grain coverings and the effect on wetness (caused by the kind of electrostatic charge on the grain surfaces) are more important factors in determining the total adhesion and the tightness of possible grain packing, or the cohesion and possible consolidation, respectively.

In soil classification, it is unfortunate that the division between the sand and gravel designations does not agree with the accepted sieve separation in concrete and road base technology. The general agreement, that sand contains all particles passing a No. 4 sieve in all cement and bituminous concrete specifications, seems to require a restudy of this item for soil classification. To make the Airfield Classification (AC) System complete, definitions of the terms used, such as "compressibility" and "dry strength" should be included. It is important to distinguish between compressibility or dilatation as an elastic phenomenon, and changes in shape without change in volume, resulting from plastic flow or viscous deformation.

---

[8] Cons. Engr., New York, N. Y.

The author's recommendation of field identification tests brings to mind a very early treatise on soil classification, presented by John Evelyn before the Royal Society of London almost three hundred years ago (42). Although he was chiefly interested in the agricultural possibilities in artificially prepared soils (as well as natural soils), the recommendations for classifications and field identification are quite similar to recent writings, and are summarized herein for the reader who does not have access to this rare book.

In the "Introduction," Evelyn cites "De Arte Combinatoria" by Athanasius Kircher in which it is stated that there are "* * * no fewer than 179,100,060 different sorts of earths, but only eight or nine are useful to our purpose." Corresponding to modern soil horizons, three strata are identified as: (1) The top layer of "underturf earth," a foot or so deep; (2) the next strata may be "loam, clay, plastic, figuline or smectic"; and (3) the lowest strata may be "chalk, marle, fullers-earth, sandy, gravelly, stony, rock, shelly, coal or mineral." Incidentally, Evelyn states, "The Ancients called them: Creta, Argilla, Smectica, Tophacea, Pulla, Alba, Rufa, Columbina, Macra, Cariosa, Rubrica." He further subdivides the top layer into:

"I. A virgin-earth, black, fat, porous, light and sufficiently tenacious, without any admixture of sand or gravel, which in the lower series may be darkest-gray or tawney, becoming veined with yellow or sometimes red.
II. An obscure color mould, with some loam and sand.
III. A mixture of the former two types with small flints and pebbles.
IV. A totally sandy with a bottom of gravel, rock and 'not seldom' clay."

Then, a general description of soil types follows, which is quoted in full because of its picturesque language:

> "Pure sand is white, black, bluish, red, yellow, harsher and milder and some mere dust in appearance, none of them to be desired alone. But the grey black and ash coloured, or of the travelling kind, volatile and exceedingly light, is the most insipid and worst of all.
>
> "Clays there are of many Kinds—some more pinguid, some more slippery, all of them tenacious of water on the surface where it stagnates without penetration, most of them pernicious and untractable. The blue, white and red clay are all unkind, the stony and looser sort is sometimes tolerable, but the light brick-earth does very well with most fruit trees.
>
> "Loams and brick earth are of several sorts, some approaching to clay, others nearer marle.
>
> "Marle is usually at greater depths, of many colours, all of them unctuous, slippery nature, slackens upon drying after a shower and crumbles into dust."

Evelyn than advised that general textural description of soils may be of less value than classification of properties by the use of the senses. Four tests are described:

(1) By odor or smell—since "Lord Verulam affirms that vegetable odours exist in the soil."

(2) By taste—since the water percolation through soil shows the kind of chemicals therein, "although some say that there is no taste or odour in the best earths."

(3) By touch—fatty and slippery, or gritty, porous and friable, if it sticks to the fingers or dissolves on the tongue. The "best earth is blackish, cuts like butter, sticks not obstinately, is sweet, and becoming mortar when wet, without crusting when dry."

(4) By sight—"grey is pre-eminent, next russett, clear tawney is worse, light and dark coloured are good for nothing, yellowish red is worst of all."

Having analyzed and shown how various basic properties could be identified, Evelyn did not entirely discredit the laboratory technician of his day; he advised the following procedure for the synthesis of desired properties in soils:

> "All these are fit to be known, as contributing to noble and useful experiments, upon due and accurate comparisons, and inquiries from the several particles of their Constitutions, Figures and Modes, as far at least, as we can discover them by the best auxiliaries of microscopes, lotions, strainers, calcinations, triturations and grindings; upon such discovery to judge of their qualities, and by essaying variety of mixtures, and imitating all sorts of mold, foreign or indigen, to compound earths as near as may be resembling the natural, for any special or curious use, and be thereby enabled to alter the genius of Grounds as we see occasion."

He then demonstrated how artificial soils had been made by mixing samples of earths from various sources with types of chemicals and fertilizers, and concluded:

> "Therefore let no man be over-confident, that because some earths are soft, fat and slippery, they may not possibly consist of sands, (of which there are so many Kinds), since 'tis evident, that even all fossile bodies which can be reduced and brought to sands, may by contrition of the particles be rendered so minute, as to emulate the finest earths we have enumerated."

The early French experimenters and theorists in soil problems distinguished only between "loose soils" and "firm soils." However, when M. Chauvelot (43) presented a paper before the French Academy of Sciences in 1783, showing how the lateral earth pressure could be derived from a knowledge of the weight, the internal friction, and the cohesion of a soil without any other description or classification, that learned body announced that the problem of the determination of lateral earth pressure was now susceptible to a rigorous solution. Later, contributors went back to a textural soil classification and M. Mayniel (44), in 1808, reports on his extensive experiments and tables to cover all kinds of soil, namely: Soil, sand, gravel, rubbish or ash, clay and debris fills. Incidentally, Mayniel's division between large and small gravel is denoted by the size of a pigeon's egg.

An anonymous author (45) quotes from the works of Sir Humphrey Davy, classifying the four earths found in soils as: "* * * aluminous (clay), siliceous (flint), calcareous (limestone) and magnesian (not to be mistaken for limestone)." However, a soil is to be classified on how it acts and not on what it contains.

To quote that author:

> "In framing a system of definitions, a soil is to take a particular designation from a particular Kind of earth, not exactly in proportion as that earth may preponderate, or not over others in forming the basis of the soil, but rather in proportion to the influence which a particular Kind of earth, forming part of the sample, has on tillage and vegetation."

That might also be said for the influence on engineering uses of soils.

The need for a universal soil classification is an old one and much credit must be given to the author of this paper in presenting a comprehensive answer to it, in the form of the AC system, which permits and provides a unique name for every type of soil, using expected action and reaction as criteria.

KENNETH S. LANE,[9] ASSOC. M. ASCE.—Of the eight classification systems presented in the paper, the writer has had occasion, since 1937, to work with four—the triangle textural classification, the master curve textural classification, the Public Roads Classification, and the Casagrande system. From this experience the writer can certainly agree with the author's designation of soil classification as the most confused chapter in soil mechanics. Although the author modestly terms the Casagrande system as the Airfield Classification System, the writer prefers to designate it as the Casagrande classification, since it has been widely known as such from its initial publication in 1942. This classification is easily the best of the aforementioned four systems (in their forms as described in the paper) for the airport-highway type of work for which it was originally designed. In its application to dams and levees, it has certain limitations which can be best considered from their relations to the primary requirements of a soil classification system intended for wide usage.

Requirements of a Classification System.—The requirements particularly considered are those for a large and widespread organization handling many projects of all sizes; for less intensive operations, or for work concentrated in a particular region, simpler requirements might suffice. In this type of work, boring logs generally include a classification of the soil into a group or type, plus a word description similar to the descriptive classification covered in the paper (under the heading, "15. Descriptive Soil Classification").

On a large airport, levee, dam, or canal, involving a hundred or more foundation explorations, it is generally not feasible to consult the original boring logs whenever questions arise, so these are usually filed as reference material. Rather, the usefulness of a soil classification system comes from its application to graphic abstracts of boring logs, wherein the most pertinent information is abstracted and placed on boring drawings. Hence, for a large project, this graphic abstract is the form of boring information most used by engineers in designing, by bidders in estimating, and by contractors and field inspectors in planning construction. For this purpose, it is essential that the classification system include some type of shorthand notation to convey maximum information at a glance. All engineering classifications described by the author are so designed, except for one variation of the textural system where the words "some, little, and trace" indicate decreasing percentages of size fractions, and require slow reading for understanding.

---

[9] Chf., Soils and Geology Branch, Garrison Dist., Corps of Engrs., Dept of the Army, Fort Lincoln, Bismarck, N. Dak.

For this type of work, the writer feels that a soil classification system should satisfy the following four requirements:

Requirement A.—It should describe the soil in well-understood terms, which convey an idea of its type and behavior.

1. In addition to soil specialists, the terms used should convey the intended meaning to designing engineers, inspectors, geologists, contractors, and courts of law, which last are the recipients of altogether too many disputes, involving boring information versus foundation conditions encountered.

2. The system should make allowance for regional use of certain terms, particularly meaningful in that region, such as glacial till, buckshot clay, caliche, and others.

Requirement B.—The system should furnish an indication of soil properties and performance.

1. It should permit a crude estimate of permeability, compressibility, and shear strength—the three primary properties of a soil. When combined with other boring information (compactness and water table location), the classification should permit a rough estimate of soil performance, such as frost susceptibility, drainage, settlement, slope stability, wheel load capacity, and compactibility (probable range of compacted density and normally suitable compaction procedure).

2. It should be capable of subdivision. Soil is so complex that no classification system can replace tests. Nevertheless, subdivision can often reduce testing by narrowing the range of properties for soils, at least within a particular region. Approximate correlations of soil properties and performance experiences with the indicators of a classification system often can be facilitated by subdivision, particularly when the testing program extends over a length of time sufficient to accumulate experience from past tests. Furthermore, such correlations, even though rough, are often a "must" for rapid handling of a large number of projects whereas necessity frequently requires that testing be limited, or omitted entirely, for smaller projects.

Requirement C.—It should be applicable from visual examination—both in a simplified form and, with experience, in a more refined form.

1. The simplified form should be suitable for determination by boring inspectors from visual examination.

2. The refined form should be such that: (*a*) It can be assigned by a well-trained classifier or chief boring inspector from visual examination, supplemented by occasional check tests; or (*b*) it can be determined from tests in the case of a less experienced classifier. For the latter case, and also so that different laboratories will arrive at the same result, reasonably definite numerical limits are necessary.

Requirement D.—It should employ a simple system of notation for graphic abstracts of boring logs on drawings recording boring information.

1. The notation should register rapidly in the mind while the reader is scanning and comparing plots of several different borings.

2. The drafting effort should be minimized in the preparation of boring drawings, including those suitable for reduction. These are generally of two types: (*a*) Contract drawings to serve bidders, contractors, and construction engineers, and which also usually form one group of exhibits in any court case; and (*b*) study drawings (usually foundation profiles) to serve soils engineers, geologists, and designing engineers in developing the design treatment and in illustrating its adequacy in reports. Unlike study drawings, contract drawings should be made to avoid interpretation, from the legal standpoint that information furnished to bidders should be basic data—not interpretations.

Requirement A, for naming a soil to cover its type and behavior, has been complicated by the practice of using the soil names, "gravel, sand, silt, and clay," to represent, also, grain-size fractions as arbitrarily delineated by one of the grain-size scales in Fig. 2. The terms, "gravel, sand, silt, and clay," describe common soil types, and like all natural soils, each is usually a composite mixture of from two to four of the size fractions designated as "gravel, sand, silt, and clay sizes." Good definitions of these four soil types have been given by H. A. Mohr, M. ASCE (23), and also in dictionaries; and the terms convey about the same meaning to engineers, geologists, contractors, and courts. The general behavior of each of these four soil types was fairly uniformly understood until soil technicians began to confuse themselves and others by using the same words for size-fraction names. This practice has degenerated to the extent that some laboratories assign a name to a soil from the percentages of different size fractions, according to certain charts or classification triangles like those in Fig. 3; sometimes this is done as a routine matter from a grain-size curve by a classifier who never even sees the sample.

If the size-fraction percentages were a reliable measure of soil behavior, this practice might be condoned; but such is far from the case, as the author has indicated, mentioning the common illustration of plastic lean clay and fine cohesionless silt or rock flour of the same gradation. As one example, samples of Manhattan silt having 20% in the clay-size fraction would be designated in some classifications as silty or lean clay. Since this material becomes quick on the slightest provocation, it would indeed be unfortunate for any contractor (and later for the owner in court) who relied on the cohesion of a true lean clay in attempting to excavate below ground water.

Although frequently of the same gradation, classification of loess as silt ignores the fact (and the consequence) that loess often undergoes a serious rapid settlement from collapse of structure under the influence of seepage, whereas silt is seldom so affected. Because of the angularity of its coarse particles and its greater compactness, glacial till generally has greater shear strength, lower permeability, and higher resistance to excavation than a rounded particle gravel of equal gradation. These and other misleading results obtained with textural classifications have convinced the writer of the necessity for requirement A in naming the soil to describe its type and behavior.

Casagrande Classification.—In most usage to date, the Casagrande classification has generally been applied in the form of the group symbols GW to Pt, as shown in Table 4, Col. 3. When so applied, it is actually a plasticity classification for fine-grained soils, and a textural classification for coarse-grained soils. Since it is based on the position and shape of the entire gradation curve, the textural classification phase is superior to the triangle classification, which is based on only three points of the gradation curve. The shape and position of the entire gradation curve have considerable bearing on important soil properties. This fact is widely recognized and is illustrated by many past attempts at better definition—such as the effective size and uniformity coefficient presented by Allen Hazen; the mean diameter and grade line introduced by Frank B. Campbell, M. ASCE (8); and the mean size, fineness dispersion, and curve shape proposed by D. M. Burmister, Assoc. M. ASCE (46)(47).

Hence, although this textural phase of the Casagrande classification is one of the best of the systems described in the paper, it is subject to the general objections to a textural classification when used alone. For example, such unlike materials as gravel, cohesionless till, talus, and caliche would be classed in group GW, and silt and loess in group ML. From the closing paragraphs of the paper, it is apparent that the author is aware of this deficiency (or possible misapplication) of the system and intends that the group symbol should be supplemented with a soil name. The writer is in agreement with this form of the system, as it then meets requirement A.

For furnishing indicators of soil properties (requirement B), the writer considers the Casagrande classification the best of any yet devised in regard to compressibility and shear strength of fine-grained soils. However, its performance has been relatively poor in indicating the permeability of coarse-grained soils. The writer has experienced ranges in permeability in ratios of from 1 to 10,000 and even from 1 to 100,000 which are considered undesirably wide for a single-class group. (Although many past attempts have shown uncertain relationships between permeability and results of simpler classification tests, the lack of success in deriving these relationships is probably explained by the difficulties encountered in permeability test procedure. With more refined testing techniques, considerable data have been accumulated since 1942 (unpublished) which, it is believed, indicate that such relationships do exist; and, of the simpler classification systems available at present, the data correlate best with a master curve system.)

If subdivisions were feasible, they would probably narrow this permeability range, as well as the range in compacted density, which has also been experienced as relatively widespread in certain groups. After several unsatisfactory attempts at subdivision, the writer has joined in the frequently-voiced comment that the Casagrande classification is not easily adapted to subdivision. In discussing possible expansion of the system in Section 14 of the paper, the author offers a scheme of subdivision, partly by the addition of new groups

(GU, SU, KL, KI, and KH) and partly by refinement using boundary groups (GW–SW, GC–SC, and so on) and by use of subscripts m, c, u, w, and p. When subdivision is practiced, it is preferably accomplished by refinement, rather than by addition, because the latter makes less feasible any later attempts at correlating data gathered prior to expanding a classification system by addition. The proposed expansion of the Casagrande classification to represent a soil as $GF_m - S_wF_c$ (to give, possibly, an extreme case with the binder near the boundary between plastic and nonplastic) would seem to indicate (by its complexity) the difficulties of subdivision.

In respect to requirement C, for determination by visual examination, the Casagrande classification is one of the best, and the author's methods for field identification of fine-grained soils in Section 13 of the paper are worthy of widespread application. However, for checking between different laboratories, it is desirable to have numerical limits for the results of usual classification tests, without the necessity of transmitting a sample for examination. Such limits are also of considerable value for checking classification of a soil by tests, especially in the case of an inexperienced classifier. For fine-grained soils, the Casagrande classification provides such limits, but only to a minor degree for coarse-grained soils.

A good feature of the Casagrande classification is the use of a simple system of notation for boring drawings (requirement D), unless it is complicated by the aforementioned scheme of subdivision. Possibly the best of the simpler systems yet devised for registering quickly in the mind is the system of rectangular and diagonal hatching usually applied with the triangle classification in Fig. 3(*b*), in which heavy symbols indicate the predominant fractions, and lighter symbols denote the two minor fractions of the three main grain-size fractions (48). However, the drafting cost required for suitable reduction is so much greater for this system of hatching (generally requiring inked tracings) that it more than offsets the advantage of quick registering.

QPC Classification.—These difficulties experienced in applying the Casagrande classification, and the greater limitations of the other systems discussed by the author, have led the writer to seek a combination of the better features of several systems. Since 1943, the result has gradually evolved into a combination of soil names from the descriptive classification; a gradation identification from the master curve system started on Quabbin Dam in Massachusetts by Karl R. Kennison and Stanley M. Dore, Members, ASCE (7), and expanded by Frank E. Fahlquist, M. ASCE, and Waldo I. Kenerson into the Providence classification (8); and the plasticity characteristics of the Casagrande classification. The combination, in these three parts, has been tentatively termed the QPC classification after its principal sources (Quabbin, Providence, and Casagrande).

Part 1. Name of Soil Type.—This consists of a soil name, generally with one modifying adjective, selected primarily to describe soil type and behavior rather than gradation. It is chosen from visual examination (preferably on a moist sample) to agree with local semitechnical usage by engineers, geologists, contractors, and courts.

Examples of Soil Names.—The following are typical examples of names, used as applicable to local conditions, with additions as necessary.

Material	Description
Gravel	Variably graded combination of pebbles and sand, sometimes including some silt and clay. Coarser particles, from 6 in. to ⅛ in., at least partly rounded from fluvial action.
Sand	Uniformly graded, bulk of material smaller than ⅛ in., individual particles readily visible to the naked eye.
Silt	Fine grained, lacking plasticity, little or no cohesion when dried, majority of individual grains not visible to the naked eye. Shaking test shows quick or "livery" condition.
Clay	Fine grained, plastic, and cohesive, strong when dried.
Till	Variably graded, unsorted glacial deposit, characterized by angularity of coarser fragments, generally very compact. Indicate whether cohesive or cohesionless (dependent on character of fines).
Loess	Unstratified aeolian deposit, homogeneous powdery soil of silt sizes, structure loose and inclined toward vertical cleavage.
Varved Clay	Alternating thin beds of clay and silt, interstratified, clay-like behavior.
Gumbo	Highly plastic clay, extremely sticky when wet, often a product of weathered shale (localized term).
Talus	Variably sized angular rock fragments, fallen to base of slope, voids seldom all filled.
Decomposed Rock	Structure preserved in place, but chemically disintegrated to soil sizes (with bonding largely destroyed). Also include name of rock.
Coral Sand	Ground-up coral.
Blow Sand (Dune Sand)	Wind-borne, free-moving sand, particles at least partly rounded.
Buckshot Clay	Compact clay, persistently breaking into uniformly small-sized fragments (localized term).
Diatomaceous Earth	Siliceous soil composed chiefly of skeletons of minute organisms.
Topsoil	Weathered surface soil containing organic matter, usually supporting vegetation. Termed loam in some regions.

Examples of Stratum Names Where Grain-Size Number Not Applicable.—

Material	Description
Peat	Partly carbonized vegetable matter, odoriferous, and fibrous. Swamp deposit.
Fill	A man-made deposit. Describe constituents, as cinder fill, rubbish fill, sawdust, ashes, cans, bricks, broken concrete, and so on. Grain-size number used only when soil a major constituent, or when knowledge of gradation desirable, as with slag, cinders, or earth fill.

Examples of Modifying Adjectives.—As frequently used on graphic abstracts of boring logs:

Coarse
Medium
Fine

Gravelly
Sandy
Silty
Clayey

Organic
Micaceous
Cemented

Kaolinitic
Bentonitic
Carbonaceous
Calcareous

Fat } Applied to Clays
Lean }

Generally not more than one adjective is used to supplement the soil name on graphic abstract logs and it is omitted when not particularly significant.

The system is flexible in allowing for the addition of terms of particular regional significance and certain geologic terms well characterizing soil behavior. Devices for obtaining a soil name, such as a classification triangle, have been purposely omitted in order to avoid classification by rote, and its resultant misleading information. For selection of the soil name, guidance of geologic training is helpful; and, for an inexperienced classifier, it might be advisable to add a few remarks to the foregoing definitions to cover behavior similar to those given by H. A. Mohr (23).

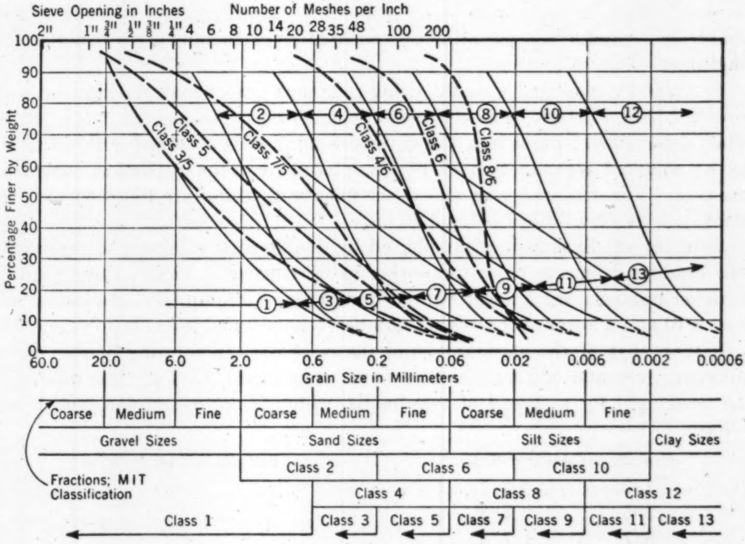

FIG. 8.—LIMITS OF GRAIN-SIZE NUMBER CLASSES

Part 2A. Grain-Size Number.—Part 2A consists of a grain-size number representing position and shape of the entire gradation curve. Thirteen basic classes are recognized as defined by the master curve bands in Fig. 8. Even numbers indicate predominantly uniform gradation; odd numbers indicate predominantly variable gradation.

When a word description is advisable for those unaccustomed to thinking in terms of gradation curves, the thirteen basic classes are defined as follows:

Class	Description of Gradation
1	Graded from gravel to coarse sand sizes with little medium sand.
2	Coarse to medium sand sizes with little gravel and fine sand.
3	Graded from gravel to medium sand sizes with little fine sand.
4	Medium to fine sand sizes with little coarse sand and coarse silt.
5	Graded from gravel to fine-sand sizes with little coarse silt.
6	Fine sand to coarse silt sizes with little medium sand and medium silt.
7	Graded from gravel to coarse silt sizes with little medium silt.
8	Coarse to medium silt sizes with little fine sand and fine silt.
9	Graded from gravel or coarse sand to medium silt sizes with little fine silt.
10	Medium to fine silt sizes with little coarse silt and clay.
11	Graded from gravel or coarse sand to fine silt sizes with little clay.
12	Fine silt to clay sizes with little medium silt and fine clay.
13	Graded from coarse sand to clay sizes with little fine clay.

In these descriptions the terms designate size fractions of the M.I.T. classification. A much better system would be the eventual acceptance of other terms for the size fractions which would not conflict with "gravel," "sand," "silt," and "clay," as soil types. Names from a dead language such as Latin, or the use of Greek letters might be acceptable, or possibly terms such as "coarse," "fines," "superfines," and "colloida." However, any possible terms would need careful consideration for correlation with languages other than English.

Samples are classified visually, using reference jars of materials graded according to the thirteen basic classes, supplemented by occasional check tests. When determined from a test, the grain-size number is obtained with a transparent celluloid reproduction of Fig. 8, placed over the gradation curve in question. For distinguishing visual classifications, these are followed by the letter "v," as "4 v," "7/9 v," and so on.

Primary subdivision is accomplished by double class numbers to represent soils grading from one band to another as illustrated in Fig. 8, thus: "8/6." A higher number over a lower number indicates a more uniform gradation (as class 8/6) and a lower over a higher number a more variable gradation (as class 4/6) than that of the standard band (as class 6). In forming double class numbers, even and odd numbers are never combined. Double class numbers are recognized for a spread of two bands, which is quite common, and is as follows:

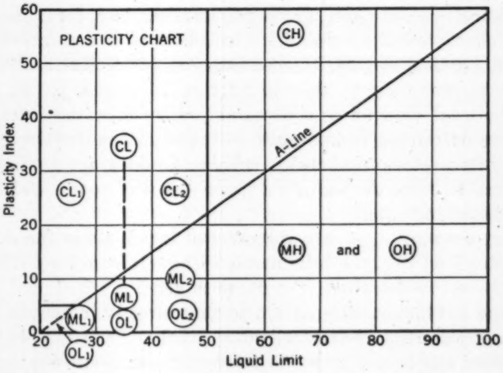
Basically variable gradation		Basically uniform gradation	
1/3	3/1	2/4	4/2
3/5	5/3	4/6	6/4
5/7	7/5	6/8	8/6
7/9	9/7	8/10	10/8
9/11	11/9	10/12	12/10
11/13	13/11		

With this primary subdivision, the thirteen basic classes are expanded to thirty-five grain-size number classes which have been found to cover most needs of the several hundred thousand samples to which this system has been applied.

Rare cases of extremely variable soils grading over a wide range can be handled by recognizing a spread of three bands from lower to higher odd numbers: 3/7, 5/9, 7/11, and so on. However, it is not advisable to reverse this by recognizing a spread in odd numbers of three bands from higher to lower numbers, since the result is one of the uniform basic classes. Thus gradations would not be designated as 7/3 or 11/7; rather these would be noted as classes 2 and 4, respectively.

If further refinement is desired, it may be accomplished by a secondary subdivision to recognize border classes, although the writer has seldom considered this necessary. A border gradation may be defined as one lying near the boundary of two of the adjacent master bands in Fig. 8. Such a gradation is represented as class 4–6 to indicate gradation near the boundary between classes 4 and 6. Other than for attempting close refinement, border classes allow for cases of uncertainty in visual classification, as class 4–6 v.

TABLE 6.—Plasticity-Characteristics Symbols for Fine-Grained Soils with Little or No Coarse Aggregate



Low plasticity When subdivided: L_1 = slight plasticity L_2 = moderate plasticity	L	M C O	Behavior characteristics of silt Behavior characteristics of lean clay Organic content causing plasticity
High plasticity	H	M C O	Behavior characteristics of quite plastic silts, such as micaceous, diatomaceous, or elastic silts Behavior characteristics of fat clay Organic content causing high plasticity, such as organic clays

In such cases of uncertainty, the last number, as "6 v," is chosen as the more probable one. Then, for simplicity, combined class numbers (whether 4/6, 8/6, or 4–6) can always be considered from the standpoint that the last number (in this case, class 6) approximates the gradation—and conservatively so, because it indicates the range of finer sizes. Hence, the thirteen basic classes are the ones to be fixed in the mind. Once these are understood, combined class numbers are easily visualized as variations.

Part 2B. Plasticity Characteristics.—This phase consists of plasticity characteristics symbols taken from the Casagrande system and, likewise, applicable only to fine-grained soils with little or no coarse aggregate. The proper symbol is determined visually as described by the author; or, where Atterberg limit tests are conducted, it is determined from the plasticity chart in Fig. 4. In Table 6 this chart has been redrawn to follow the author's suggestion of dividing the L-group at a liquid limit of 35. However, the writer prefers to retain the original L-group as the simple form (requirement C) and to use the two subdivisions as the refined form designated by subscripts as shown in Table 6.

In application of the QPC system, classification is accomplished visually by examining moist samples—for fine-grained soils, employing the shaking test and examination of plasticity characteristics as the author describes (under the heading, "13. Field Identification of Fine-Grained Soils"). Laboratory tests are employed only when the classifier feels uncertain, or for purposes of checking, or for training an inexperienced classifier.

Boring logs include soil name, grain-size number, and, for a fine-grained soil, the plasticity-characteristics symbol. Also included is a complete description covering color, particle angularity, consistency, plasticity, and dry strength. Such description is similar to that in Section 15 of the paper, except that, considering the legal viewpoint, the writer prefers to avoid interpretation by using adjectives describing compactness. Instead, it is preferred to give basic data without interpretation wherever such basic data are available, as blows per foot required to drive the sampling spoon (sizes of spoon and hammer, and height of fall being indicated).

On contract drawings, graphic abstracts of logs include the symbols aforementioned under Part 2, plus a brief name of the soil from Part 1 for the benefit of bidders. On study drawings, the name is generally included only when it would add some significant information to that already indicated by the grain-size number and plasticity-characteristics symbol. The simpler form (requirement C) includes soil names plus the thirteen basic grain-size number classes with only limited use of border classes. The refined form includes soil names plus grain-size numbers from the thirteen basic classes and from the primary subdivision if applicable, plus plasticity-characteristics symbols.

Summary.—In addition to reasonably satisfying requirements A to D, the features of the QPC system have been demonstrated to be sound from considerable experience with many types of work—airports, highways, dams, levees, and foundations. The use of soil names in Part 1 of this classification follows the oldest system—the descriptive classification. The grain-size numbers (Part 2A) have been used since 1937 with soils from New England to the Gulf Coast, and have been recommended by Joel D. Justin, M. ASCE (49), as well as by others who have given this system a serious trial. As a part of the Casagrande system, the plasticity-characteristics symbols (Part 2B) have been used intensively in airport construction since 1942, and are based on data collected by the author over a much longer period. Taken together, these three phases of the QPC system reasonably cover the results of classification tests for gradation, Atterberg limits, and organic content. For judging the major soil properties, these three classification tests are considered the best currently available when used in conjunction with information on the grain shape and mineral composition. Although additional symbols could be added to cover the last two factors, the writer feels that this can be handled adequately by proper choice of the soil name.

The author is to be congratulated for the excellence of his critical review of the various classification systems, and for devising a classification which is a decided improvement over prior systems. If, from his efforts and those of others, the profession eventually succeeds in evolving a truly adequate system of soil classification, that would, indeed, be a forward step.

GEORGE F. SOWERS,[10] JUN. ASCE.—The purpose of a classification is to make it possible for materials which have similar characteristics to be considered and treated as a group. Those characteristics of immediate interest determine the grouping and the boundaries of the groups. The Airfield Classification (AC) System classifies soils by solid ingredients. Soils whose grains are coarser than 0.1 mm are classified by grain size and grain-size distribution; soils finer than 0.1 mm are classified by the liquid limit and plastic index. These properties serve as guides to the capabilities of the soil as an airfield subgrade, but they may be misleading in other applications, as implied by the author in the "Introduction."

Two properties closely linked with the performance of the soil as a foundation material are not considered in the AC system. These are the water content and the consistency. A soft clay of low "plasticity" may be a worse foundation material than a hard, dried-out clay of high "plasticity." A highly plastic clay is not highly compressible unless it has a high water content. Although the author stresses this fact when he states that compressibility must be compared at the same preconsolidation loads, further qualification should be made. Compressibility is dependent on water content; to ignore this in classification may lead to trouble. The meaning of the terms plasticity and consistency are often confused, and the inclusion of the one factor and the exclusion of the other in the AC system might make the situation worse. To a soils engineer, plasticity refers to the range in water content through which the soil is in a plastic state. However, many engineers and especially contractors and drillers use "plastic clay" to mean just what the name implies—clay in a soft or plastic state. To the man who has to dig the soil, or to build on it, the important point is the consistency of the soil, or its water content with regard to its plastic range. Ignoring these points may be dangerous, especially in the light of the confused terminology.

The greatest difficulty with all classifications is the fact that the soils are grouped according to laboratory tests. The nature of the soil deposit is usually given only secondary consideration, although it is often extremely important. For example, a varved clay consisting of alternate layers of silt and clay probably would be tested in the laboratory as a mixture of both. The classification tests might reveal a sandy or silty clay (perhaps CL) whereas the actual deposit may exhibit entirely different characteristics. Glacial deposits with erratic inclusions of clay, silt, and gravel defy simple classification; their variations in structure are far more important that the characteristics of each individual material.

---

[10] Asst. Prof., Civ. Eng., Georgia School of Technology, Atlanta, Ga.

Loess soils, which cover large areas in the Mississippi Valley, are as hard as concrete in their dry state, but are soft when saturated. These cannot adequately fit into any system of classification that depends on the index tests of soil solids in a disturbed condition. The same holds true for cemented soils, such as the red sands of the south and southwest. The density of natural sand deposits may be more important than the size or size distribution of the grains, and the presence of water only complicates the possibilities.

The discussion of the uses and of the limitations of soil classification systems by the author in the "Introduction" is a sensible approach to this problem. In order to reduce the soil groups to a finite number, many important characteristics must be ignored. Special classifications, such as the AC system applied to airfields, serve an important purpose, but their limitations should be clearly understood. Too often a classification such as this, coupled with such tabulations as Table 4, give some technicians a false sense of security.

The descriptive system in Section 15 has none of these defects because the descriptive terms can be modified to suit conditions at hand. The greatest difficulty with such a classification is a lack of standard terminology. This obstacle need not be condemnatory, for it has been encountered in other fields, such as meteorology and mineralogy. In Section 15, various degrees of each characteristic in the list of descriptive adjectives (as applied to soils, covering such points as consistency, plasticity, and gradation) could be indicated by numbers, similar to Moh's scale of mineral hardness, or to Beaufort's scale of winds. The degrees should be few so as to be distinguishable through the field tests and through the hand identification methods described in the paper, and they should be standardized by appropriate laboratory tests.

The author's plasticity chart (Fig. 4) would be well suited to standardizing the plasticity and the potential compressibility of the fine-grained soils. Consistency could be defined by the unconfined compressive strength as suggested by K. Terzaghi, M. ASCE. On the other hand, engineers are at such great odds as to the meaning of "silt" and "clay" that it probably will be better to use these terms only in a qualitative sense.

In the application of the descriptive method, both the trained soils specialist and the design engineer will have a better picture of the important characteristics of the soil, unhampered by insertion into limited pigeonholes. As Professor Casagrande points out in the "Introduction," "Those who really understand soils can, and often do, apply soil mechanics without any formally accepted classification."

René S. Pulido y Morales,[11] **Esq.**—The subject of soil classification, as stated by the author, is the most confused chapter in the study of soil mechanics. Most people believe erroneously that any soils classification can be used indiscriminately. In order to be successful, the classification must be in accord with the physical properties so that, by using the identification tests, the two most important requisites of compaction and plasticity can be found. It is necessary to know the specific gravity, apparent specific gravity, water content, mechanical analysis, Atterberg limits, and even the elementary chemical tests, so as to establish a relation between the compaction of the soil and the load applied to it.

---

[11] Chf. Engr., Soil Laboratory, Public Works Ministry, Havana, Cuba.

A knowledge of these properties is important, but one must also study the performance of each soil within a given profile for similar work in other places (highways, foundations, dams, and others) so that, once the relations between the tests and their performance are established, the soils can be classified as types.

The research required to correlate the tests with the performance of the finished works can be obtained only after long periods of time. After the completion of a project the tests can be correlated with experience only by extensive research. The first and most important characteristic to be determined is cohesion, which is a function of the resistance of a soil to consolidation. Therefore, it is necessary, and most important, to include the consolidation test in the research program. The granulometric test is also important, and it must be taken into account as well as a measure of the structure as an index type.

The disintegration of igneous rocks will be more or less in an advanced state if the percentage of fine particles is more or less high. Hence, the result of the disintegration state may be determined by the granulometric curve, which is concave upward if the state is advanced, and downward if it proceeds gently. Intermediate grades are represented by a straight line.

The Public Roads (PR) classification has been used to classify for soils for highways. One of the uncertainties of this system is in group A-4 (Table 3), in which, frequently, one finds silty clays with high capillarity; but this is not the general case since silty clays and silty loams, with little cohesion and low capillarity, are also found. Another uncertainty occurs in the elimination of the material retained in the 40-mesh sieve for the determination of the physical properties and also in the exclusion of the physical determinations of the state of compaction of the soil.

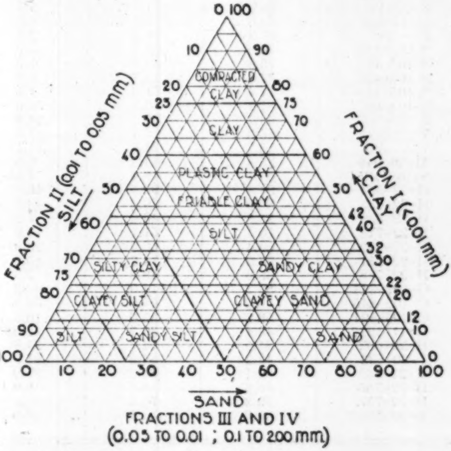


Fig. 9.—Classification by Swiss Engineers

The author reviews many systems of soils classification with great success. The trilinear graphs in Fig. 3 find an interesting comparison in the textural classification of Swiss engineers (50) as illustrated by Fig. 9.

The latest modification of the PR classification, presented for the Highway Research Board to its Committee on Classification of Materials for Subgrades and Granular Type Road (51), is probably the best tool yet devised for the highway engineers. This system eliminates overlapping, subdivides several groups, and introduces the "group index" which is very useful for evaluating the soil within a given group.

In this new classification the silty clay (group A-4 in the previous PR system) has been made A-6, limiting group A-4 to silty materials. The indeterminancy of the previous system has been eliminated by inserting other subgroups.

It is difficult to discuss soil classification for highway engineering purposes without mentioning the California Bearing Ratio (Porter method). This system provides the best way to determine the soil properties for a definite project and, with the help of the modified PR classification, is the more logical method. Table 7 is an example of some soils tests, made by the writer at the Soil Laboratory of the Public Works Department in Havana, Cuba, which have been classified under the PR and the modified PR classification (51) for comparison and also to show the "group index."

In conclusion the writer wishes to congratulate Professor Casagrande on his clear presentation of this soil classification, a problem that is sorely in need of international standardization.

Raymond F. Dawson,[12] M. ASCE.—A stimulating review of the various soil classification systems which have been used is presented in this paper. A new method of classification is also described which will be a real help to engineers working with soils; but, equally important, Professor Casagrande emphasizes the limitations of any soil classification system. Regardless of these cautions many engineers will adopt or continue to use a single classification system for all types of earthwork, and sooner or later this practice will cause difficulty.

A review of the soil investigations published since 1917 reveals an amazing number of classification triangles that have been proposed. It appears that every investigator wished to insure his name for posterity by attaching it to a classification triangle. Actually, these men were attempting to determine all the soils characteristics from the classification triangle, and this was impossible. Instead of seeking new information they continued to juggle old charts, looking for a combination that would be the panacea.

Not until the Atterberg limits were included in the criteria was any real progress made in the classification of soils for engineering purposes. One of the first schemes using the Atterberg limits was the Public Road (PR) classification system, of which the author correctly states (in Section 6): "This classification, therefore, is essentially a grouping applicable to the use of soil in a road surface or as a base beneath a thin bituminous wearing surface." Regardless of this limitation, highway engineers continually use the PR classification system for all types of earthwork construction. Sometime ago, an engineer called the writer's attention to a paper describing a construction method using an A-7 soil in a northern state. He said, "They cannot use that procedure with an A-7 soil; I know, because we tried it." Thereupon he visited the project and found that they were using the method as described. The soil in the northern state had a liquid limit of 42 and a plasticity index of 25, whereas the Texas soil had a liquid limit of 86 and a plasticity index of 50. Both soils were classified as A-7 by the PR system; however, they were two entirely different materials for the construction involved.

The author's Airfield Classification (AC) System is a forward step in the classification of soils for use as subgrades of pavements in airports and similar structures. The AC system will undoubtedly be the standard of classification for subgrade soils in airfield construction.

Another subgrade classification system (51) uses the group index which utilizes both the grading and the Atterberg limits of the soil. To the writer, the group index appears to offer a valuable classification system, although he is of the opinion that modifications of the limit ranges may be necessary. It will be interesting to have the author's discussion of the group index system.

---

[12] Associate Prof., Civ. Eng.; Associate Director, Bureau of Eng. Research, The Univ. of Texas, Austin, Tex.

Professor Casagrande comments (in Section 10) that "Experience has proved that the liquid limit is a good measure of relative compressibility." It is of considerable importance, and further discussion of this statement is desirable.

Engineers must be cautious, or they may be misled by local terminology in describing soil formations. In the Texas gulf coast area, old-time drilling operators call the first clay stratum beneath a sand stratum a "shale" regardless of how soft it may be. Under such conditions the engineer who is unfamiliar with these colloquialisms and who does not examine the cores may not be aware of a serious condition that exists.

D. F. Glynn,[13] Jun. ASCE.—Since a soils classification provides a uniform standard of nomenclature for field identification and for condensing engineering experience with soils, the confusion reviewed by Professor Casagrande's paper is most disturbing. Thus, immediate considerations arising from it concern: "What order could be produced in the existing position?" and "which of the systems described are suitable for incorporation in a coordinated classification?"

Any comprehensive standard classification system would have to meet the needs of agricultural scientists and geologists in addition to civil engineers. Any single system, sufficiently comprehensive to cover all these different interests, would probably be too complex for convenient use. An alternative would be the adoption of a multistage system, the first stage being a simplified field identification and the second a series of detailed functional classifications for each profession. If these were kept as simple logical systems they would form the uniform standards and allow sections with special interests to formulate additional stages to cover their own local interests. It would appear from Professor Casagrande's description that agricultural scientists and geologists already have functional classifications that meet their requirements. Thus the problem is reduced to providing a uniform field identification for general use and to formulating a standard engineering classification.

For a uniform system of field identification, a modified descriptive soil classification would seem very attractive. As a result of wartime cooperation by engineers, geologists, and agricultural scientists in the Southwest Pacific Theater, such a system has already been widely adopted in Australia. This system has sufficiently standardized soil terminology to avoid the disadvantage referred to by Professor Casagrande. It is essentially a field identification system, however, and the ultimate test of the description of any soil is the majority verdict of the experienced field surveyors. In order to keep such opinions up to date and uniform, periodic conferences are held, to which all interested persons are invited. Thus, the formal descriptive standards for adjectives and soil textures are subordinate to field usage and are periodically amended where necessary (52).

An alternative to this simple descriptive standard would be the field identification system based on the Airfield Classification (AC) System. It is difficult for anyone who has not served an apprenticeship with this system to assess its value in practice. Nevertheless, it would seem more complex and less flexible than the simpler descriptive type of classification. As such, it would probably be much harder to reach an international agreement on the basis of this system than with the more widely accepted descriptive classification.

---

[13] Superv. Engr., Soils and Hydr. Testing, Melbourne and Met. Board of Works, Melbourne, Australia.

As a functional engineering classification, the Texas and Civil Aeronautics Administration (CAA) systems would appear too limited in their acceptance. The Public Roads (PR) system is widely used by highway engineers, but in addition to Professor Casagrande's criticism as to the difficulty in keeping abreast of the latest "edition," its basic structure is too closely tied to highway requirements to be a good general system.

From its first appearance in Australia in 1943 the AC system has been regarded by many soils engineers as the most suitable general system. After use by the Corps of Engineers, United States Army, it is probably the most widely adopted of all systems. For these reasons the most recent revision and the discussion on the soils of the various groups are extremely welcome. It impresses one as being simple and easily understood and as following logically from the simpler field description. The principal objection offered in Australia has been due to the lack of definition in the group boundaries. It is suggested, however, that this may be a distinct advantage in that it prevents indiscriminate use by people who have no knowledge of the significance of soil test results.

If the AC system could be accepted as the basic classification to be used for samples, selected from the results of simple descriptive field mapping, it is suggested that the proposed further subdivision of classes should be limited to special applications. The general system, summarized in Fig. 4, would appear sufficient for general use and more detailed subdivision might lead to unnecessary confusion.

Another feature referred to by Professor Casagrande, the grain-size scale, might be also amended to achieve greater uniformity. In Australia an increasing number of laboratories have reverted to the international standard. At a conference of regional officers of the Division of Soils, Council for Scientific and Industrial Research, at Adelaide, Australia, in September, 1946, the sand-silt size boundary of 0.02 mm was discussed (52), in the light of the proposal by R. Glossop and A. W. Skempton (5). Although no change was recommended, it is believed that change to 0.05 mm or 0.06 mm would be readily accepted if sufficiently valid reasons could be offered. On other hand, it is understood that the United States Department of Agriculture is by no means irrevocably committed to 0.05 mm. The time would thus seem ripe for discussion to achieve uniformity on at least this one point.

In view of the proposed international soil conference in Holland, Professor Casagrande's able summary of the present soils classifications is most timely. It is to be hoped that this favorable opportunity for using Professor Casagrande's wide experience in soils mechanics, soils classification, and international cooperation with engineers will not be allowed to pass.

In conclusion, it is desired to thank Professor Casagrande for the comprehensive review of the present state of soils classification and particularly for his discussion on the AC system.

L. F. Cooling,[14] Esq., A. W. Skempton,[15] Esq., and R. Glossop,[16] Esq.—One of the most important, present needs in applied soil mechanics is for a universal acceptance of at least some broad general classification of soils, and in his paper Professor Casagrande has done much to clarify the position in a field where there is admittedly much confusion. The writers met the difficulties involved in this problem a few years ago when they were engaged in preparing drafts for a British code of practice on site investigations. It was soon realized, as stated by the author, that it is not possible to classify all soils into a relatively small number of groups in such a way that the system would adequately meet the requirements of the many divergent problems of applied soil mechanics. However, it was felt that it would be desirable first to adopt a broad classification which would serve as a basis from which, by expansion and amplification within the original framework, the more detailed and specific classification systems required for various practical problems could be built up. For this reason, the approach was to formulate a general basis for the field identification and classification of soils using a system similar to that presented by the author in Section 15. It was considered sufficient for this purpose to take into account two essential characteristics—the size and nature of the particles composing the soil and the strength and structural features of the soil as it exists in the ground. The type of general arrangement suggested is indicated in Table 8.

Six principal types are recognized on the basis of the size and nature of the particles (Col. 1, Table 8), and the simple tests by which these types are distinguished in the field (Col. 2, Table 8) are similar to those described by the author. In this connection the term "dilatancy" corresponds to the property described by the author under "shaking test."

The subdivision of the uniform, well-sorted sands into coarse, medium, and fine is perhaps an elaboration, but it can be readily made and, since the subdivisions can often be associated with important changes in engineering properties, has much to commend it. The division of clays into "lean" and "fat" can be made on the basis of the extent to which the soil exhibits the typical colloidal properties of plasticity, cohesion, and shrinkage. Col. 3, Table 8, gives the more important types of composite soils. These are primarily natural mixtures of two or more of the principal soil types, but mineralogical variations which have an important influence on the soil properties (mica, organic matter, and calcareous material) are also recognized.

Cols. 4 and 5, Table 8, are concerned with the "in-situ" strength and structural characteristics. Since, in most engineering problems, the strength or density of the soil in its natural condition is of controlling importance and since, similarly, the structural features of the deposit (such as laminations and fissures) can be very significant, the writers would stress the importance of their inclusion in any basic classification.

Finally, the color of the soil should be stated since this often has local significance and is helpful for identification. From the terms defined in Table 8, therefore, it is possible to give a fairly accurate picture of a particular soil in a manner that could be generally recognized. The author's suggestion, that with fine-grained soils a note on the effect of remolding should also be included, is a valuable one.

[14] In Chg. of Soil Mechanics Div., Bldg. Research Station, Watford, England.

[15] Reader in Soil Mechanics, Univ. of London, London, England.

[16] Engr., Messrs. John Mowlem and Co., London, England.

The writers attach particular significance to the strength classification of clays in all problems except those concerned with near-surface soils, and it would be appreciated if the author would give his opinion on this question. The grouping suggested in Table 8 is based largely on the Boston Building Code with an additional class at each end of the scale. These descriptive terms are implicitly connected with shear strength and, within the writers' experience, they are roughly related in the following manner:

Class	Unconfined compression strength (lb per sq in.)
Very soft	<5
Soft	5 to 10
Firm	10 to 20
Stiff	20 to 40
Hard	>40

From this relation it is possible to develop more specialized classifications for such purposes as foundation bearing capacities and earth pressures.

In cases of near-surface soils and soils used for constructional purposes when the "in-situ" properties are likely to be drastically changed, it is agreed that a classification system leaning more heavily on the composition of the soil is required. Consequently, for site investigations in relation to roads and airfields, the Airfield Classification (AC) System, adopted in 1942 by the United States Engineer Department, was recommended in the aforementioned code of practice.

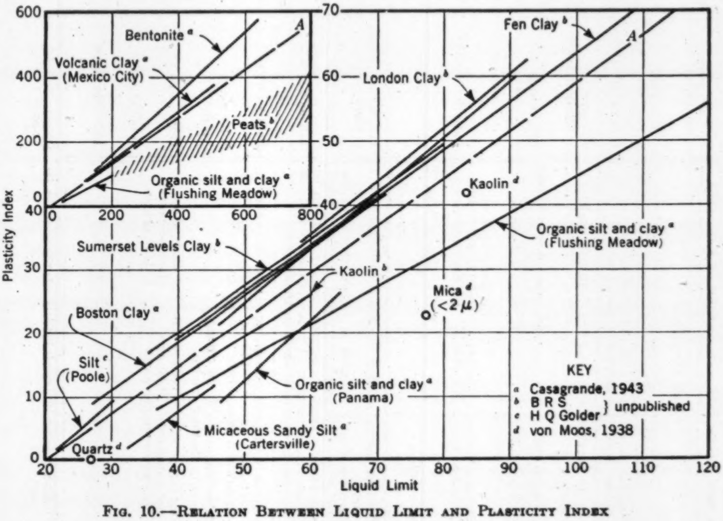

Fig. 10.—Relation Between Liquid Limit and Plasticity Index

TABLE 8.—General Basis for Field Identification and Classification of Soils

Principal Soil Types; Size and Nature of Particles			Composite types	Strength Characteristics		Structural Characteristics	
Divisions (1)	Types (2)	Field identification (3)	(4)	Term (5)	Field test (6)	Term (7)	Field identification (8)
Coarse grained, noncohesive	Stones	Boulders; larger than 8 in. in diameter. Cobbles; mostly between 8 in. and 3 in.	Boulder gravels	Loose	Can be excavated with spade. 2-in. wooden peg can be easily driven.	Homogeneous	Deposit consisting essentially of one type.
	Gravels	Mostly between 3 in. and No. 7 British Standard sieve.	Hoggin[a] sandy gravels				
	Sands	Particles mostly between Nos. 7 and 200 British Standard sieves. Particles visible to naked eye. No cohesion when dry. Uniform Graded Coarse—between Nos. 7 and 25 British Standard sieves. Medium—between Nos. 25 and 72 British Standard sieves. Fine—between Nos. 72 and 200 British Standard sieves.	Silty sands Micaceous sands Lateritic sands Clayey sands	Compact Slightly cemented	Requires pick for excavation. 2-in. wooden peg hard to drive more than few inches. Visual examination. Pick removes soil in lumps which can be abraded with thumb.	Stratified	Alternating layers of varying types.
Fine grained, cohesive	Silts	Particles mostly passing No. 200 British Standard sieve. Particles mostly invisible or barely visible to the naked eye. Some plasticity and exhibits marked dilatancy. Dries moderately quickly and can be dusted off the fingers. Dry lumps possess cohesion but can be powdered easily in the fingers.	Loams (silt, sand, clay) Organic silts Micaceous silts	Soft Firm	Easily molded in fingers. Can be molded by strong pressure in the fingers.	Homogeneous Stratified	Deposit consisting essentially of one type. Alternating layers of varying types.
	Clays	Smooth touch and plastic, no dilatancy. Sticks to the fingers and dries slowly. Shrinks appreciably on drying, usually showing cracks. Dry lumps can be broken but not powdered. They also disintegrate under water Lean clays show these properties to low degree. Fat clays show these properties to high degree.	Sandy clays Silty clays Marls[b] Organic clays Boulder clays Lateritic clays	Very soft Soft Firm Stiff Hard	Exudes between fingers when squeezed in fist. Easily molded in fingers. Can be molded by strong pressure in the fingers. Cannot be molded in fingers Brittle or very tough.	Fissured Intact Homogeneous Stratified Weathered	Breaks into polyhedral fragments along fissure planes. No fissures. Deposits consisting essentially of one type. Alternating layers of varying types. If layers are thin the soil may be described as laminated. Usually exhibits crumb or columnar structure.
Organic	Peats	Fibrous organic material, usually brown or black in color.	Sandy, silty or clayey peats.	Firm Spongy	Fibers compressed together. Very compressible and open structure.	....	....

[a] Hoggin: Sandy gravel with small admixture of clay. [b] Marl: Calcareous clay.

However, it was considered that this classification system could be legitimately regarded as a development and expansion of the basic descriptive soil classification and that it was in the same category as others designed for special engineering purposes, such as foundation bearing capacities, limits of the applicability of various geotechnical processes (5*a*), and so on.

The author's discussion on the properties of fine-grained soils and their field identification is a valuable contribution to the subject. His method of using the liquid and plastic limit values for soil identification by use of the plasticity chart has been followed with interest in Great Britain, and Fig. 10 summarizes results on typical British soils.

A further relationship for fine-grained soils, which seems to the writers to be significant, is that between the liquid limit and the percentage clay fraction—that is, the proportion of particles of a size less than $2\ \mu$. For samples from a given deposit the liquid limit increases with percentage clay fraction and the relation for some typical British soils is given in Fig. 11. Most clays fall within the zone marked "normal clays." However, the kaolins and boulder clays show quite low liquid limits even for fairly high clay contents. This is probably explained by the "inactive" nature of kaolinite compared with the minerals in most clays and by the fact that the particles of the boulder clay have been produced by mechanical comminution and not by weathering. On the other hand, some of the highly weathered clays and organic muds show a high liquid limit even with a comparatively small percentage clay fraction. This may be indicative of a more than usually "active" clay mineral or the presence of unusually fine particles in the clay fraction or, more probably, of a combination of these two effects. In this connection it is interesting to note that the alluvial clay of the River Lea in England has been derived largely from the weathering of the London clay, itself a fairly fat clay, being the product of the weathering and transport of the soil mantle in Eocene times. The indication of the "quality" of the clay fraction which this relationship reveals is considered helpful in assessing the probable characteristics of the soil. As a matter of interest the relationship for seven of the soils given by the author in Table 1, Section 3 are plotted as spot points in Fig. 11. The results agree with the characteristics described with the exception of the diatomaceous earth (No. 5) which, the author states, shows little plasticity although its plasticity index is 42. It would be of interest to know if the diatomaceous earth behaves in an anomalous manner in other respects.

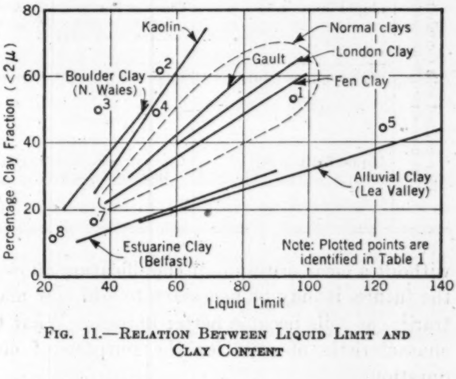

FIG. 11.—RELATION BETWEEN LIQUID LIMIT AND CLAY CONTENT

Milton Vargas,[17] **Jun. ASCE.**—In Section 1 (under the heading, "Development of Systems") Professor Casagrande states that "* * * soil classifications used in civil engineering reflect in their chronological order the development of soil mechanics." This is likewise true of other sciences. Classification systems only reach perfection when the corresponding sciences reach a certain final stage of equilibrium. The existence and success of the Airfield Classification (AC) System shows that this final stage, in the case of soil mechanics, is already in sight.

However, there are some points where explanations are needed. First, in order to be considered perfect, a classification system must be able to divide the things to be classified according to the fundamental characteristics that are significant for the entire class. The AC system begins classifying the soils into two major divisions, according to grain size—the first division referring to coarse-grained soils and the second to fine-grained soils. However, the author was compelled to add a third major division for fibrous organic soils which cannot be classified according to grain-size characteristics. This shows that grain size is a significant characteristic only for a certain class of soils and not generally for all soils. The existence of the third major division without a clear criterion of classification allows the engineer to expect that, in the future, it may be necessary to add new major divisions, more or less arbitrarily, as soils become better known. What then should be the most general characteristic of soils for the purpose of classification? That is an open question.

TABLE 9.—Suggested Subdivision of Soil Groups According to Mineralogical Composition.

1		2		3
Major divisions		Soils groups and subgroups and typical names		Group symbols
Fine-grained soils containing little or no coarse-grained material	Low to medium compressibility Liquid limit < 50	Silts and very fine sands, silty or clayey fine sands, silty clays, slight to low plasticity	Inorganic (except kaolin type)	ML
			Organic	OL
		Clays of low to medium plasticity, sandy clays, silty clays, lean clays	Inorganic (except kaolin type)	CL
			Kaolin type	KL
	High compressibility Liquid limit > 50	Fine sandy and silty soils, elastic silts	Micaceous Diatomaceous Others	MH
		Clays of medium to high plasticity, fat clays	Organic	OH
			Inorganic (except kaolin type)	CH
			Kaolin type	KH

Following the same line of thought, the adopted criterion for separating the major divisions into subdivisions (according to grain-size composition, in the case of coarse-grained soils, and compressibility, or value of liquid limit, in the case of fine-grained composition) appears to be excellent, and the inclusion of intermediate subdivisions among them would do no harm to the system. The same could be said of the groups that divide the major divisions of the coarse-grained soils. However, the groups of the two subdivisions for the fine-grained soils are separated according to two different criteria—grain size and organic matter content. If a new group for the kaolin-type clays is added, as suggested by the author, certainly a third criterion will be introduced—that is, the mineralogical composition.

---

[17] Chf., Soils and Foundations Div., Inst. for Technological Research, Sao Paulo, Brazil.

It would be much simpler, in any future expansion, if the two major divisions of the fine-grained soils were both subdivided into only two groups, that is, the silt group and the clay group, according to grain-size composition. These groups could then be divided into subgroups according to the mineralogical composition and organic matter content, as suggested in Table 9. The systematic framework of the AC system would thus be improved with practically no change. Thus, the way is open for future additions of new groups without the possibility of confusion.

Another requirement for a perfect classification system is that it be suitable for general use under different conditions. A good soil classification must be as useful for the design of airfields as for foundations or tunnels. The author appears to limit his classification system in referring to it as an Airfield Classification System. Its applicability seems to be very much wider.

In his paper the author does not explain whether the group symbols he proposes are intended to be simple initials of the group names, in order that the users may easily remember them, or whether his intentions were to propose symbols of world-wide significance for soils, in the way that chemical symbols represent the chemical elements. In the first case it would be logical that the group symbols should be changed in each language; on the other hand, in order to maintain the universal significance of the symbols they should not be translated. This would be really advantageous for the proper understanding of engineers all over the world—at least as far as soil properties are concerned. The fact that the group symbols are initials of English words would be no impediment when one realizes that the English language is as widely recognized today as Latin was in the days when botanic nomenclature or chemical symbols were established.

DONALD M. BURMISTER,[18] ASSOC. M. ASCE.—A worthwhile contribution to the engineering profession has been made in this critical review of the soil classification systems now in use and in the presentation of the Airfield Classification (AC) System, which served such a useful purpose in the work of the Corps of Engineers, United States Army, during World War II. It is significant that the AC system has been developed on the basis of the important behavior characteristics of soils, and therefore has a broader application than to airfield construction alone.

The greatest practical use of the AC system in the postwar period is in the preliminary exploration, design, and construction stages of projects involving earthwork and foundation problems, where the information obtained is put to immediate and practical use. Those engaged in the soil engineering work on a given project become intimately familiar with the class designations and symbols of the different classes of soils encountered, and they are able to infer accurately the general qualities and behavior characteristics. The group symbols become a convenient tool and expedite the work wherever a large number of samples must be examined and identified. The author has properly warned against the abuse of classification symbols wherein only the group symbol is given without more specific information. Use of symbols alone short-circuits the process and assumes the triple role of identification, description, and classification. After a lapse of some time following the completion of a project such a classification of the soils encountered on a project inevitably becomes more and more vague and less significant as to the actual character and behavior of the soils, because symbols or class designations can never convey a sufficiently precise meaning.

---

[18] Associate Prof. of Civ. Eng., Columbia Univ., New York, N. Y.

For all permanent records of an organization engaged in soil engineering work, as well as for presentation of information in papers and articles in the technical journals, the more precise and significant descriptive classification, such as that discussed by the author, should be used so as to convey a definite meaning to those who have not had the benefit of examining and working with the soils firsthand. The greatest field of progress in soil engineering lies in the accumulation of detailed, accurate information on the physical character and properties of soils and on their behavior under the varied conditions encountered in practice. Thus, a body of authoritative knowledge on soil behavior, which would be of great practical value and use, can be built up, not only in a given organization but also for the profession as a whole. Therefore, in the interest of greatest progress in soil engineering, and of maximum usefulness of data on soil behavior, greater emphasis should be placed on the development and continued use of thoroughness in examining, identifying, and describing soils. These considerations far outweigh any consideration of convenience.

In order to satisfy these essential requirements and needs in the postwar period the base of the AC system should be broadened to make the system more fundamental, and at the same time more precise and significant for all types of foundation and earthwork problems. There are two basic steps in such a process.

The first step is to come to some agreement on the definitions of soil components, which may find general acceptance and which may form a common basis for work in soil engineering. Recommendations have been presented by the Foundations and Soil Mechanics Committee, Civil Engineering Division, American Society for Engineering Education (A.S.E.E.), for the consideration of those interested in soil engineering work (24). These definitions are intended to define terms to be used in identifying and describing soils, and are not a textural classification. The following is quoted from the report of this committee:

> "The definitions of the principal soil components: GRAVEL, SAND, SILT, and CLAY should be based on significant criteria. From an engi-

neering point of view the primary difference between sand and gravel is the size of the constituent grains, which can be recognized visually. The primary differences between sand and silt are that the constituent particles of silt cannot be readily distinguished by the unaided eye and that silt exhibits considerable capillarity. The significant and distinctive difference between silt and clay is that clay exhibits plastic properties and silt does not. In the case of fine-grained soils containing clay the influence of grain size is dominated by the influence of mineralogical and chemical composition. Thus, gravel and sand should be defined on the basis of grain size; sand and silt should be defined on the basis of grain sizes and of capillarity; while silt and clay should be defined on the basis of plasticity. These universally comprehended terms form an adequate and satisfactory basis for the definitions of soil components."

In order to have a workable system of definitions for practical use, it was considered desirable by this committee to define the size limits of the principal soil components and of the coarse, medium, and fine fractions directly in terms of sieve sizes, which convey a definite idea of particle size. The term "CLAY–SOIL" is used instead of "CLAY" in order to be more precise in terminology, because the silt admixture cannot be separated out to determine the proportion of the true clay fraction. The A.S.E.E. recommended definitions are given in Table 10. [Capitalized terms, as "CLAY–SOIL," and soil names are given in quotation marks throughout this discussion to indicate that they are proposed special terminology for describing and naming soils.—Ed.]

TABLE 10.—American Society for Engineering Education Recommendations for Soil Components and Fractions

Principal components (1)	Description (2)	Sieve limit (3)	Sieve Sizes for Subcomponents		
			Coarse (4)	Medium (5)	Fine (6)
BOULDERS and ROCK[a]	Retained on 3-in. sieve	Lower	....	....	3 in.
GRAVEL and STONE[a]	Passes 3-in. sieve; retained on No. 10 sieve	Upper	3 in.	1 in.	⅜ in.
		Lower	1 in.	⅜ in.	No. 10
SAND	Passes No. 10 sieve; retained on No. 200 sieve	Upper	No. 10	No. 30	No. 60
		Lower	No. 30	No. 60	No. 200
SILT	Passes No. 200 sieve; nonplastic, little or no strength when air-dried	Upper	No. 200	....	....
CLAY–SOIL	Passes No. 200 sieve; exhibits plastic properties and clay qualities within a certain range of moisture content; considerable strength when air-dried	Upper	No. 200	....	....

[a] BOULDERS and GRAVEL refer to waterworn material; ROCK and STONE refer to angular fragments.

The second step is to establish a common language for description of soils so that the soils examined and identified can be properly named and described in simple engineering and technical terms. The author points out that at present there is no uniformity in the terms used to describe soils. The descriptive terms, however, should be sufficiently precise and accurate, and at the same time sufficiently flexible in nature, so that the entire range of natural soils can be readily described. The soil name should have a clear, well-defined meaning to enable people who have not had the benefit of examining the soils firsthand to readily understand and to interpret them. These descriptive terms should be suitable, not only for rapid field identification by visual and manual means, but also for the more detailed laboratory identification based on soil tests.

The descriptive terms shown in Table 11, which have been used and found to be satisfactory by the writer, are suggested. Such terms have been used to a considerable extent by field engineers and boring foremen, but without having the precise, well-defined meanings given in Table 11. Although natural soils are composite materials composed of various proportions of the principal soil components in almost infinite variety, recognizable proportions can be defined for practical use. Descriptions of typical soils are given at the end of this discussion to illustrate the use of this terminology in naming soils.

The proportions given in Table 11 cover recognizable ranges, sufficiently obvious for practical purposes. In borderline cases between two proportions either designation is acceptable. The descriptive terms for these recognizable ranges of proportions are used instead of percentages directly because they form a more suitable soil name, which is sufficiently precise for all practical purposes, considering the variation to be expected from sample to sample in the same deposit. The proportions of the gravel and sand components can be readily determined visually; the proportions of the sand and silt components can be determined by feel and by simple manual tests. In the laboratory or in the field office a standard set of bottle samples should be made up for reference. Thus, a person who is not continuously working with soils and identifying them can refer to these standards and check himself, until he has again acquired

TABLE 11.—Descriptive Terms for Cohesionless Soils to be Used in Forming the Soil Name

Soil component (1)	As written in the soil name (2)	Descriptive or qualifying terms as written (3)	Range of proportions (4)
Principal	GRAVEL, SAND, SILT	....	50% or more[a]
		and	35% to 50%[a]
Others	Gravel, Sand, Silt	some	20% to 35%[a]
		little	10% to 20%[a]
		trace	1% to 10%[a]
Subcomponents		coarse to fine	all sizes
		coarse to medium	<10% fine
		medium to fine	<10% coarse
		coarse	<10% medium and fine
		medium	<10% coarse and fine
		fine	<10% coarse and medium

Additional descriptive terms:

(1) Color, grain shape, etc.
(2) Degree of compactness, degree of plasticity.
(3) Inorganic constituents (mica, shells, and foreign matter).
(4) Organic matter (roots, humus, peat, and muck).
(5) Geological origin (alluvial, glacial, wind, beach, swamp, etc., also horizon).

[a] Finer than, or coarser than, the principal soil component.

the sense of identification and of proportions, which really involves seeing and comparing volumes, at the same time giving due consideration to weight and size of grains, and other characteristics.

Such a set of standard bottle samples should be composed of at least fourteen combinations covering the limits of the proportions corresponding to the descriptive terms in Table 11: (*a*) Seven of dry gravel-sand mixtures in the percentage proportions 90–10, 80–20, 65–35, 50–50, 35–65, 20–80, and 10–90; (*b*) three of dry sand of coarse, medium, and fine sizes, respectively; and (*c*) four of moist sand-silt mixtures in the percentage proportions 90–10, 80–20, 65–35, and 50–50. All samples should be at least one pint in volume, and preferably larger.

In examining and identifying soils one should start with the coarsest component and work by stages to the finest component. The proportion of the gravel component and its character as to coarse, medium, and fine fractions should be determined on a fairly large sample. The sand component and finer fractions are then examined to determine the proportion and character of the sand component and of the silt or clay-soil component. Visual means are satisfactory for sands containing not more than a trace of silt. The fine-grained soils or fractions of a soil are more difficult to identify; it is also more important to identify them accurately. Simple manual tests, such as the shaking test for silty soils and the plasticity test (thread rolling test) for clay-soils, can be used satisfactorily for proper identification by adjusting the moisture content to some particular condition. Plasticity and certain clay qualities are the most distinctive and characteristic properties of clay-soils. Therefore, they form a satisfactory and significant basis for identifying and naming these soils. Table 12 lists suggested descriptive terms based on the degree of plasticity of the sand-clay-soil fraction to be used in forming the soil name. These terms have also been used and found to be satisfactory by the writer for a number of years.

TABLE 12.—DESCRIPTIVE NAMES OF CLAY-SOILS BASED ON THE DEGREE OF PLASTICITY[a]

Degree of plasticity (1)	Plastic index (2)	Descriptive name as written (3)	Qualities (4)
Nonplastic	0–1	SILT	Friable
Slight plasticity	1–5	trace Clay	Desirable
Low plasticity	5–10	little Clay	Cohesiveness
Medium plasticity	10–20	CLAY and SILT	Increasingly objectionable plastic displacements and compressibility
High plasticity	20–35	Silty CLAY	
Very high plasticity	>35	CLAY	

[a] Over-all plasticity of sand-clay-soil fraction.

For a field and laboratory identification the over-all plasticity of the sand-silt-clay proportion of the soil as determined by the simple plasticity test is the most significant property, because it has a more direct relation to the behavior characteristics of the soil, and because a separation is not conveniently possible. The gravel sizes can be picked out by hand for the plasticity test.

The range of the degree of over-all plasticity expressed in terms of the plasticity index for each clay-soil type in Table 12 is broadened and adjusted to be more suitable and significant for identifying the soils. The proportion of sand can be determined by the feel of the soil.

The author has given a few examples of descriptive soil classification to illustrate how the AC system can be expanded. The descriptions do not, however, convey a sufficiently definite meaning to a person working in another field of soil engineering, who has not had the benefit of examining the soil firsthand, but who wishes to use the information on the behavior of such soils for the practical purposes of sizing up and judging his own particular problem and for reaching a satisfactory solution. Examples 1, 2, and 3, hereinafter, illustrate some advantages and the general usefulness for all purposes of the descriptive names of soils, based on the terminology in Tables 10, 11, and 12. It is intended that the soil name be put together in a certain definite fashion to emphasize the significant characteristics of the soils examined. The capitalized term in the soil name stands out as the principal component of the soil, so that it can be spotted at a glance. The significant detail then follows, expressed by the qualifying terms giving the proportions of the other soil components, usually in order of their importance. As is frequently necessary one can glance down a boring record, soil profile, or a list of soils from an area, and pick out immediately the types which have certain significant characteristics bearing directly on a given problem. The descriptive names of the soils can be abbreviated somewhat for a large group of similar soils, provided that the upper and lower limits of the group are given in detail.

Example 1.—

(*a*) "Light tan coarse to fine GRAVEL, and coarse to fine SAND, trace Silt." (Maximum size 1½ in.; plus No. 4 sieve, waterworn.)

(*b*) "Light brown coarse to fine GRAVEL, some coarse to fine Sand, trace Silt." (Maximum size 1½ in.; plus No. 4 sieve, waterworn.)

Certain important conclusions can be drawn from the descriptions of these soils based on a general knowledge of the behavior characteristics of different classes of soils. First, the soils will be free draining because there is not more than a trace of silt. Second, the soils ranging from "GRAVEL and SAND" to "GRAVEL, some Sand" (as an abbreviated descriptive classification) represent about the limits of drainable soils that can be considered well-graded. Third, the large gravel content and the large sizes indicate that high supporting capacity can be expected in the compacted condition. The quality of being well-graded is significant only for soils containing a large proportion of gravel, not only because it connotes compactibility to high densities (exceeding 135 lb per cu ft), but also because the close packing and contacts, together with the interlocking and proper bedding of the large particles, provide a high supporting capacity.

Example 2.—

(*a*) "Light brown coarse to fine SAND, trace Silt"; medium compact.

(*b*) "Light brown medium to fine SAND, little Silt"; medium compact.

(*c*) "Light brown medium to fine SAND, some Silt"; loose.

From these descriptions certain significant characteristics are immediately apparent. These soils are nonplastic in character. Soil (*a*) is free draining, has only slight capillarity, and is not susceptible to frost heaving. Soil (*b*) is not as free draining, but can be drained by well points, has some capillarity, and is slightly susceptible to frost heaving with high ground-water levels. Soil (*c*) is more difficult to drain with well points, has rather objectionable capillarity, and has frost heaving characteristics. On the basis of natural compactness, soil (*a*) would be much superior to soil (*c*) in the natural state as to supporting capacity. On the other hand, soils (*b*) and (*c*) would show better compactibility because the silt fills the void spaces and provides a bedding for the sand.

Example 3.—

(*a*) "Brown medium to fine SAND, some Silt, trace Clay"; slight plasticity.

(*b*) "Gray-brown SILT, some medium to fine Sand, little Clay"; low plasticity.

(*c*) "Gray CLAY and SILT, little medium to fine Sand"; medium plasticity.

All these soils are relatively impervious. Soil (*a*) would have fairly good compactibility. The supporting capacity would be only slightly affected by capillary saturation in the compacted state. Soil (*b*) is on the borderline of objectionable plastic displacement characteristics and softening by capillary saturation in the compacted state, particularly with a high ground-water level. Soil (*c*) would compact to a low density and would definitely have objectionable characteristics. However, this soil might have a fairly good supporting capacity in the natural state, if the natural consistency was stiff or better.

The amount of extra effort and time required to identify and describe soils in the more thorough fashion described herein is small when compared to the greater usefulness and value of the information obtained for all purposes, especially to people who wish to use such information to aid the solution of their own particular problems. Such descriptions and soil names, if generally used in boring records and in soil profiles and soil sections, would give far more significant and valuable information to the designing engineer, and, as a part of the contract drawings, to the contractor and construction engineer, than is obtainable at present from the vague and often wholly inaccurate terms generally used. Such information can be interpreted, as noted in the foregoing examples, on the basis of a person's particular experience, into terms of significant behavior characteristics, which would have a more direct bearing on the solution of the practical problems of foundation design and of the practical problems of foundation construction. If a typical soil near the upper limit and another near the lower limit of a group of soils, which have in common similar characteristics, are tested in detail in the laboratory to determine all the pertinent physical properties and strength characteristics, and the results are reported with the descriptive classifications of the whole group, then the range of behavior characteristics to be expected for the entire group can be fairly reliably known. When the actual behavior and performance of the different groups of soils have been observed in sufficient detail in the field and have been correlated with significant soil characteristics, the information would become an important part of a body of authoritative knowledge, which would be extremely useful and valuable to the engineering profession.

M. G. SPANGLER,[19] M. ASCE.—The fundamental purpose of a soil classification system is to provide a language by means of which one person's knowledge of the general characteristics of a particular soil can be conveyed to another person or group in a brief and concise manner, without the necessity of entering into lengthy descriptions and detailed analyses. Since soils are so widely heterogeneous in character, it is not to be expected that one kind of classification system can cover all the possible features of a soil which it may be desirable for one person to convey to another—hence, the desirability of several bases for classification. In engineering work, it is frequently appropriate to use at least several of, or all, four classifications for describing soils, such as: (1) The geological classification, which provides a language for stating the geological history and background of a soil; (2) the textural classification which provides names for describing the relative proportions of sand, silt, and clay size particles in a soil; (3) the pedological system of classification which reveals the nature of the soil profile as affected by the climatic and other environmental conditions under which the profile developed; and (4) an engineering classification that groups soils on the basis of their characteristics which influence engineering performance.

Great care should be exercised not to read into these various classifications more information than they are intended to convey. Particularly, caution is urged against leaning too heavily upon soil classification as a basis for design, since many of the factors that influence design cannot be incorporated into an engineering soil classification. For example, the susceptibility of a road or runway to frost damage is a question that involves not only the properties and characteristics of the soil itself, but climatic and geophysical factors as well.

With reference to the grain-size scales used in various branches of applied soil science, it would be more convenient for civil engineering usage if the arbitrary division between silt size and sand size were established at 0.074 mm (the size of opening of a standard No. 200 sieve) instead of sizes 0.02 mm, 0.05 mm, or 0.06 mm, shown in the various scales quoted by the author in Fig. 2. This is for the purely practical reason that a No. 200 sieve is about the smallest size that can be used in routine soil testing. Sieves with much smaller openings are manufactured, as is well known, but they are much more delicate and expensive and will not wear under rigorous usage as well as the No. 200 sieve. At present, many engineering organizations distinguish between coarse-grained soils and fine-grained soils on the basis of the quantity of material passing the No. 200 sieve, and it would be convenient if this size also marked the boundary indicated by the terms sand size and silt size.

The author mentions the difficulty involved in the fact that textural classifications based on the percentages of sand, silt, and clay size in a soil do not reflect all the physical properties of interest to the civil engineer. The term "texture," as originally used in the United States (53) was not intended to convey any information concerning a soil beyond the relative proportions of the size groups of the material less than 2 mm in diameter. It was not intended to indicate such properties as plasticity, shrinkage, swell, and others. Rather, those additional properties should be expressed by other kinds of classification or by specific test results. The term "texture" is used in some European countries (German *textur*) to embrace properties of soil other than relative amounts of the various size groups, such as soil structure and the form and relative size of the void spaces, but in the United States, so far as this writer is aware, "texture" has always referred only to grain-size relationships. It is the writer's belief that less confusion will ensue if this meaning of "texture" is preserved and emphasized.

---

[19] Research Prof., Civ. Eng. Dept., Iowa State College, Ames, Iowa.

No discussion of triangle textural classification is complete without pointing out that all the information given on an equilateral classification triangle can be shown on a right triangle (54) and that the process of determining the textural class of a soil is much simplified by using the right triangle chart. Since the sum of the percentages of sand, silt, and clay size in the portion of a soil smaller than 2 mm is 100%, the values of only two of these percentages are required to establish a point in an equilateral triangle such as shown in Fig. 3. By virtue of this fact, a right triangle can be constructed, as shown in Fig. 12, on which the percentages of any two of the three size groups can be scaled along the legs of the triangle. The point of intersection of the percentage lines representing the two groups for which the triangle is constructed can be more quickly spotted on such a diagram because of the orthogonal arrangement of the coordinates.

Soils that contain sufficient material larger than 2 mm to be especially noticeable (say, about 8% or 10%) should be qualified by prefixing the term "stony" or "gravelly" to the textural class indicated by the triangle chart, as stated by the author. The principal textural class name of such a soil is determined on the basis of that part of the material smaller than 2 mm. Obviously if a soil contains an appreciable quantity of +2 mm material, the percentage that each of the three smaller sizes bears to the total soil will not be the same as the percentage of these groups in relation to the amount of the sand, silt, and clay only. It is this latter percentage which should be used in the triangle chart classification. The percentages relative to the whole soil can be quickly converted to the percentages of the sand, silt, and clay by multiplying each of the original percentages by the ratio, $\frac{100}{100 - \text{gravel } (\%)}$.

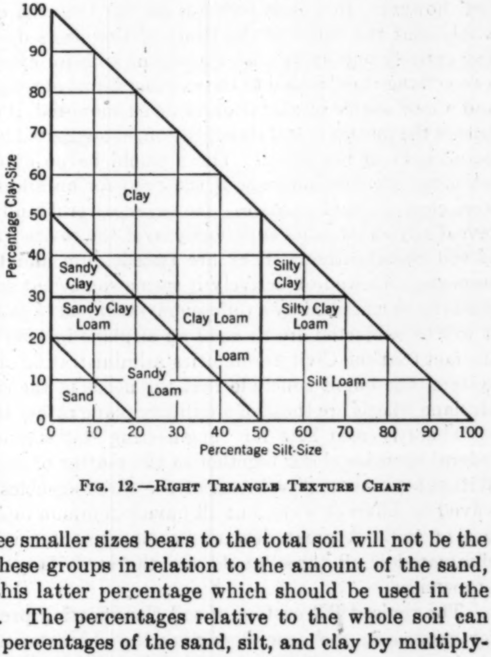

FIG. 12.—RIGHT TRIANGLE TEXTURE CHART

Thus, if the mechanical analysis of a soil shows it to consist of 17% gravel, 26% sand, 36% silt, and 21% clay, the ratio by which the percentages of the three smaller sizes should be increased is 1.2. The new values for these sizes then become 31% sand, 43% silt, and 25% clay. Entering the triangle chart (Fig. 3(*a*)) with these revised figures, the point of intersection falls within the clay loam area and the textural classification of this soil is "gravelly clay loam." If the material larger than 2 mm consists of broken stone fragments instead of rounded gravel particles, the soil would be classed as a "stony clay loam."

If one attempts to use the original percentages of sand, silt, and clay (that is, the percentages referred to the whole soil) three different points of intersection can be obtained on the equilateral triangle chart, depending on which pair of the three sizes is used. In the foregoing example 26% sand and 36% silt gives a point within the area labeled clay; 26% sand and 21% clay gives a point in the silty clay loam area; and 36% silt and 21% clay yields a point in the clay loam area. The necessity for reducing the percentages to the weight of material smaller than 2 mm as a base is apparent.

This writer has no particular criticism relative to the Airfield Classification (AC) System proposed by the author and tentatively adopted by the United States Engineer Department. It is a good system of classification. He does feel, however, that it is unfortunate for the civil engineering profession as a whole that the Office of the Chief of Engineers deemed it necessary to adopt any entirely new system for classifying soils for engineering purposes. Here is a new "language" added to the existing Babel of tongues which must be learned, and a new source of confusion to be surmounted, if an engineer is to avoid pitfalls in the matter of soil classification, as suggested by the author in the opening paragraphs of his paper. There would be no objection to the necessity for learning this new language if the need for an additional classification system were clear cut and positive. However, careful study of the AC system fails to reveal any substantial superiority over the revised Public Roads (PR) System of soil classification. They are tweedledum and tweedledee in many major respects. Viewed objectively it seems somewhat specious to argue that a soil needs to be classified by a different system just because the wheel loads to which it will be subjected are those of an airplane instead of a truck; and, in view of the fact that the Civil Aeronautics Administration also has its own classification system, one might conclude that the needs of the situation are different if the airplane wheels are those of a military plane rather than those of a civil aircraft.

There is need here for "engineering statesmanship" to bring these three federal agencies closer together in the matter of engineering soil classification. Without doubt, the problems of the three agencies are different and must be solved in different ways, but all have a common interest in engineering properties of soil. A great deal of "compartmentation" and confusion could be eliminated if all three would use the same language when discussing those properties.

The revised PR system of soil classification provides an excellent medium for expressing the general engineering characteristics of soils with sufficient clarity for practically all engineering applications and with a degree of precision commensurate with that which can be expected of any classification system.

It has been used by engineers since about 1928, and on an ever widening scale, until nearly all who deal with the soil have a general understanding of the meaning of the symbols A-1, A-4, and others. It is true that local engineering organizations often have had to modify the system to fit their local situations but, by and large, such modifications were readily made within the framework of the basic system, so that the language was essentially preserved.

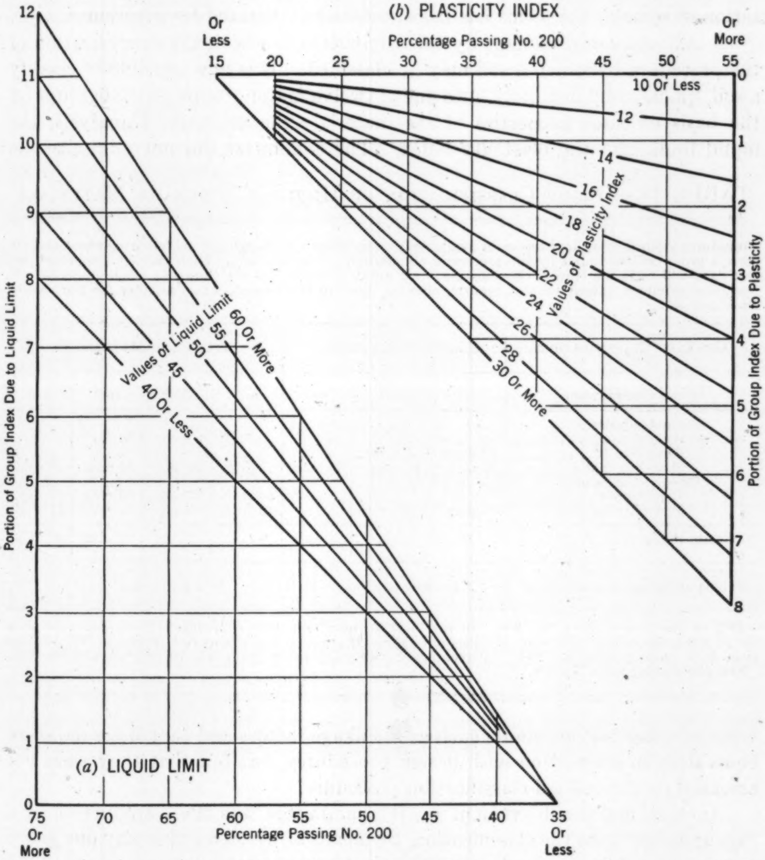

FIG. 13.—GROUP INDEX CHARTS

It is also true that the PR system has undergone a number of revisions since its introduction, which is to be expected in the case of any new tool or device as use demonstrates the need for modification. The author states that the AC system has been revised three times since its inception in 1942. Undoubtedly both systems will undergo further revision as time passes.

The most recent and the most extensive revision of the PR system is that which has been made by a committee of experienced engineers designated by the Highway Research Board, under the chairmanship of Harold Allen, M. ASCE, of the United States Public Roads Administration. The findings of a highway subcommittee of this committee (51) constitute a major revision in the PR system which brings it up to date in the light of many years of experience. This revision retains the basic framework of the system, with changes in detail here and there which are clearly set forth in the report. In other words, the classification language has not been changed, but the meaning and connotation of some of the terms has been modified as dictated by experience.

A major accomplishment by this committee has been the simplification of the procedure by which a soil may be classified. It is now possible to classify a soil, quickly and definitely, into one of twelve major groups and subgroups on the basis of three properties of the material—the mechanical analysis, the liquid limit, and the plasticity index. The committee did not minimize the value of other test constants such as shrinkage factors and centrifuge moisture equivalent in connection with design procedures, but felt that they were not essential in a simplified classification procedure.

TABLE 13.—GROUP CLASSIFICATION OF HIGHWAY SUBGRADE MATERIALS

Procedure: With the required test data available, proceed from left to right in the following chart and the correct group will be found by the process of elimination. The first group from the left into which the test data will fit is the correct classification. All limiting test values are shown as whole numbers. If fractional numbers appear on test reports, convert them to the nearest whole number for purposes of classification.

GENERAL CLASSIFICATION	GRANULAR MATERIALS[a]			SILT-CLAY MATERIALS[b]			
Group Classification	A-1	A-3	A-2	A-4	A-5	A-6	A-7
Sieve Analysis[c]							
Sieve No. 10..........	....	....	....	....	....	....	....

Group index................	....	....	4 max.	8 max.	12 max.	16 max.	20 max.
General rating as a subgrade..	Excellent to good			Fair to poor			

[a] 35% or less passing sieve No. 200. In the "left to right" elimination process it is necessary to place group A-3 before group A-2; but this does not signify that group A-3 is superior to group A-2. [b] More than 35% passing sieve No. 200. [c] Percentage by weight passing sieves No. 10, No. 40, and No. 200. Fraction passing sieve No. 40.

Another major achievement by the committee was the introduction of a "group index" into the classification, by means of which a soil in any one group or subgroup of fine-grained materials may be rated within its own group on the basis of variations in percentages of coarse material, liquid limit, and plasticity index. This group index or "in-group" rating is determined from an empirical formula, which is derived from experience with the original PR classification. It is based on the relationships between the amount of fine-grained material (material passing a No. 200 sieve) in a soil and the liquid limit and plasticity index within the significant ranges of variation of these properties. It can be quickly determined for a given soil by two simple charts which provide a

TABLE 14.—SUBGROUPS CLASSIFICATION OF HIGHWAY SUBGRADE MATERIALS

(Letter M Designates Maximum Values; Letter m Designates Minimum Values)

Procedure: With the required test data available, proceed from left to right in the following chart and the correct group will be found by the process of elimination. The first group from the left into which the test data will fit is the correct classification.

GENERAL CLASSIFICATION	GRANULAR MATERIALS[a]							SILT-CLAY MATERIALS[b]			
Groups	A-1		A-3	A-2				A-4	A-5	A-6	A-7

Group index[f]	0		0	0		4 M		8 M	12 M	16 M	20 M
Usual types of significant constituent materials	Stone fragments, gravel, and sand		Fine sand	Silty or clayey gravel and sand				Silty soils		Clayey soils	
General rating as a subgrade	Excellent to good					Fair to poor					

[a] 35% or less passing sieve No. 200. As in Table 13, group A-3 precedes group A-2; but this does not signify that group A-3 is superior to group A-2. [b] More than 35% passing sieve No. 200. [c] Percentage by weight passing sieves No. 10, No. 40, and No. 200. [d] Fraction passing sieve No. 40. [e] The plasticity index of subgroup A-7-5 is equal to, or less than, the liquid limit −30. The plasticity index of subgroup A-7-6 is greater than the liquid limit −30. [f] The group index is computed by reference to Fig. 13 and is shown in parentheses after the group symbol; thus: A-2-6(5).

Granular Materials—Containing 35% or Less Passing a No. 200 Sieve.—

Group A-1.—The typical material of this group is a well-graded mixture of stone fragments or gravel, coarse sand, fine sand, and a nonplastic or feebly plastic soil binder. However, this group includes also stone fragments, gravel, coarse sand, volcanic cinders, etc., without soil binder.

Subgroup A-1-a includes materials consisting predominantly of stone fragments or gravel, either with or without a well-graded binder of fine material.

Subgroup A-1-b includes those materials consisting predominantly of coarse sand, either with or without a well-graded soil binder.

Group A-3.—The typical material of this group is fine beach sand or fine desert blow sand, without silty or clay fines or with a very small amount of nonplastic silt. The group includes also stream deposited mixtures of poorly graded fine sand and limited amounts of coarse sand and gravel.

Group A-2.—This group includes a wide variety of "granular" materials which are border line between the materials falling in groups A-1 and A-3 and the silt-clay materials of groups A-4, A-5, A-6, and A-7. It includes all materials containing 35% or less passing a No. 200 sieve, which cannot be classified as A-1 or A-3 due to fines content or plasticity, or both, in excess of the limitations for those groups.

Subgroups A-2-4 and A-2-5 include various granular materials containing 35% or less passing a No. 200 sieve and with a minus No. 40 portion having the characteristics of the A-4 and A-5 groups. They include such materials as gravel and coarse sand with silt content or plasticity index in excess of the limitations of group A-1, and fine sand with nonplastic silt content in excess of the limitations of group A-3.

Subgroups A-2-6 and A-2-7 include materials similar to those described under subgroups A-2-4 and A-2-5, except that the fine portion contains plastic clay having the characteristics of the A-6 or A-7 group. The approximate combined effects of plasticity indexes in excess of 10 and percentages passing a No. 200 sieve in excess of 15 are reflected by group index values of from 0 to 4.

Silt-Clay Materials—Containing More Than 35% Passing a No. 200 Sieve.—

Group A-4.—The typical material of this group is a nonplastic or moderately plastic silty soil usually having 75% or more passing a No. 200 sieve. The group includes also mixtures of fine, silty soil and up to 64% of sand and gravel retained on a No. 200 sieve. The group index values range from 1 to 8, with increasing percentages of coarse material being reflected by decreasing group index values.

Group A-5.—The typical material of this group is similar to that described under group A-4, except that it is usually of diatomaceous or micaceous character and may be highly elastic as indicated by the high liquid limit. The group index values range from 1 to 12, with increasing values indicating the combined effect of increasing liquid limits and decreasing percentages of coarse material.

Group A-6.—The typical material of this group is a plastic clay soil usually having 75% or more passing a No. 200 sieve. The group includes also mixtures of fine clayey soil and up to 64% of sand and gravel retained on a No. 200 sieve. Materials of this group usually have a high volume change between wet and dry states. The group index values range from 1 to 16, with increasing values indicating the combined effect of increasing plasticity indexes and decreasing percentages of coarse material.

Group A-7.—The typical material of this group is similar to that described under group A-6, except that it has the high liquid limits characteristics of the A-5 group and may be elastic as well as subject to high volume change. The range of group index values is from 1 to 20, with increasing values indicating the combined effect of increasing liquid limits and plasticity indexes and decreasing percentages of coarse material.

Subgroup A-7-5 includes those materials with moderate plasticity indexes in relation to liquid limit and which may be highly elastic as well as subject to considerable volume change.

Subgroup A-7-6 includes those materials with high plasticity indexes in relation to liquid limit and which are subject to extremely high volume change.

graphical solution for the group index formula. The group index of a soil is reported as a whole number in parentheses after the group or subgroup symbol, as, A-4 (5) or A-6 (12). This method of reporting automatically indicates the "edition" of the PR system which was used to classify a soil.

The classification system embodied in this committee report has been variously called the Highway Research Board system and the group index system. The writer prefers to call it the "Revised PR" system, since that is actually what it is. It is strongly recommended as a complete and comprehensive language for expressing the engineering characteristics of soil material—a system whose terms are widely understood and recognized, which is based on long usage and experience, and which is easy to apply in day to day practice.

The following description of classification groups is extracted from the report, as are Tables 13 and 14 and Fig. 13.

E. W. LANE,[20] M. ASCE.—It is believed that engineers working in soils would be glad to know of the size classification recently proposed by a Sub-Committee on Sediment Terminology of the American Geophysical Union (55) for use in work in sediments as given in Tables 15 and 16. The addition of a discussion of this classification to Professor Casagrande's excellent paper, therefore, seems justified.

TABLE 15.—SCALE OF LARGE PARTICLE SIZES, IN METRIC AND ENGLISH UNITS

Class name (1)	Metric unit (mm) (2)	English unit (in.) (3)
Very large boulders	4,096–2,048	160–80
Large boulders....	2,048–1,024	80–40
Medium boulders..	1,024–512	40–20
Small boulders....	512–256	20–10
Large cobbles.....	256–128	10–5
Small cobbles.....	128–64	5–2.5
Very coarse gravel.	64–32	2.5–1.3
Coarse gravel.....	32–16	1.3–0.6
Medium gravel....	16–8	0.6–0.3
Fine gravel.......	8–4	0.3–0.16
Very fine gravel...	4–2	0.16–0.08

TABLE 16.—SCALE OF SMALL PARTICLE SIZES

Class name	METRIC UNITS	
	(Mm)	(Microns)
(1)	(2)	(3)
Very coarse sand..	2.000 –1.000	2,000–1,000
Coarse sand......	1.000 –0.500	1,000–500
Medium sand.....	0.500 –0.250	500–250
Fine sand........	0.250 –0.125	250–125
Very fine sand....	0.125 –0.062	125–62
Coarse silt.......	0.062 –0.031	62–31
Medium silt......	0.031 –0.016	31–16
Fine silt.........	0.016 –0.008	16–8
Very fine silt.....	0.008 –0.004	8–4
Coarse clay size...	0.004 –0.0020	4–2
Medium clay size.	0.0020–0.0010	2–1
Fine clay size.....	0.0010–0.0005	1–0.5
Very fine clay size.	0.0005–0.00024	0.5–0.24

---

[20] Hydr. Consultant on Chf. Engr.'s Staff, Bureau of Reclamation, Denver, Colo.

The classification is practically a modification of the classification (56) of C. K. Wentworth substituting the term gravel for his terms granule and pebble, subdividing his silt and clay sizes according to the widely used classifications proposed by J. A. Udden (57), and adding subdivisions of Mr. Wentworth's boulder classification. Most of the Wentworth-Udden classification has been widely used among geologists for many years and has been adopted by engineers in many sediment studies, but the granule and pebble classifications were not generally accepted.

The purpose of the Sub-Committee was to obtain agreement among engineers and geologists on a large number of terms in the sediment field, on which there was considerable difference of usage, including that of particle size. The Sub-Committee was composed of engineers and geologists, the engineers being G. H. Matthes, Hon. M. ASCE, L. G. Straub and the late G. C. Dobson, Members, ASCE, C. B. Brown, Assoc. M. ASCE, and the writer. The other members were equally well-known geologists.

The principal advantages of the proposed classification are believed to be as follows: (1) It gives exact subdivisions over the full range of particle sizes of sedimentary materials; (2) the terms used are common ones, and are applied to the range of sizes in common usage; and (3) the lower limit of each size is exactly one half of the upper limit, thus making the division points easy to remember and causing them to plot equally spaced on the semilogarithmic diagrams so widely used to indicate particle size distribution.

This equal size of classes is also a great advantage in the use of statistical methods in treating size ranges. Since the sizes of most sediment samples tend to form straight lines when plotted on logarithmic probability paper, the standard deviation of the logarithm of the sizes indicates the spread of the particle sizes. The composition of a sample can thus be closely represented by two numbers, the median (or geometric mean) and the standard deviation of the logarithm of the size. With these numbers, the composition of a large number of samples can be represented more conveniently than with a large number of size composition curves. It is sometimes possible to analyze a large mass of data by this method in illuminating ways which would be impossible by using the curves. This method of analysis was largely introduced into sedimentary science over a decade ago by W. C. Krumbein and has been widely used. It has more recently been independently introduced into soil mechanics by Donald M. Burmister, Assoc. M. ASCE.

B. K. Hough, Jr.,[21] Assoc. M. ASCE.—One of the many controversial aspects of this significant paper is the distinction between, and the relative importance of, the subject processes of soil classification and soil identification. It is noted that the author gives most attention to classification of soils, said classification being based on soil characteristics which are of various but generally limited interest, and which generally do not include identification. The question is raised herein as to whether identification may not be of major importance in all applications and the basis for more reliable classification and indication of probable soil behavior under service conditions.

---

[21] Associate Prof. of Soil Mechanics, Cornell Univ., Ithaca, N. Y.

It is suggested that such terms as clay and silt, for example, are inadequate for true identification, although they may be sufficient in some applications as classifications. To designate a soil as clay, for instance, is scarcely more satisfactory than to designate one of a number of unidentified construction materials as wood. The differences between clay minerals are as basic and, in some respects, may be as important as the differences between oak and balsa, or pine and cedar. Not only mineralogical, but also chemical distinctions of great importance, notably base exchange capacity (BEC) and type of exchangeable ion, are in some cases of major interest.

Many engineers would agree that identification of soils (especially fine-grained soils) on the basis of their fundamental properties, mineral type, and composition in particular, is sound and desirable in principle but so difficult in practical application as to be of very limited utility, especially in the field. This rather general view may be influenced by misconception of the difficulty of such identification and insufficient knowledge of its practical value. It may now be the case that the practical value can be demonstrated and that identification methods have been simplified to such an extent that in the near future there will be a trend in engineering toward soil identification rather than toward the development of more complex empirical classification systems.

Mineral identification for many years was based on optical methods, which required highly specialized training and experience, usually in the field of geology or physics. For engineering applications this type of analysis has never seemed to be necessary and this may still be true although the increasing evidence of the value of such analysis might justify it. Other methods are available, however, such as the differential thermal analysis method, which can be simplified in application to almost any reasonable degree. Equipment for field use was developed during World War II by the United States Department of Agriculture and is now available for engineering purposes. This equipment can be operated quite satisfactorily by engineers in the junior professional categories. More elaborate equipment for analysis by the same method may be obtained and utilized in soils engineering laboratories without employment of specialists in this field.

The chemical analysis of a soil can also be organized in any reasonably well-equipped laboratory so that it may be conducted by technicians with minimum technical training, and in fact it is now on this basis in many agricultural laboratories. Equipment for field use is also available for certain types of chemical determinations.

In most, if not all soils engineering laboratories, the mechanical analysis is now a standard test and the data from such tests are considered essential in many systems of soil classification. It may well be, however, that in fine-grained soils specific surface is a more significant measurement than gradation or particle diameter, particularly when the latter are determined by such methods as the analysis of sedimentation by the specific gravity hydrometer. This observation is made as an extension of the foregoing comments on chemical analysis, inasmuch as specific surface, although in itself a physical characteristic, is usually indicative of chemical activity. In this respect it is fundamentally preferable to grain-size measurements as the basis for estimating such soil characteristics as permeability, capillarity, plasticity, stability, and many other features which are of engineering interest. Data from hydrometer tests are of little use in such determinations and, in fact, are often accorded no more attention by engineers than a cursory examination despite the considerable cost of performing such tests.

The practical value of the identification of the clay minerals has been more clearly established in recent years. The swelling propensites of the montmorillonite group are generally recognized, although it is still not common practice to make an analysis of mineral types in cases where swelling is of particular importance. Many other correllations between mineral type and engineering behavior may be possible as studies in this area are undertaken. During recent soil tests under the writer's supervision, for example, standard Proctor compaction tests on an unknown clayey soil indicated an optimum moisture content of approximately 30% (dry weight basis). This value considerably exceeded that for any other soil tested by the writer in the course of many years of practical testing experience. Mineralogical analysis revealed the predominant clay mineral to be illite, which with its distinctive potassium bonding may well have characteristics that differ appreciably from those of the more common kaolinite group.

With reference to determination of the type of exchangeable ion, an almost classic example of the practical value of this soil characteristic is the treatment of the Treasure Island (Calif.) Lagoon lining (58) with ocean water to reduce its permeability. None of the soil classification systems described by the author would have indicated the feasibility of this eminently practical and effective treatment. Other examples of the practical importance of chemical reactions in soil in the field of highway engineering are almost too numerous to cite.

In conclusion, it is recommended that efforts be made by engineers to identify soils on the basis of fundamental properties—specifically, mineral type, exchangeable ions, BEC, and specific surface—and that thereafter soils be classified for various purposes. The basic identification will then be valid, no matter what the application or use of the soil may be, and might well serve as the common denominator for the many diversified interests now engaged in soil study and research.

ARTHUR CASAGRANDE,[22] M. ASCE.—The discussions have rounded out the contents of the paper by the addition of valuable material and of many helpful suggestions, for which the writer is grateful.

There is one misunderstanding noticeable in several of the discussions which is caused by the brevity of paper—namely, that the purpose of the Airfield Classification (AC) System is merely to classify the raw material of which the soil is composed, without regard to the engineering properties of the material in its undisturbed state. This interpretation is definitely not the writer's intent. All the data listed in Cols. 1 to 6, Table 4, must be considered as an integral part of the complete classification. Cols. 1, 2, 3, 4, and 6 classify the material in the "disturbed state"—that is, the raw material. In Col. 5 are listed characteristics which refer to the engineering properties of the material in the condition in which it will be used by the engineer. Since Table 4 is prepared specifically for the use of the AC system in airfield projects, the observations and tests listed in Col. 5 are selected for this purpose. When dealing with other types of engineering projects, Col. 5 will obviously require revision. No formal grouping has been proposed for the data which are to be included in Col. 5. However, it is conceivable that, for specific engineering projects, the observations and tests relating to the material in place could be subjected to further classification.

---

[22] Prof. of Soil Mechanics and Foundation Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

Several of the discussions have pointed out that in many cases a geologic classification of the soils should be included in the general classification, and that use should be made of local soil names. The writer agrees with these views and suggests that another column should be added in Table 4 with the heading, "Geologic Description and Local Name." In this connection it should be noted that there is also some danger in the use of local soil names because in different parts of the United States they may refer to materials differing greatly in their engineering characteristics. For example, the term "hardpan" has led to numerous lawsuits in which the lawyers had no difficulty in finding in the literature definitions which suited their individual purposes. It seemed to the writer that the older the quotation the more weight it carried in the Court of Law.

Professor Fadum offers several practical suggestions for promoting agreement on soil terminology. The writer agrees with Professor Fadum that it would be more significant if the Atterberg limits were performed on material smaller than 0.1 mm in diameter, rather than on the fraction passing the No. 40 sieve. Since separation of the fraction smaller than 0.1 mm is cumbersome and time consuming, general acceptance of such a suggestion is not probable until a much faster procedure is developed for the separation of this fraction.

Colonel Stratton reviews the circumstances leading to the development of the AC system, and demonstrates in Fig. 7 how the system was combined with the design procedure for flexible pavements, which was developed under his direction by the Office of the Chief of Engineers, United States Army. Then he reviews the comments made in 1942 by various divisions and districts of the United States Engineer Department—that is, soon after the AC system was adopted as a tentative standard by the Corps of Engineers for military construction. More recently, a modification was developed by the Office of the Chief of Engineers for civil works purposes, based on the experience gained in the use of the AC system since its inception.

Professor Belcher presents a competent discussion on the advantages of the pedological classification. It is true that the thoroughness of exploration on which a pedological classification of a given locality is based results in information which is of value to the engineer, and that much time and effort can be saved by utilizing such available information. However, the writer does not believe that the pedological classification is suitable in general for engineering purposes.

Messrs. Haine and Hilf describe an adaptation of the AC system which is used by the Bureau of Reclamation for use with earth dam projects (59). They emphasize that proper field identification is the primary objective in soil surveys, and found it necessary to subdivide the GF and SF groups according to the type of fines. This step is logical, particularly in connection with the use of soils for the construction of rolled earth dams. In addition, Messrs. Haine and Hilf have rated the various groups of materials according to their usefulness in the design of earth dams—a helpful supplement when using this classification for earth dam projects.

Mr. Feld has brought a welcome diversion into this rather prosaic subject, by reviewing some of the history of soil classification.

Kenneth S. Lane first presents an analysis of the requirements which a classification system should fulfil, and then proposes a new system referred to as QPC (Quabbin, Providence, and Casagrande) classification, in which he combines the advantages of several systems by using a descriptive name, a grain-size number, and the group symbol of the AC system. The writer is in full accord with Mr. Lane's discussion of typical soil names, with emphasis on the geology of the soils. The use of a grain-size number is a desirable supplement in classifying many coarse-grained soils of a great variety, such as are encountered in glacial deposits. In such instances, a man could be trained to estimate the grain-size class by visual inspection. However, when working in areas where coarse-grained soils are rather limited in extent, the necessary skill for a fair differentiation between thirty-five grain-size classes will usually not be available. If high accuracy in classifying the grain-size distribution is needed, one will have to depend on laboratory analyses. Because of Mr. Lane's extensive experience, his recommendations deserve serious consideration by those who wish to use a comprehensive method for classifying soils.

Professor Sowers points out the difficulty resulting from the fact that the term "plastic" is used by builders and drillers to designate the consistency of a soil in its natural state. He also emphasizes the importance of a detailed description of the properties of the undisturbed material and suggests the use of numerical scales to replace the uncertainty of descriptive adjectives. The writer believes that in visual and manual examination only a small number of grades can be distinguished, which are better described by generally understood adjectives. However, there is no question that a quantitative basis should be established for the purpose of standardizing the use of the adjectives.

Mr. Pulido y Morales expresses preference for the modified Public Roads (PR) Classification. He compares (Table 7) the group symbols for forty-four different soils according to the original and the modified PR classification, which to the writer demonstrates the confusion that must result if both classifications, which differ so greatly, make use of the same group symbols.

Because of space limitation the writer must forego a detailed discussion of the group index in the modified PR classification, and of the relationship between the liquid limit and compressibility, which Professor Dawson desires.

Mr. Glynn points out that in Australia a descriptive soil classification has been widely used as the basis of field identification. He suggests that, to prevent confusion, further subdivisions in the AC system should be limited to special applications. The writer is inclined to agree with this suggestion.

Many of the features which are insufficiently presented in the AC system are very well covered in the classification proposed by Messrs. Cooling, Skempton, and Glossop in Table 8. Although specifically adapted to the soil conditions in England, Table 8 may well serve as a general basis for establishing similar classifications in other parts of the world. In Fig. 11, the relationship between the liquid limit and the clay fraction (percentage smaller than 2 microns) is plotted, to illustrate that, for two clays having the same liquid limit, the clay with the more potent colloidal content has the smaller clay fraction. Whether such a relationship will yield information in addition to what can be derived from the plasticity chart, is questioned. Besides, difficulties arise when one also plots the results of materials with high liquid limit which lie well below the A-line, such as organic clays, or micaceous and diatomaceous soils.

Mr. Vargas suggests that the organic and inorganic silts may be grouped together into a major division. The writer questions the value of such a combination, since organic silts and inorganic silts are really quite different types of soils.

Mr. Vargas raises the question as to whether the group symbols, which are abbreviations of English names, should in other languages be changed to the initials of the corresponding names. He answers his question by suggesting that the original symbols should also be retained in other languages. This would certainly prevent confusion. The writer admits that in devising the symbols he has not thought about the possibility that this classification might spread to other countries. The purpose of the group symbols was to give the user something that would not tax his memory. Thus, it would be logical to create new symbols in each language. On the other hand, if this classification should become widely used, it would be desirable to have only one set of symbols which are internationally accepted. There is already one symbol in these groups which is not derived from the English language, namely, the letter, M. Considering that the majority of important references in soil mechanics are, and probably in the future will be, in the English language, and that English is the only language used for the International Soil Mechanics Conferences, the adoption of the present symbols as an international standard would not be too great a hardship. It would mean that, in teaching the classification, the student would have to learn the English names of about one dozen soils. After he has mastered these words, the use of these symbols would be just as understandable to him as if the symbols referred to the names of these soils in his own language.

Professor Burmister proposes to broaden the AC system by a better definition of the principal soil components, and by establishing a common language in describing soils. His discussion contains many valuable suggestions, which merit attention in any future improvements of existing soil classifications.

Professor Spangler has presented a competent defense of the new PR system. By including sufficiently detailed information on this new system, he has contributed a necessary supplement to the paper. Professor Spangler expresses regrets that other organizations deemed it necessary to adopt an entirely new system, when the PR system would have been satisfactory. However, that the original PR system was not satisfactory was admitted tacitly by those who created the new PR system, after the AC system was already in existence. In fact, it seems to the writer that, except for the symbols, the new PR system is closer to the AC system than to the 1929 PR system. Therefore, the writer reiterates that it would have been less confusing and more straightforward if the new PR system had received a new and more logical set of symbols, instead of retaining the original symbols.

Professor Spangler misunderstood the writer's remark regarding the revisions of Table 4 to mean that the AC system has been revised three times since its inception in 1942. Some minor revisions were made in Cols. 12 to 15, Table 4, which are not an inherent part of the AC system.

If none of the existing methods for identifying and classifying soils for engineering purposes makes use of their mineralogical and chemical composition and surface area, the reason is simply that the very complex relationships between these characteristics and the engineering properties of soils have not been established to any useful and practical extent. The writer, however, agrees with Professor Hough that more research along these lines is desirable.

E. W. Lane discusses a new grain-size classification recently proposed by the American Geophysical Union. In soil mechanics there has not developed, so far, any need for such detailed grain-size classifications, and the writer doubts that they will ever be needed.

The writer should like to point out that the soil classifying procedures actually used by the Bureau of Reclamation and by the Corps of Engineers, as well as by the Bureau of Yards and Docks, United States Navy (the latter according to written information received from L. A. Palmer), differ only in minor points. It would seem to the writer feasible and eminently desirable for these three large users of soil mechanics to initiate a cooperative effort, which should eventually lead to a uniform soil classification. If such an effort succeeds, it would constitute the most important step toward resolving order from the chaos of the past.

ESTIMATING DATA FOR RESERVOIR GATES

By Frank L. Boissonnault,[1] Esq.

With Discussion by Messrs. Theodore B. Rights, George R. Latham, D. A. Buzzell, A. E. Niederhoff, Joseph R. Bowman, and Frank L. Boissonnault.

Synopsis

Charts for the determination of weight and cost data on some of the most common forms of water control gates used in conjunction with dams are presented in this paper. The types included are: High-pressure hydraulic operated slide gates, radial crest gates, roller crest gates, drum crest gates, and Broome gates.

There are some published data on weights and costs of gates, but in most cases the exact items included are not known. Where tables of weights are given (in other publications), some gates may include much more conduit lining than others of the same type. Also, some may include considerable auxiliary equipment such as valves and piping, whereas others in the same table do not. In the case of radial gates, sometimes it is not clear whether or not the hoist or even the anchorages and other stationary parts are included. If adequate information is not given, no data are available for easily approximating the necessary addition for a complete estimate. Therefore, the utility of such data is limited, and it is believed that charts, such as those presented in this paper, fill a definite need.

Introduction

The charts in this paper were developed to assemble accurate information on weights and costs of existing gates in convenient graphic form so that they could be compared easily and so that the weight of any gate could be interpolated quickly from the nominal gate dimensions and maximum head on the gate center. The intent is to present all the pertinent data required to enable the engineer to use his own judgment in making an intelligent estimate of weight to fit the individual case, without the necessity of tedious research work each time an estimate is required. To accomplish these objectives with curves, in each chart an expression (involving only the nominal gate dimensions

---

Note.—Published in September, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Engr., U. S. Engr. Office, Los Angeles, Calif.

and maximum head as variables) is developed, some power of which will be as nearly as possible proportional to the weight of the gate. The weights and the costs (in some cases) were then plotted as ordinates against this expression as abscissas. Where the evaluation of the expression involves more than a simple slide rule operation, other curves are given to assist in the evaluation of this function. The dimensions are in feet in all cases.

The various dams mentioned in the text or noted in illustrations are further summarized and identified, as follows:

Dam	Location
Structures of the Bureau of Reclamation—	
Alamogordo	New Mexico
Alcova Tunnel	Wyoming
American Falls	Idaho
Black Canyon	Idaho
Boulder	Colorado River, Nevada
Caballo	New Mexico
Deadwood	Idaho
Easton	Yakima Project, Washington
Friant	Central California
Grand Coulee	Central Washington
Grassy Lake	Wyoming
Guernsey	Wyoming
Island Park	Idaho
Jackson Gulch	...
Madden	Panama Canal Zone
McKay	Northeastern Oregon
Norris	Tennessee
Owyhee	Oregon
Salinas	Southern California
Shoshone	Wyoming
Stony Gorge	Central California
Taylor Park	Colorado
Tieton	Yakima Project, Washington
Structures of the United States Engineer Department—	
Beach City	Ohio
Brea	Southern California
Caddoa	Arkansas River, Colorado
Conchas	New Mexico
Dover	Ohio
Fullerton	Southern California
Hansen	Southern California
Kanawha No. 1	West Virginia
Lytle Creek	Southern California

FIG. 1.—ASSEMBLY DRAWING OF A STANDARD HIGH-PRESSURE SLIDE GATE (5 FT BY 6 FT) AS BUILT BY THE BUREAU OF RECLAMATION (SEE ALSO TABLES 1 AND 2)

MAJOR PARTS OF HIGH-PRESSURE SLIDE GATE SHOWN IN FIG. 1

Gate:	
Upstream frame	1
Downstream frame	2
Bonnet	3
Leaf	5
Seats	6, 7, 8, 9, 10, 11
Stuffing glands	31, 42
Bonnet cover	4
Hoist:	
Cylinder Piston—	
Stem extension	19, 25, 41
Stem and stem nuts	22, 23
Upper cylinder head	20
Conduit:	
Lining	(not shown)
Lining transition	(not shown)

DESIGN DATA

Maximum Designed Head, for Gate Leafs, in Feet:	
Cast iron	90
Semisteel	140
Cast steel	250
Pressure in Cylinder, in Pounds Per Square Inch:	
Working pressure	750
Designed pressure	1,000
Coefficient of Friction at Starting:	
Bronze gate seat	0.6

The concrete surrounding conduit and bonnet castings are designed to carry all the load.

HIGH-PRESSURE SLIDE GATES

Fig. 1 shows an assembly drawing of a typical high-pressure slide gate, so called because, in moving, the leaf slides on its sealing strips. The hoist is a hydraulic cylinder and the greatest part of its capacity is required for overcoming the seal friction created by the static pressure of the water against the upstream face of the leaf. The cast-iron conduit lining (not shown) is bolted to the flange on the body or "frame" of the gate and the entire assembly, including the bonnet, is embedded in the masonry structure up to the bonnet cover, which, with the hoist, projects into the gate chamber as shown.

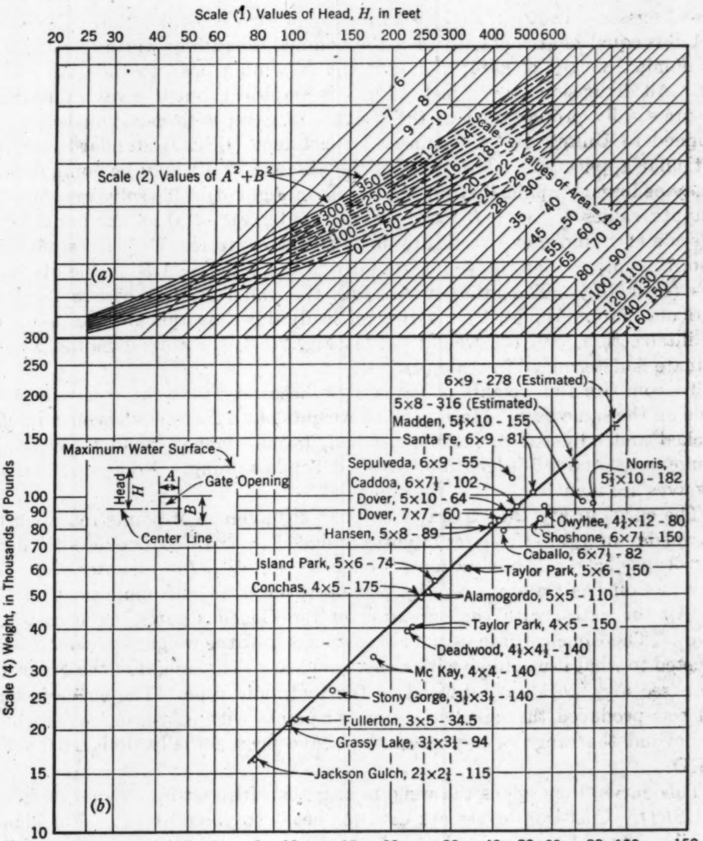

FIG. 2.—WEIGHT OF HIGH-PRESSURE SLIDE GATES WITH HYDRAULIC HOISTS

The weight curve of Fig. 2 is plotted with the weight of the gate as ordinates and the expression—

$$F(W) = \frac{(\text{area})}{10^5} (A^2 H + B^2 H + 6{,}420 \sqrt{H} + 30{,}000) \ldots\ldots\ldots (1)$$

—as abscissas. In Eq. 1, $F(W)$ is a function of the weight W; "(area)" is equal to $A\ B$ is equal to area of gate; A is the nominal breadth or width of gate; B is the nominal height of gate; and H is the maximum head to the gate center line. All dimensions are in feet. Eq. 1 is empirical, but it gives values that are practically proportional to the weights of gates with cast-iron leaves, as designed to United States Engineer Department (USED) standards for the particular application. The value of the abscissa $F(W)$ may be computed or it may be found graphically from the curves in Fig. 2(*a*). To solve graphically, compute values of $(A^2 + B^2)$ and $(A\ B)$. Enter Fig. 2(*a*) at maximum head H (scale (1)), and move vertically down to the curve for $A^2 + B^2$ (scale (2)). From this intersection, move horizontally to the value of $A\ B$ on the diagonal lines (scale (3)). The intersection gives the value of the abscissa for that particular gate. Hence, by moving vertically down on this abscissa value to the intersection with the weight curve (Fig. 2(*b*)), the corresponding weight ordinate is determined in scale (4).

To compare the weights of gates, it is necessary that the comparison be made on the same basis. In Fig. 2 the weights of all gates have been carefully checked and adjusted to include the leaf, frame, bonnet, bonnet cover, hydraulic hoist, and a 5-ft length of cast-iron conduit lining. No hanger, piping, or valves are included.

The curve in Fig. 2(*b*) is drawn through the average of points representing the weights of a range of sizes of gates designed by the USED offices for flood control projects. The notation "Conchas—4 × 5—175" denotes that the gates at Conchas Dam are 4 ft by 5 ft operating at a maximum head of 175 ft. All the gates, with the exception of the Conchas gates, have cast-iron leaves. The Conchas gate leaves are cast steel, but the weight shown has been adjusted to what it would be with a cast-iron leaf. The weight of the Fullerton gates (see Fig. 2(*b*)) was adjusted to the hydraulic type. The curve in Fig. 2(*b*) was produced through two estimated points with cast-iron leaves which are beyond the range of any gates that have been actually designed by the USED.

This curve, then, gives the weights of gates with cast-iron leaves designed by USED. Cast-iron leaves are used for heads to about 100 ft. For higher heads, cast-steel leaves would be used and the gates would be somewhat lighter. However, the unit cost of the steel casting is considerably more than that of cast iron, so that the over-all cost of the gate would be approximately the same as that for the cast-iron leaf gate shown. Therefore, Fig. 2(*b*) gives the weights, for cost purposes, of gates designed to USED specifications, although for heads greater than 100 ft, where the leaf is cast steel, the actual weight will be from 2% to 3% less.

The USED gates shown in Fig. 2 are those for Fullerton, Conchas, Hansen, Dover, Caddoa, Sepulveda, and Santa Fe dams. They were designed for each job, on the basis of a coefficient of sliding friction of 1.00 as set up by the Office of the Chief of Engineers for flood control gates. This coefficient is probably higher than actually exists but, no doubt, was felt to be justified for flood control gates which may not operate under head for years, thus accumulating much corrosion on the sliding surfaces. However, when at last needed during a flood, they must not fail. The normal working pressure in the hoist cylinder is 750 lb per sq in. with a maximum of 1,000 lb per sq in. by the setting of a relief valve.

All other gates shown are designs of the Bureau of Reclamation (USBR). All except Madden, Norris, and Owyhee dams are part of a more or less standard line of slide gates, each size of which is used over the entire range of heads by changing the material in the leaf and applying the proper one of several sizes of hoist cylinders designed to fit mechanically. For heads to 90 ft, cast-iron leaves are used; for heads from 90 ft to 140 ft, semisteel leaves are substituted; and, for heads from 140 ft to 250 ft, cast steel is standard.

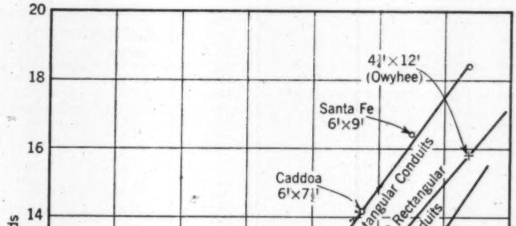

FIG. 3.—WEIGHT OF CAST-IRON CONDUIT SECTIONS

These standard gates are not closely designed for actual heads, therefore; and, when the actual head is used in plotting, they could not be expected to follow a smooth curve as well as if each was designed for an individual condition. Nevertheless, these USBR gates are generally lighter than the flood control gates because the USBR uses a coefficient of sliding friction of 0.60—requiring a hoist and stem only 60% of the capacity of the USED hoists for the same standard working pressure of 750 lb per sq in. In addition, most of the USBR gates shown, have cast steel or semisteel leaves which still further reduce the weight in comparison to the flood control gates. However, the trend of weights in the standard line is roughly proportional to the function $F(W)$ as defined by Eq. 1, with an exponent slightly less than 1.00. On the other hand, the Norris and Madden gates are considerably lighter than would be expected from the trend of the other USBR dams. This deviation is explainable by the fact that the gates were of special size and shape and were specially designed so that the weights are very nearly the most economical for the particular conditions. Also, the normal working pressure on the hoists of these gates is increased to 1,000 lb per sq in., whereas the maximum pressure available for "cracking" the standing friction is at least 50% greater than that of the flood control gates, thereby allowing a further saving in the weight of the hoist for this reason.

TABLE 1.—UNIT COST OF SLIDE GATES, IN CENTS PER POUND

Dam	Location	Year	Number of gates	Size (ft)	Cost bid (¢ per lb)
Hansen	Los Angeles, Calif.	1939	8	5 by 8	14.3
Sepulveda	Los Angeles, Calif.	1940	4	6 by 9	13.4
Stony Gorge	Orleans, Calif.	1926	2	3.5 by 3.5	14
Conchas	New Mexico[a]	1936	12	4 by 5	17.55[b]
Conchas	New Mexico[a]	1939	4	6 by 7.5	12.2[c]
Deadwood	Idaho	1929	2	4.5 by 4.5	15
Alamogordo	New Mexico	1936	2	5 by 5	10
Grand Coulee	Los Angeles, Calif.	1939	..	8.5[d]	15.1
Santa Fe	Los Angeles, Calif.	1946	16	6 by 9	27.25
Bull Shoals	Arkansas	1946	32	5 by 9	31.4[e]

[a] The gates for Conchas Dam were built in Los Angeles. [b] After adjusting this unit cost to west coast delivery, the cost is 16.25¢. [c] This price was too low and should not be considered as a legitimate bid. [d] Ring seal gate, 102 in. in diameter; unit cost is F.O.B. the shop at Los Angeles. [e] After adjusting this unit cost to west coast delivery, the cost is 29¢.

Conduit Lining.—It is anticipated that varying lengths of conduit lining will be required in some cases. Fig. 3 has been developed so that the weight of extra conduit lining can be found. This chart gives weights of 4-ft and 5-ft lengths of rectangular sections and also of 4-ft lengths of circular sections of cast-iron conduit lining. It should be understood that the unit cost used with extra conduit should be lower than the unit cost for the gate. Equations for the weights of conduit sections, in pounds (that is, the equations of the curves in Fig. 3), are: For the 4-ft length of rectangular conduit—

$$W = 1{,}151\,(A + B) - 3{,}445 \qquad (2a)$$

for the 5-ft length of rectangular conduit—

$$W = 1{,}338\,(A + B) - 3{,}943 \qquad (2b)$$

and, for the 4-ft length of circular conduit—

$$W = 370\,D^{1.731} \qquad (2c)$$

Costs.—The approximate shop cost of the gate can be estimated by multiplying the weight by a suitable unit cost for cast iron, machined and fabricated complete. This unit cost will vary with the general economic situation and with conditions in the particular shop. Some idea of the unit costs at which gates of this type have been sold or offered in the past is given in Table 1. The unit cost will also vary with the number of duplicate units involved. Table 2 gives an approximate idea of how the unit cost is thus affected. The table arbitrarily assumes 100% unit cost for the case of ten gates and shows the percentage unit costs for other gates. The data are based on a study of the fixed costs of eleven different jobs as bid by a large manufacturer in the Los Angeles (Calif.) area. This study showed a considerable range between the highest and lowest percentage of fixed costs to total costs when adjusted to a comparable number of gates. The table is arranged to show the effect of this range of variation from the average. In choosing the unit cost factor for a given number of gates, the following general principles should be used as a guide. The fixed costs tend to be higher than average if:

(*a*) The gates are small in size;

(*b*) The costs are quoted when pattern costs are relatively high compared to other costs, as in 1946 postwar conditions; and

(*c*) A large number of gates are involved.

TABLE 2.—VARIATION OF PERCENTAGE UNIT COST OF SLIDE GATES FOR DIFFERENT NUMBERS OF GATES IN CONTRACT

Number of gates involved	RELATIVE FIXED CHARGES IN THE STUDY		
	Lowest	Average	Highest
(1)	(2)	(3)	(4)
1	114	127	134
2	106.3	112	117
3	103.8	106.8	109.7
4	102.5	104.4	106.4
5	101.6	102.9	104.2
6	101	102	102.8
7	100.6	101.3	101.9
8	100.35	100.7	101.1
9	100.1	100.3	100.5
10	100	100	100
11	99.8	99.7	99.6
12	99.7	99.5	99.25
13	99.6	99.3	98.95
14	99.5	99.2	98.7
15	99.4	99	98.5
16	99.4	98.9	98.3
17	99.35	98.8	98.15
18	97.3	98.7	98
19	99.25	98.6	97.8
20	99.2	98.5	97.75
21	99.2	98.45	97.65
22	99.15	98.4	97.6
23	99.1	98.3	97.5
24	99.05	98.25	97.45
25	99.03	98.2	97.4
26	99	98.15	97.35
27	99	98.1	97.3
28	98.95	98.1	97.2
29	98.95	98.05	97.2
30	98.9	98.05	97.15

To obtain the installed cost, transportation cost to the site and erection cost must be added. Erection cost will vary with the location conditions. For average conditions before World War II it was between 3¢ per lb and 4¢ per lb.

RADIAL CREST GATES

The radial or Tainter gate is quite often the most economical type of spillway gate, where it can be used. The length of Tainter gates is usually limited to from 50 ft or 60 ft by the expansion joint spacing in the dam, although gates 80 ft long are in operation at dam No. 24 on the Upper Mississippi project. A service bridge with sufficient headroom is required for the hoisting equipment. Fig. 4, with Tables 3 and 4, gives the weights (including the moving and stationary parts) of a number of radial gates plotted as ordinates against the function:

$$F(W) = \frac{A^2 B H}{10^4} \qquad (3)$$

These weights do not include the hoist and chains. All gates are noncounterweighted for electric hoists except as noted.

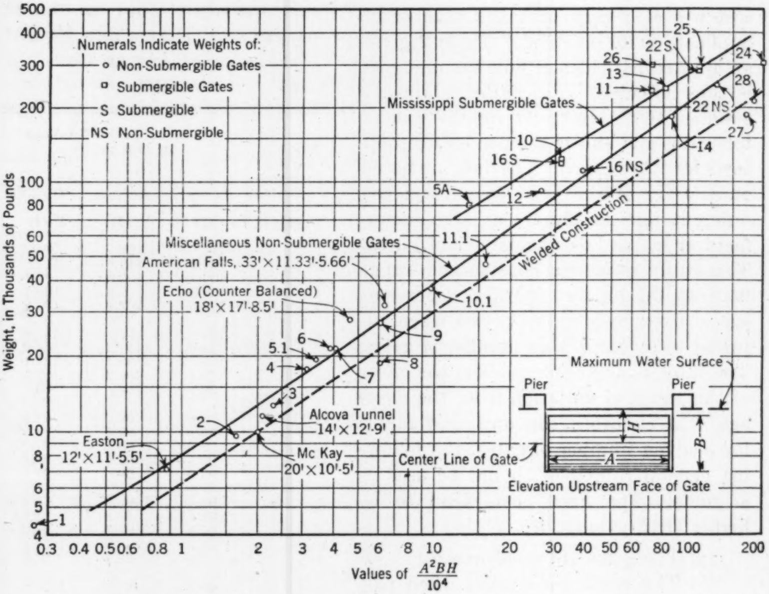

FIG. 4.—WEIGHTS OF RADIAL GATES, MOVING AND STATIONARY PARTS, EXCLUDING HOISTS AND CHAINS

TABLE 3.—UNIT COST OF RADIAL GATES, IN DOLLARS PER HUNDREDWEIGHT, 1939 DATA (PACIFIC COAST DELIVERY[a])

Gates[a]	COMPLETE[b] WITHOUT HOIST AND CHAINS		COMPLETE[b] WITH HOIST AND CHAINS	
	Range	Average	Range	Average
Mississippi gates[c]	\$ 8.70 to \$13.78	\$11.80	\$13.05 to \$17.55	\$13.65
Smaller gates	\$11.00 to \$16.37	\$13.40	\$11.60 to \$21.10[d]	\$16.12

[a] The unit costs in this table are for gates of the conventional riveted construction. The unit costs for welded construction are probably slightly higher. [b] The weights include all moving and stationary parts, with exceptions noted. [c] The freight allowance, on Mississippi gates, from the Mississippi River to the Pacific coast, is \$0.75 per hundredweight. [d] Higher figure due in part to high installation cost.

The information on the Mississippi gates was taken from the contract drawings and specifications and tabulated data made up by the designing offices of the USED. The first twelve items of Table 4 were taken from the work of W. P. Creager and Joel D. Justin,[2] Members, ASCE. Other data were obtained from USBR Specifications 400 to 1,200 and from other publications of USBR.[3,4]

27.......	Wolf Creek[e]	50	37	18.5	1939	16.9

[a] All gates were submergible except 16NS, 14, and 22NS, which are nonsubmergible. [b] These data are from "Hydro-electric Handbook," by W. P. Creager and Joel D. Justin, John Wiley & Sons, Inc., New York, N. Y., 1927, p. 317. Identity of dams and other comparable information were not given. [c] Upper Mississippi River navigation dams. [d] Alloy steel. [e] Welded.

The Mississippi gates are designed for navigation control. For this reason, many of them are submergible—that is, they are arranged for lowering to allow ice and debris to go over the top. Consequently, the submergible gates are heavier than spillway gates, and are shown in a separate curve in Fig. 4.

Except at Caddoa and Wolf Creek dams, all the gates in Fig. 4 are of conventional riveted construction. In the most recent designs, substantial savings have been made in both weight and cost by the use of welded construction. The Caddoa and Wolf Creek gates are of this type. A chart prepared by A. E. Niederhoff,[5] Assoc. M. ASCE, gives the weights of radial gates representative of this type of construction. The dashed weight curve, designated "Welded Construction" in Fig. 4, is plotted to give weights in line with Mr. Niederhoff's chart. Not many gates of welded construction have been built, but the calculated weights of recent designs seem to show fairly close agreement with the "Welded Construction" curve (see Fig. 4). It is possible that better methods of analysis may effect further savings in the weights of this type of gate.

Cost.—The cost of the gate structure can be obtained by taking the weight from the appropriate weight curve and applying a suitable unit cost, estimated from the unit cost data given in Tables 3 and 4—with due regard for the type of construction to be used, location of the installation, and factors peculiar to that particular installation that would affect shop costs or erection costs, or both. The cost of the hoist must be added to obtain the total cost of the gate.

[5] "Selection of Tainter Gates," by A. E. Niederhoff, *Western Construction News*, December, 1943, p. 555.

The weight and cost of the hoist can be obtained from the chart in Fig. 5. Since the weight and cost of hoists are plotted against the hoist capacity, it is

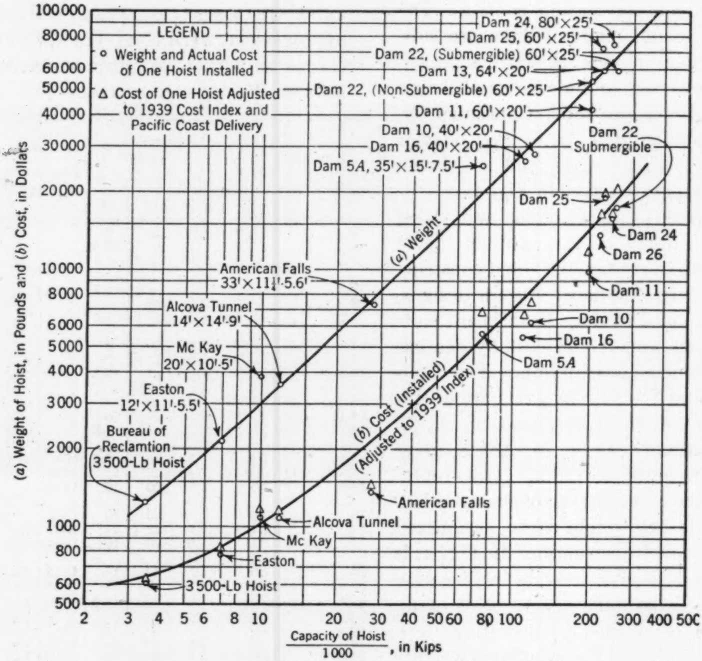

Fig. 5.—Weight and Cost of Radial Gate Hoists

first necessary to estimate the maximum hoist pull required. The hoist pull on the Mississippi gates varies considerably because of differences in ice and silt loading. The weight of the moving part of the leaf on these riveted gates averages about 77% of the total weight, whereas for welded construction the leaf may be nearer to 70% of the total weight as given in Fig. 4. To obtain a rough estimate of the required hoist capacity, it will be on the safe side to take the chain pull due to dead load of leaf, chain, and friction at the point of maximum pull as about equal to the weight of the leaf. To this estimate must be added the ice and silt loading allowed for the particular application. On the Upper Mississippi gates this allowance varies from 30% to 45% of the dead load. In many localities no allowance for ice load is required. The unit cost of the hoist may be taken from the auxiliary curve in Fig. 6.

Roller Gates

The roller gate (sometimes called rolling gate) consists of a steel cylinder with a large pinion at each end, which engages racks built into each abutting pier, and the gate is raised by rolling up these inclined racks. Because of the high section modulus per unit weight, inherent in a cylinder, the roller gate can be built for long spans, thus making a saving in the number of piers required. Also, for the same reason, it is practicable to hoist the gate from one end only. The piers and pier foundations, however, must be larger than those required for radial gates with shorter spans.

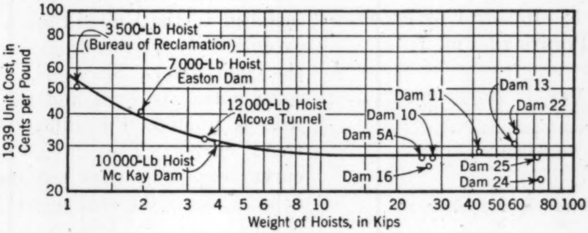

FIG. 6.—AUXILIARY CURVE SHOWING 1939 UNIT COSTS

Although not many roller spillway gates are used, in a complete economic study on a project where a long spillway or wide channel is involved, it is usually necessary or desirable to consider this type of gate against a greater number of radial or other types of gate with much shorter spans. For this reason it is desirable to include weight and cost curves on the roller gate in this paper, although applications (and also available data) are somewhat limited.

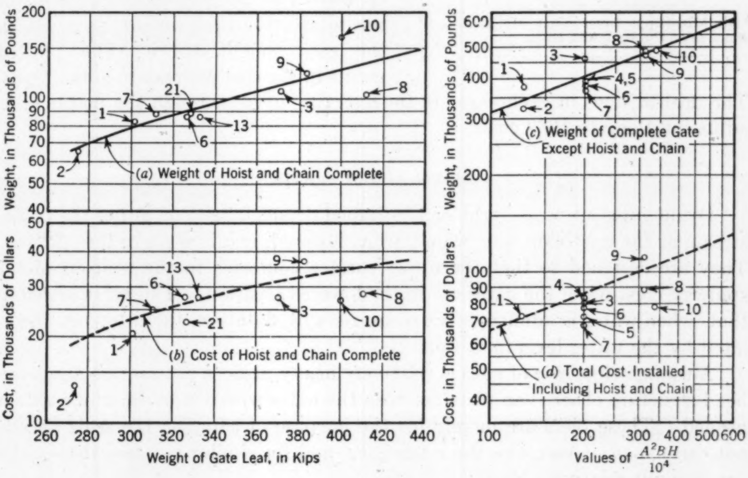

FIG. 7.—WEIGHTS AND COSTS OF ROLLER GATES AND HOISTS

Fig. 7 shows the weights and cost of roller gates and roller gate hoists. The weight and cost of the gates are plotted against the function $F(W)$ as defined by Eq. 3. The identity of the plotted points in Fig. 7, including dimensions (in feet) and other data, are given in Table 5.

[a] All Mississippi River dams except No. 10, which is on the Kanawha River.

Except for one dam on the Kanawha River (point No. 10, Table 5) these gates are all on navigation dams on the Upper Mississippi River. They include the majority of gates of this type installed in the United States, with the exception of a number of similar gates on the Ohio River. Since only very large roller gates are built and the range of sizes is limited, it is difficult to draw trend curves. The "weight of gate" curve (Fig. 7(*c*)) does not include the hoist, whereas the cost curve (Fig. 7(*d*)) is for the gate and hoist complete. The plotted points show the actual cost.

The hoist curves show the weight (Fig. 7(*a*)) and cost (Fig. 7(*b*)) of the hoist and chain plotted against the weight of the moving part or leaf. The average weight of the moving parts may be estimated roughly as about 83% of the total structural weight, as given in the gate weight curve. The plotted points in the cost curves are actual costs. The dashed lines in each case are the average curves through the points after adjusting them to 1939 costs.

DRUM CREST GATES

Drum gates are watertight sector-shaped drums hinged on either the downstream or the upstream side, which, when lowered, rest in a pit in the spillway. They are designed so that the upper surface conforms to the contour of the spillway crest when the gates are in the lowered position. The pit is sealed so that, when water is admitted, the drum rises by flotation, the rate being regulated by the water level in the pit.

Although this type of gate is relatively heavy, it does not require any overhead structure other than piers between the gates where more than one gate is needed. These piers are merely for the purpose of carrying the seals and do not carry load. Also, like the roller gate, and for similar reasons, these gates can be built relatively long.

The weights and costs of representative medium and large-size drum crest gates are given in Fig. 8. The weight and costs are plotted as ordinates against the function $F(W)$ as defined by Eq. 3. Weights are for the complete gate including all anchorages, hinge castings, and other stationary parts as well as piping and apparatus for automatic control. The costs are for the complete gate installation, except in the case of Salinas gate. Adjusted unit costs (1939 basis) are as follows:

Dam (Fig. 8)	Cents per pound	Remarks
Tieton	13.2	....
Sepulveda	11.45	Hinged downstream
Florence Lake	25	Long truck haul into high mountains
Black Canyon	15.1	....
Guernsey	13.27	....
Easton	12.2	....
Boulder	10.91	....
Salinas	15.7	Includes 3.1¢ per lb for installation
Grand Coulee	11.78	....
Morris	....	Hinged downstream

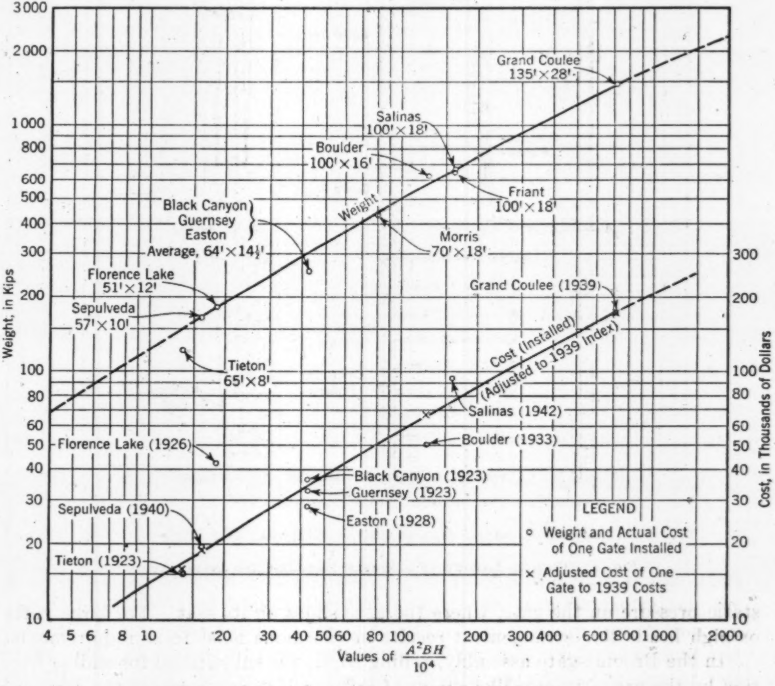

FIG. 8.—WEIGHTS AND COSTS OF DRUM CREST GATES

As indicated, all gates were hinged on the upstream side except those at Sepulveda and Morris dams.

Quite close estimates should be obtained from these data since all the points lie fairly close to the curves. Because of this it seemed justifiable to extrapolate the weight curve at both ends, thus extending the range considerably. However, the extensions are shown by dashed lines to the limits of the page.

Broome-Type Caterpillar Gates

Under the heading, "High-Pressure Slide Gates," it was mentioned that hoisting capacities are required in the order of from 60% to 100% of the entire static pressure on the gate, where the gate slides on its seat. For large gates or high heads this arrangement results in enormous hoist force requirements.

Fig. 9.—Typical Layout of a Simple Broome-Gate Installation

In the Broome-gate assembly, rolling friction is substituted for sliding friction by the use of tractor-like chains of rollers which roll between the gate leaf and a stationary vertical track on the gate frame. The leaf moves in a vertical direction, therefore; but the seals are inclined at a slight angle from the direction of travel so that when the gate is closed the sealing surfaces at each side just touch. Any movement upward, in opening, lifts the leaf from the seals—eliminating sliding friction on the seal surfaces, with the result that the friction force is reduced to less than 5% of the static pressure. The gate is so designed that there is a sufficient downward component in the hydrostatic pressure on the gate at all times to insure closure, without requiring downward thrust from the hoist. This construction makes possible the use of simple drum hoists and sheaves. Fig. 9 shows a typical layout of the gate.

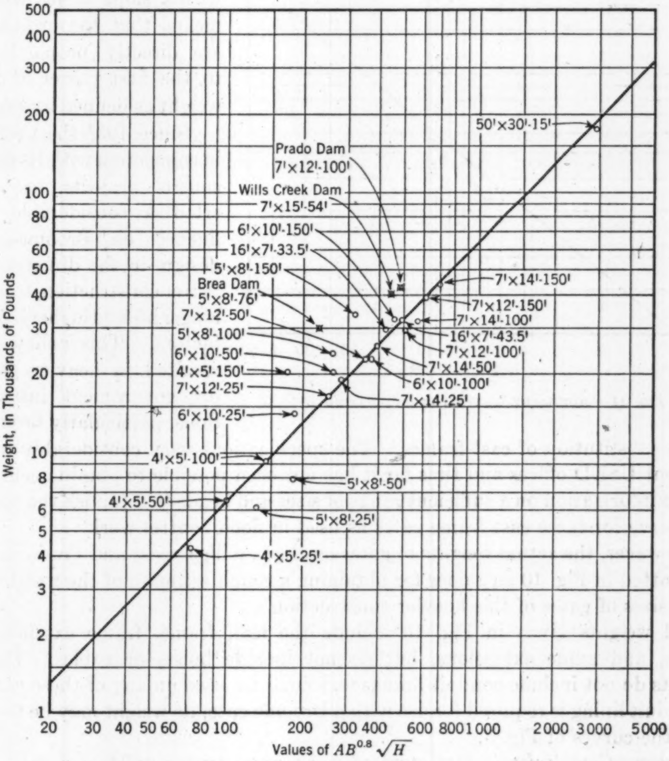

FIG. 10.—WEIGHTS OF BROOME GATES

To obtain an authoritative estimate of the price and weight of the gates made by any individual manufacturer, it is, of course, necessary to submit the requirements and some details of the installation to him before a quotation can be obtained. However, for rough preliminary studies, this is inconvenient and takes time. In Fig. 10 the available weights of a considerable range of this particular make of gates have been plotted as ordinates against the empirical function:

$$F(W) = A\,B^{0.8}\,\sqrt{H} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The auxiliary curve is also given (see Fig. 11) to evaluate $B^{0.8}$ quickly so that values of the abscissa can be obtained by a simple slide rule operation.

In Fig. 10, the points marked by the gate size only, represent a more or less standard line of gates which have been supplied to the hydroelectric industry for many years. The leaves of these gates, and in most cases the frames, are constructed of structural steel. The line drawn through the average of these points is a straight line with a slope of 45° which means that the ordinates are directly proportional to the first power of the weight as defined by Eq. 4.

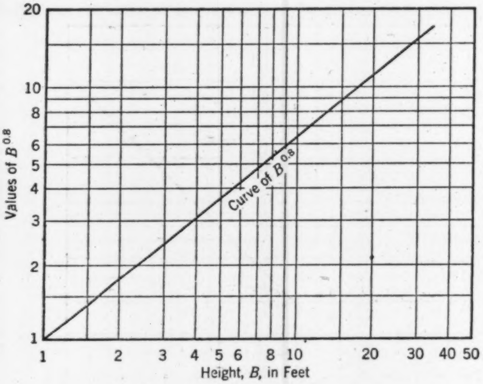

FIG. 11.—AUXILIARY CURVE FOR EVALUATING $B^{0.8}$

Since 1935 the USED, in connection with its flood control projects, has exerted a considerable influence on Broome-gate design, in the direction of better construction, to give longer life and higher safety factors. This policy has resulted in heavier gates for government installations, particularly because of the substitution of cast frames. The specifications vary considerably with different USED offices and thus far it has not been possible to obtain accurate weight information on a sufficient range of sizes and heads to establish the trend of a curve for these cast frame gates as used in flood control work.

However, the actual weights of gates on Brea, Wills Creek, and Prado dams are plotted in Fig. 10 as guides for obtaining a rough estimate of the weight of other sizes of gates of this heavier construction.

All weights given in Fig. 10 include the leaf, frame, frame extensions, guides, and guide extensions, but do not include hoists or cables. These weights do not include conduit linings and none are used on any of these gates. If conduit lining is required for use with a Broome gate, its weight may be taken from the curves of Fig. 3.

Broome-Gate Hoists.—The required hoist capacity for a Broome gate depends, among other conditions, on the displaced volume of the leaf which, for preliminary estimates, is not known. Fig. 12 was developed from a study of the hoist requirements of existing gates. Hoist capacities are plotted against the empirical expression:

$$F(W) = A^{1.173} B^{0.82} H^{0.94} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Auxiliary curves are given for the determination of the fractional powers of the variables (see Fig. 13). Curve No. 2, Fig. 12, shows approximate hoist capacities for the utility line of gates, whereas curve No. 1 is for use on the higher class of gates described. Knowing the required hoist capacity, the weight of the nearest standard hoist can be determined. Each hoist has a considerable range of capacity depending on the roping. The speed will vary inversely as the capacity for the same hoist with different roping.

Costs.—As a rough guide to obtain the cost of Broome gates for government projects, the following unit costs, adjusted to 1939 level, are given:

Gates installed at:	Cents per pound
Ohio Dams (1935)—	
Wills Creek	25.1
Beach City	25.1
Southern California Dams—	
Prado (1939)	20.2
Brea (1940)	23.7

These costs are for gates delivered complete at the site with hoists, but do not include installation. The weights of the gate and hoist should be added together in applying these costs. The installation cost may be taken at from about 3¢ to 4¢ per lb for average conditions and locations close to centers of population.

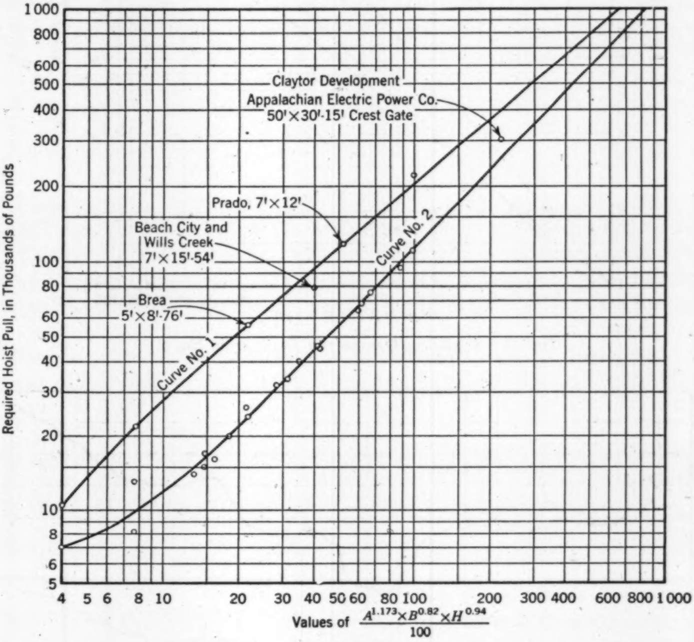

FIG. 12.—WEIGHTS OF HOISTS FOR BROOME GATES

Cost Index.—The cost level of 1939 has been taken as a representative level of prices before the inflation caused by World War II. For convenience in adjusting costs to this base, the curves in Fig. 14 have been plotted from the *Engineering News-Record* Construction and Building Cost Index of April, 1946.

The cost adjustments in Figs. 5 to 8 have been made in accordance with the yearly averages shown in the building cost index curve (Fig. 14(*b*)), since the

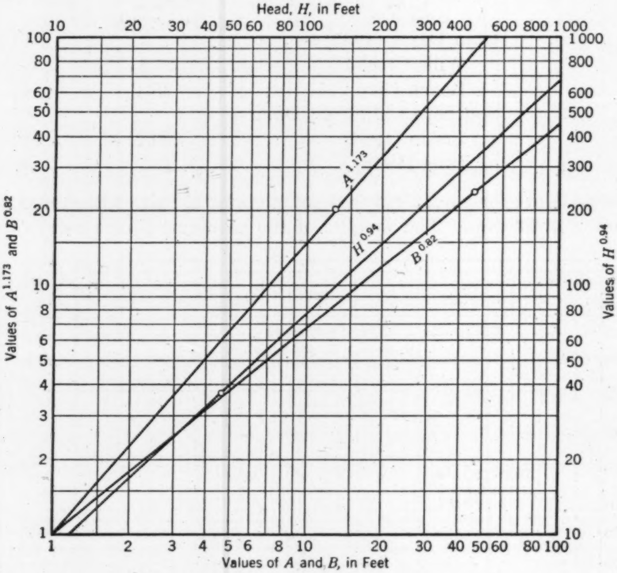

FIG. 13.—AUXILIARY CURVES FOR EVALUATING EQ. 5

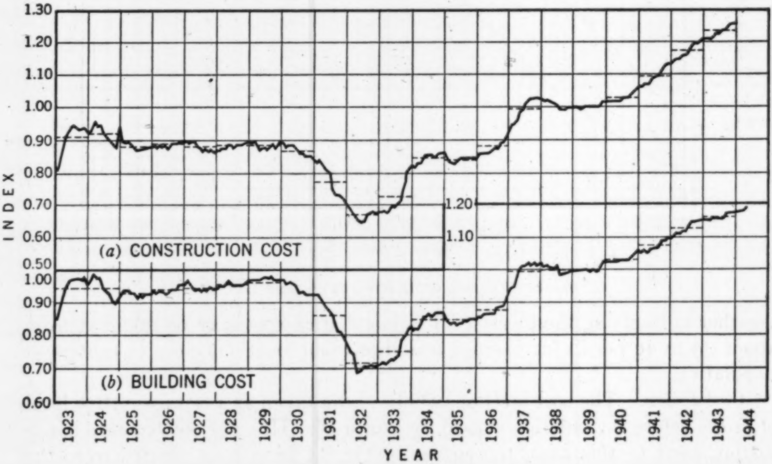

FIG. 14.—COST INDEX CURVES, ASSUMING THE 1939 AVERAGE COSTS EQUAL TO 1.00

best information obtainable seemed to indicate that this curve most nearly represented changes that occurred in shop cost previous to the war. However, a review of bids on both the cast-iron gates and fabricated steel gates received during 1946 definitely indicates that this curve does not reflect the true increase in gate costs for the postwar conditions. Unit costs in 1946 seem to be about double the 1939 costs.

SUMMARY

The estimating charts in this paper can be utilized to advantage in three different ways:

a. As timesavers in preliminary studies to determine the most economic type of gates and the most economical over-all arrangement on the project;

b. As instruments for making consistent preliminary estimates of weights and costs for definite project reports before actual design of gates has been made; and

c. As checks to compare final designs with those compiled previously, to assure the designer that he is not wasting material on the one hand, and as checks against gross error or omission affecting the safety of the structure on the other.

ACKNOWLEDGMENT

Various offices of the United States Engineer Department furnished valuable data for this paper in connection with the radial and roller gates on the Upper Mississippi and Ohio rivers. The writer is also indebted to the Bureau of Reclamation, United States Department of the Interior, both for data furnished directly through the courtesy of the Chief Engineer's Office in Denver, Colo., and for data taken from its various publications and specifications. The courtesy of the Phillips and Davies Company, the Southern California Edison Company, and the Consolidated Steel Corporation in furnishing data on gates is also greatly appreciated.

In particular, the writer acknowledges the helpful suggestions and criticisms given by associates in the Los Angeles Office, USED, and the courtesy of that office in extending permission for publication of these data.

DISCUSSION

Theodore B. Rights,[6] Assoc. M. ASCE.—In this discussion the writer will confine his remarks to radial crest gates. Unless the stress used is noted on the design of the structure a person who is seeking to compare his structure with the one previously designed, is "in the dark." In comparing a newly designed radial gate with an older gate that had a head 5 ft less, the writer was amazed that his designed sections were smaller in size. On investigation he found that, although the skin or face plate of this older gate was designed for 16,000 lb per sq in., the supporting members were only stressed to a maximum of 10,000 lb per sq in., whereas the writer was using 18,000 lb per sq in. throughout. It would be worthwhile if Mr. Boissonnault were to qualify his charts by taking the design stresses into account. For example, the following equation for the weight of the radial or Tainter type of gates[7] makes allowance for unit stress:

$$W = \frac{935\, B\, H_d}{\sigma} \left(A_s^2 + 700\right) \qquad \text{(6a)}$$

and

$$w = (A_s + 2\, B)\, 125 + 225\, L \qquad \text{(6b)}$$

in which, conforming to the notation of the paper: W is the weight of the gate (moving parts), in pounds; w is the weight of the embedded metal, in pounds; L is the length of gate lift, in feet; B is the height of the gate, in feet; H_d is the design head to the bottom of the gate measured in feet; σ is the design stress of the material, in pounds per square inch; and A_s is the clear span width of the gate, in feet.

(Incidentally, it may not be amiss to re-emphasize the widespread misspelling of the word "Tainter." Although the author spells it correctly, it appears as "Taintor" even in some of the most modern technical textbooks. The records of the United States Patent Office for July 6, 1886, show, under "canal lock," that patent No. 344,879 was registered by Jeremiah Burnham Tainter of Menomonie, Wis. The device therein described is the well-known Tainter gate.)

Many of the gates used by the power companies are adaptations of old gates, in which the stresses at the time of their design were 16,000 lb per sq in. One company, specializing in hydroelectric design, does not have a gate in their files that has been designed for 18,000 lb per sq in. When this company receives an order from a client company to design a gate, they search their files, select one of these gates (16,000 lb per sq in), secure "photolithos," and block out titles and elevations. In fact, one of the greatest difficulties in doing this is to detect the old sections that have not been rolled in the past few years. This company should not be overly criticized for using these uneconomical designs as the steel detailed drawings have been made. Photolithos of these details serve the shop just as well as new details, and the cost of making the shop drawings is thereby reduced about 80%, which should give the client company a cheaper job than if a new design with new detail drawings were used. Of course, in order to do this the contract for the gate must be given to the original fabricator.

[7] "Engineering For Dams," by W. P. Creager, J. D. Justin, and Julian Hinds, John Wiley & Sons, Inc., New York, N. Y., Vol. III, 1945, p. 906.

The writer has used the charts by A. E. Niederhoff[5] and the results approximate closely the weights obtained from the writer's designs. These weights are for the gate only and not for the anchorage which comprises the larger part of the embedded steel. For an estimate for the larger gates, the writer uses 60% of the gate weight for the weight of the embedded steel. The weight of the anchorage is not directly a function of the gate weight. The location of the pin, both horizontally and vertically, will change the hinge reactions. For identical gate widths and heights, but with different pin locations, different anchorages may be required. For a small hinge reaction, the pier width is usually narrow. Most installations of these small gates have a continuous pin that runs through the pier, so that one arm of one gate and one arm of the adjacent gate rotate on the same pin. This pin is held back by pin plates with anchor rods bolted to them, and the entire assembly is grouted into the pier with only the pin ends cantilevering out. The main anchor rod can be placed in the line of action of the hinge reaction. For gates more than 33 ft wide with a 30-ft head, the piers must be much wider for stability. It would be impracticable to run the pin through the piers, so an anchorage casting placed on cantilever beams is used most frequently. These cantilever beams, both horizontal and vertical, are held down by anchor rods. Since these anchor rods are horizontal and vertical, they must take the components of the hinge reactions, and they are larger, therefore, than the anchor rods placed in the line of the hinge reaction. This type of construction increases the weight of the anchorage considerably. The writer believes that this in part explains the discrepancy between the actual weights and the weights obtained from Eq. 6*a*.[7]

The weight of the embedded steel as well as the hoist weight may vary because of the nature of the installation. If a music-note seal (such as that used on some of the Tennessee Valley Authority radial gate installations) is used instead of a wood seal, the friction of the seals is increased and the hoist may have to be increased for this item. In some climates, as stated by the author, the weight of ice and silt on the gate is considerable. The writer has found that it is better actually to compute the hoist requirements, than to use any published data.

The writer further believes that a distinction should be made in this paper between fixed and movable hoists. Some dam installations have been made in the United States, in which a movable or traveling hoist car is used for three or four gates. Of course, a suitable structure must be provided for this movable hoist but, as it is made of structural steel, its cost can more easily be computed.

The writer believes one of the reasons that the welded gates weigh less than the riveted ones is that they, being more modern, have been designed for the higher stress of 18,000 lb per sq in.

The values obtained from the charts in this paper are useful; but it must be remembered that they should be used for estimating purposes, rather than as a rigid control on the design weight. Discussing this point, James S. Bowman, M. ASCE, states:[8]

> "The general layout of a Tainter Gate is a matter of trial and judgment since there is no fixed relation between the length of the arms and the height of the gate. The pins should be above ordinary high water, and the bottom of the gate when raised should clear floating material carried by the extreme flood. The shorter the radius of the face or the greater the inclination of the chord from the vertical, the heavier the gate will be."

Elsewhere it is stated:[9]

> "The radius of curvature affecting the direction of this upward pressure (upward vertical component of the water pressure), also has an important bearing on the relative dead load reaction at the chain and trunnion, on the length and height of the pier, and the weight of the struts."

From the foregoing it can be seen that two gates of identical widths and heads can be of different weights because of the different radii to the face plate and because of the different heights of pins above the crest. A good example of this can be seen in gates 3 and 4, Table 6. With the exception of gate No. 10, the curved skin plate is supported by horizontal channels variably spaced which in turn are supported by vertical ribs that frame into the trunnion arms. Gate No. 10 has the curved skin plate supported on equally spaced vertical ribs which are in turn supported by horizontal beams that frame into the trunnion arms.

For the writer's work, it would be best to have the gate weight separated from the total weight of the gate and the embedded steel. The charts do not give the height of hoist or lift as a variable. In canal work, most gate installations will have approximately the same lift, but in power or water dams, where large flows of water must be passed so as to have a constant head on the turbines or pumps, the lift of gate must be peculiar to that installation.

[9] "Manual of Engineering Construction," Canalization, Vol. II, The Engineer School, U. S. E. D., Fort Belvoir, Va., 1940, p. 289.

George R. Latham,[10] Assoc. M. ASCE.—Presented in convenient form, these detailed data based on actual water control gates and hoists should prove of considerable value in estimating costs and preparing preliminary designs. The data have been wisely divided into weights and unit costs to permit the engineer to make proper allowances for the various factors affecting a specific project. The materials included are clearly noted and, as the author states, published data are usually too vague in the material included. In a typical Tainter gate design, the weight of the embedded steel and the anchorage commonly varies from one fourth to one half of the weight of the Tainter gate itself, which indicates the relative importance of the embedded material and of its inclusion in the estimate.

The weights of Tainter gates for private utility projects with which the writer has been associated have been plotted and checked with Fig. 4, and are in close accord with the curve for nonsubmergible gates. However, the weights and costs of the hoists are slightly higher than the values shown in Fig. 5; these would vary somewhat, as the actual hoist construction is dependent upon the requirements of the governing specifications. The data for the Tainter gates and hoists are given separately, thus enabling the designer to determine the relative saving by using a traveling hoist in place of fixed hoists when there are a large number of gates.

TABLE 7.—Cost of Materials per Pound for Tainter Gates and Hoists[a]

Project	Gates				Hoists

[a] Delivered at job site.

For the designer to make a comparison and determine the most desirable gate for a specific project, all suitable types of gates should be considered. This paper covers the usual types of gates with the exception of the common wheeled lift gate with either plain or roller bearings. This popular gate has been proved satisfactory, being used both for crest gates and for submerged intake gates; a pertinent article has been published by G. R. Rich and Ross M. Riegel,[11] Members, ASCE, as well as a discussion by P. E. Gisiger,[12] M. ASCE, on the same topic. Its cost compares favorably with other types, since it is a relatively simple fabricated structural steel gate, and good competition is usually obtained on bids. Published data on costs and weights of lift gates and hoists are also scarce and vague concerning the material included. Information on lift gates in a form similar to that provided in this paper would be of value, and would provide excellent material for a subsequent paper.

---

[10] Structural Engr., Ebasco Services, Inc., New York, N. Y.

In a period when material and labor costs are skyrocketing the estimator is in a very difficult position to prepare a reasonably accurate cost estimate. The writer has had occasion to install duplicate gate and hoist equipment on several projects and it is believed that the costs given in Table 7 may be of interest. To these prices must be added the erection costs, which indicate that the author's closing comment, "Unit costs in 1946 seem to be about double the 1939 costs" does not err, conservatively speaking.

In closing, the writer wishes to commend the author for an excellent paper.

D. A. Buzzell,[13] M. ASCE.—A valuable tool for the estimator's use in computing the probable weight and cost of certain types of gates is provided in this paper. An excellent model is set up for further investigations along the same or related lines.

It is noted that the vertical-lift crest gate is not covered by the author. The vertical-lift crest gate, in widespread use on larger rivers, is usually a fixed-wheel type from 40 ft to 50 ft wide and up to 50 ft high. Such gates usually are operated with one or more traveling gantry cranes; and, for comparison, it is necessary to take account of the costs of both these cranes and the required heavy operating bridge. In other words, a cost study of a dam spillway, for which either Tainter gates with fixed individual hoists or crane-operated vertical-lift gates are considered suitable, necessitates the preparation of two rather complete designs. This problem arises quite frequently in planning spillways and it is obvious that cost and weight curves given in this paper have only limited application to such a comprehensive problem.

The type of hydraulic slide gate shown in Fig. 1 has been considerably modified in the recent design practice of the Corps of Engineers, and higher cylinder working pressures are in common use. The air inlet area has been stepped up from 5% to 10% of the gate area depending on water velocity; the sill depression has been eliminated, and many changes have been made in the gate leaf details. The extent of conduit length protected by liner plates has also been reduced. The net effect of these changes has been a reduction in the over-all weight and cost. All-welded carbon steel designs are being considered for this type of gate.

The Corps of Engineers has developed a new Tainter or radial crest gate with inclined side frames and a box girder anchorage which has effected a marked saving in weight over the values shown in Fig. 4. A recent instance in which Tainter gates already contracted for and designed according to older practice were redesigned according to the new standards furnished decisive proof that the latter design would result in pronounced economy.

[12] "Economic Design of Waterways and Gates," by P. E. Gisiger, *ibid.*, May, 1941, p. 308.

[13] Office, Chf. of Engrs, Washington, D. C.

The fact that future design practice will not be limited to the types of gates discussed in this paper is indicated by a recently proposed installation of Tainter gates in the outlet conduits of a large dam. There would be single 24-ft by 24-ft gates under 180 ft of head in each of seven outlet tunnels, 23 ft in diameter. The indicated saving over vertical-lift outlet gates was $300,000 per conduit or $2,100,000 for the project.

It is regretted that the study was not extended to include caterpillar gates, a large variety of which are used in flood control outlets and power conduit intakes.

A. E. Niederhoff,[14] M. ASCE.—The tabulations and charts given by Mr. Boissonnault have filled in gaps in data on reservoir gates. It is very commendable that the author has taken the time to assemble this information and to correlate it for use by other members of the profession. As stated in the "Summary," the charts are of immense value in making preliminary estimates quickly and consistently. Any engineer who has worked in the planning department of the United States Army Engineers knows how necessary it is to have charts such as these for reference. Exception is taken, however, to the use of the charts in checking a detailed and finished design.

The charts yield only traditional or historic values and do not take into account advances made in design. If the final, detailed design of reservoir gates had to conform in weight to values from the charts, no improvement would have been made over former designs. New materials and new techniques of fabrication are available which reduce the weights of gates and it is entirely conceivable that other improvements will be made in the future. The trend is away from steel toward noncorrosive light metals.

The text of the article is excellent in content but one important phase has been omitted. If the author had included a discussion on the applicability of the various types of gates, his paper would have been a veritable treatise. Under what conditions does one use a slide gate? In addition to personal preference, there are several other reasons why slide gates are used instead of Broome or submerged Tainter gates. Similarly, drum gates are used on the crests of dams under certain conditions which make the cheaper Tainter gate inapplicable. Not only are economic items involved, but also hydraulic characteristics and operational factors. Perhaps the author will cover these very significant items in his concluding discussion as well as a typical example of the use of his charts.

One important crest gate on dams that was not mentioned is the vertical-lift gate. The writer published a short article on this subject,[15] during the preparation of which it became more and more apparent that the vertical-lift gate is economical for streams having large discharges where ice conditions are unusual. Curves were developed yielding the weight of the gate and the discharge through a gate opening. By the use of formulas the cost of the gate could be obtained, the discharge through a gate could be computed, and the number of gates composing the spillway could be calculated. Through a typographical error in the text the formula for the cost of a gate gave ridiculous results. Using the author's nomenclature and a construction cost index of 116 for the year 1940, this formula should have been:

---

[14] Specification Writer, U. S. Naval Ordnance Test Station, China Lake, Calif.

[15] "Vertical Lift Gate Selection," by A. E. Niederhoff, *Western Construction News*, February, 1944, pp. 73–75.

$$\text{Cost per gate} = 60\left(\frac{A^2 B^2}{2{,}000}\right)^{0.87} \quad\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

It would be of interest to know if the author checks this formula for cost of vertical-lift gates for dams.

The author mentions that welded Tainter gate weights are in fair agreement with the dashed line shown in Fig. 4, and that weights derived therefrom agree with curves published by the writer. He qualifies the use of this curve with the statement (under the heading, "Radial Crest Gates"):

> "Not many gates of welded construction have been built, but the calculated weights of recent designs seem to show fairly close agreement with the "Welded Construction" curve (see Fig. 4)."

Since World War II, when speed of production, economy, and safety dictated that welded steel ships and welded armored steel tanks were necessary, the knowledge of the art of welding has increased. Many ship building concerns used welding equipment exclusively and did not have the tools for doing riveted construction. As a result it is believed that in the future Tainter gates will be welded and Mr. Boissonnault's dashed line curve in Fig. 4 will represent weights that are more currently correct.

The writer wishes to reiterate that, in spite of a thorough checking and rechecking of this fine paper, he has found little cause for complaint. The author has had the time and opportunity to do a fine job of assembling and correlating information and is to be congratulated on his work.

JOSEPH R. BOWMAN,[16] Assoc. M. ASCE.—A great deal of painstaking work in assembling data on gates and hoists and in correlating the several factors contributing to the cost of such equipment is reflected in this paper. The graphical estimating methods presented by the author should have considerable practical value to engineers engaged in the study of water storage and power projects. Although the general methods employed are not new,[2] much of the data presented concerns recently designed equipment, thus reflecting modern trends in engineering practice. The writer endorses the use of graphical methods for estimating purposes in preference to more direct methods because the practical limitations may be shown more clearly in graphical form.

The particular types of gates with which the paper deals have been given excellent treatment, but the field of extensively used modern reservoir gates has not been fully represented. The general field of vertical-lift gates, of which the Broome gate is but one type, should receive further consideration; consequently, much of this discussion will be devoted to gates in this field.

---

[16] Hydr. Engr., Harza Eng. Co., Chicago, Ill.

High-Pressure Slide Gates.—The author has presented a seemingly reliable method of determining the weight of hydraulically operated, high head sluice gates, but Eq. 1 appears to be rather complex for estimating purposes. The writer notes that the weight curve in Fig. 2 has been drawn through points representing only United States Engineer Department (USED) flood control gates, whereas an additional curve, lying somewhat below the author's curve, can be drawn to represent the Bureau of Reclamation (USBR) general-purpose type of high-pressure slide gate.

It is regretted that methods for determination of weights were not presented for high head gates of the ring follower, ring seal, paradox, coaster, and tractor types—as well as for the butterfly, needle, Howell-Bunger, and other types of high-pressure valves. It is hoped that the author may see fit to include supplementary information of this nature in his closing discussion.

The effects of standardization of design on unit prices for the fabrication of gates are well illustrated in Table 2. Although the comparative values shown in this tabulation were derived from prices for high-pressure slide gates, they may be applied with a reasonable degree of accuracy to other types of gates. Further economies are to be realized from standardization of design in the reduction of design costs and other indirect costs.

Tainter Gates.—The writer sees no justification for changing the direction of a gate weight curve to qualify a single (and possibly doubtful) point, as the author has done in the case of the lower end of the middle curve in Fig. 4.

The curves for Tainter gate weights published by A. E. Niederhoff,[5] M. ASCE, replotted in Fig. 4 to express the weights of welded Tainter gates, appear to be quite reliable; inspection of Mr. Niederhoff's article[5] substantiates Mr. Boissonnault's implied belief that the weights expressed by this curve include the combined weights of gate, guides, and anchorages.

The author implies that no relationship can be shown to exist between Tainter gate weights and hoist capacities. However, it can be shown that the majority of points in Figs. 4 and 5 will lie on common curves corresponding to submergible and nonsubmergible types of Tainter gates, respectively, when hoist capacity is plotted against Eq. 3.

Roller and Drum Crest Gates.—Because roller and drum crest gates are usually designed to satisfy the specific requirements of the respective jobs for which they are selected, their weights should be expected to conform to definite characteristic curves. This observation seems to be borne out by the drum gates in Fig. 8, but does not appear to be substantiated by the roller gate points in Fig. 7. Conformity of the drum gate points to a common characteristic curve may be due to the more exacting operational requirements imposed on this type of gate.

Broome Gates.—Figs. 10 to 13, inclusive, for the Broome-type caterpillar gates use parameters considerably more complex than expressed in Eq. 3, but the results obtained through the use of such expressions appear to be more consistent than those obtained by the employment of other methods of analysis. However, the weights of these gates may be indicated approximately in terms of Eq. 3 with sufficient accuracy for preliminary comparison with other types of gates, as will be shown later.

Vertical-Lift Gates in General.—Both the Broome and fixed-wheel types of vertical-lift gates have been used extensively in the low head field as submerged intake gates. Both may be used advantageously as spillway crest gates, particularly where large flows are to be passed over comparatively short regulated spillways; their ability to be raised entirely clear of the water surface gives these gates a further advantage over Tainter gates. Although the Broome gate generally has better seating characteristics than the fixed-wheel gate, the latter has the distinct advantage of considerably lower gate cost. Moreover, the fixed-wheel gate can be split readily into two or more individually handled sections, thereby materially reducing hoist costs with but a small increase in the weight of the complete gate.

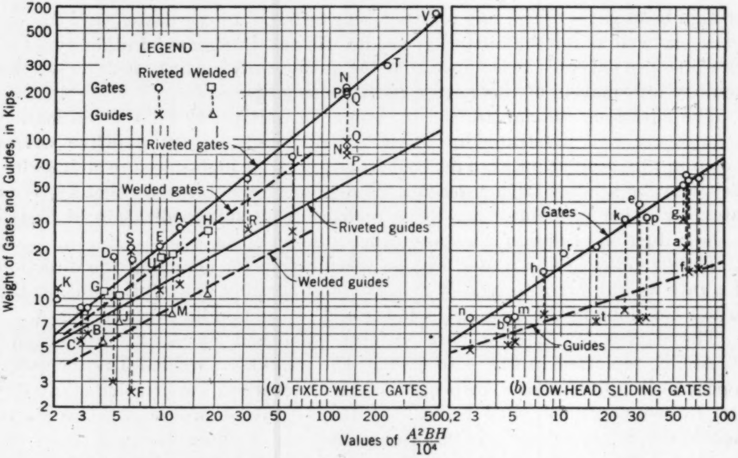

Fig. 15.—Weight of Fixed-Wheel and Low Head Sliding Gates and Guides

Although Broome and fixed-wheel gates may be operated against either full or balanced heads, low head sliding gates are restricted to operation against balanced heads because of their relatively high frictional resistance, and hence are used primarily as bulkheads. Gates of this type have been used on spillway crests as temporary bulkheads, and at hydro plants to close draft tube outlets so that the water passages may be unwatered. Sliding bulkhead gates are frequently used in hydro plant intakes in conjunction with Broome or fixed-wheel gates, thus effecting a saving in intake gate costs.

Fixed-Wheel Gates.—The weights of several fixed-wheel gates and their guides (embedded parts) are shown in Fig. 15(*a*); accompanying dimensional and cost data are given in Table 8. The majority of these gates are of a conventional type of construction, wherein the skin plate is welded to a framework of standard structural shapes with riveted connections. The development of all-welded gates has progressed to an extent which permits their segregation from gates employing older methods of construction. The writer has found it advantageous to be able to make a distinction between gate and guide weights; accordingly, the points and weight curves shown in Fig. 15(*a*) indicate the separate weights of gates and guides for both riveted and welded types of construction. Weight curves developed for fixed-wheel spillway crest gates by Mr. Niederhoff,[15] when replotted in terms of Eq. 3, coincide with the writer's weight curve for riveted gates (exclusive of guides)—thus applying to intake as well as to spillway crest gates.

[a] Installed on projects designed by consulting engineer. [b] Designed by manufacturers. [c] Spillway crest gates; remainder, power intake gates. [d] All-welded construction. [e] Designed by the Tennessee Valley Authority (TVA); corrosion allowance of 1/16 in. added to skin plates and principal frame members.

The points representing gate K lie considerably above their respective weight curves; the gate was designed for a probable future increase in operating head, and the guides presumably were designed to reduce installation costs at a small increase in first cost. Unfortunately, installation cost data to substantiate the latter conclusion are not available to the writer. The guides of gates N, P, and Q consist of rails mounted on steel towers embedded in the concrete piers;[17] the accomplishments of this design were twofold in that accurate field alinement of the guides was assured at low unit costs of installation.

The writer has indicated no graphical relationship between gate weights and weights or capacities of hoists for fixed-wheel gates, as the methods of application of hoisting equipment in the hydroelectric power field vary considerably. However, in the case of spillway crest gates having wheels equipped with antifriction bearings, the capacity of the hoist should at least equal the weight of the gate plus frictional resistance of about 3% of the total water pressure on the gate. In considering the use of a traveling hoist, the weight of a lifting beam or other device should be added; the weight of a lifting beam depends on its application and may vary from 5% to 25% of the weight of the gate. Hoist capacities may be reduced by sectionalizing gates handled by traveling hoists, or by counterweighting gates lifted by fixed hoists. Hoist capacities for power intake gates vary widely, depending on the method of operation (whether against full or balanced heads) and on the design of the gates themselves. A typical example of the effect of gate design on hoist capacity is given in Table 9, which summarizes a study made to determine the most economical design for gate M in Fig. 15(*a*); this gate is designed for operation against full hydrostatic head, and its wheels are equipped with grease-lubricated roller bearings. Price estimates furnished by a gate manufacturer indicate that the cost of a 16,000-lb gate of built-up plate construction would be approximately the same as the cost of a 19,000-lb gate of standard shape construction. Thus, the cost of gate 3M is greater than that of gate 4M by the cost of ballast required to seat gate 3M.

---

TABLE 9.—SUMMARY OF ECONOMIC STUDY FOR SELECTION OF DESIGN FOR ALL-WELDED GATE M IN FIG. 15(*a*)

Design	LOCATION OF:		Construction	WEIGHT (LB)		Required hoist capacity (tons)
	Skin plate	Bottom seal		Gate only	Ballast (seating)	
(1)	(2)	(3)	(4)	(5)	(6)	(7)
1M	Upsteam	Downstream	Standard shapes	19,000	29,000	27.5
2M	Upstream	Upstream	Built-up plates	16,000	None	35.0
3M	Downstream	Downstream	Built-up plates	16,000	3,000	20.0
4M	Downstream	Downstream	Standard shapes	19,000	None	20.0

FIG. 16.—WEIGHT OF OUTDOOR GANTRY CRANE GATE HOISTS

Fig. 16 shows approximately the variation of crane weight with hoist capacity (based on project reports for several TVA projects) for outdoor gantry cranes. Installed unit costs (adjusted to 1939 index) for outdoor gantry cranes with trolleys and auxiliary hoists ranged from 20¢ per lb to 30¢ per lb.

Low Head Sliding Gates.—The weights of several low head sliding gates and their guides are shown in Fig. 15(*b*); accompanying dimensional and cost data are given in Table 10. Hoists designed exclusively for handling low head sliding gates operated against balanced heads ordinarily require capacities slightly in excess of the weights of the gates. The excess capacity is equivalent to the weight of a lifting device plus a nominal force required to break the gate away from its sealed position; where sloping guides are used, frictional resistance due to the weight of the gate will be encountered. Gates f and j were sectionalized to reduce hoist costs. Fig. 16 also indicates approximately the variation of crane weight with hoist capacity for outdoor gantry cranes with fixed hoists. Installed unit costs (adjusted to 1939 index) for these cranes ranged from 25¢ per lb. to 40¢ per lb.

[a] Designed by consulting engineer. [b] Power intake gates; remainder, powerhouse draft tube gates. [c] TVA projects. [d] All-welded gates.

Miscellaneous Types of Gates.—During the period between World War I and World War II many types of water control gates were developed; the gates treated in the paper and in this discussion represent the surviving types more commonly used in modern practice. Occasionally, however, it is necessary to resort to special gate equipment adaptable to unusual site conditions. A few noteworthy examples of the use of special gates include the utilization of butterfly spillway crest gates at Exchequer Dam[18] (California), cylinder intake and outlet gates at Hoover Dam[19] (Arizona and Nevada), and a floating ring spillway gate at Owyhee Dam[20] (Oregon). The use of such special types of gates is generally so infrequent that progressive improvements in design and construction make the prediction of their weight and cost a complex problem.

Comparison of Types of Gates.—It is frequently desirable to draw quick comparisons between several types of gates under given dimensional conditions. Accordingly, weight curves for the types of gates so treated in the paper and in this discussion are shown in Fig. 17 as functions of Eq. 3. The weights indicated include the gates and their embedded parts.

Conclusion.—Mr. Boissonnault has made an important contribution in assembling reliable estimating data for reservoir gates, and it is hoped that the supplementary data given in this discussion will add to the value of the original paper.

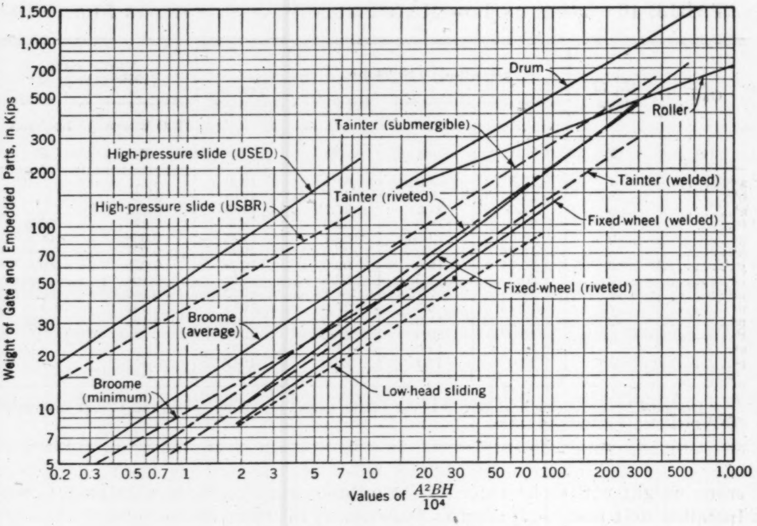

FIG. 17.—COMPARISON OF GATE WEIGHTS

Acknowledgment.—The writer should like to express his gratitude to H. G. Gerdes, M. ASCE, for inspiration derived from his unpublished work on gates, and to Kenneth C. Roberts, James S. Bowman, and Calvin V. Davis, Members, ASCE, and E. Montford Fucik, Assoc. M. ASCE, for their many valuable suggestions.

FRANK L. BOISSONNAULT,[21] ESQ.—The fine reception accorded this paper is very gratifying to the writer and the many commendatory remarks in regard to it, both in the published discussions and in personal correspondence, are greatly appreciated.

Possibly it would be in order to further clarify the method of approach used in the paper, which will serve to answer some of the points brought up in the discussion. The approach is empirical; the data, on as many different gates of the given type and covering as wide a range as possible, were carefully checked to be sure that the same parts were included and that all, therefore, were properly comparable. These data were then correlated graphically by the methods described so that conclusions could be drawn for any set of conditions within the range of the data. The expressions used as abscissas do not purport to be rational formulas for the weight of a gate, but are empirical expressions developed for the purpose of correlation. Therefore, the results are the averages of those which actual practice has shown to exist under present and past states of the art, rather than any individual's idea of what they should be theoretically. Consequently, such details as working stresses, length of radii in Tainter gates, etc., are beyond the scope of these charts, which were developed for making quick preliminary estimates.

---

[21] Engr., U. S. Engr. Office, Los Angeles, Calif.

As brought out in the "Introduction," all the information is given on each point and its position plotted, so that the engineer can use his own judgment in intelligently comparing past practice with the case in hand.

It is believed that too much refinement as to design details is neither warranted nor even desirable because most engineers would rather be a little on the safe side in preliminary estimates. Reliable data of this character, which have sufficient detail and a wide enough range of sizes to establish curves, are very difficult to obtain. The writer has scoured every public source of such information which suggested itself and has used all that could be found in the preparation of the paper. Such data on many other types of gates simply do not exist in the ordinary sources. Neither time nor available data permit the introduction of additional material to the paper at this time.

All the discussions as well as private correspondence addressed to the writer reveal a demand for estimating data on vertical-lift gates in similar form to those presented in the paper. Mr. Bowman's discussion presents some weight and cost data. These, together with Mr. Niederhoff's corrected cost formula and his previous paper on this subject,[15] should be of value in estimating gates of this type.

Mr. Niederhoff takes exception to the use of the charts as "checks to compare final designs with those compiled previously," as suggested in the "Summary" of the paper. In this statement, it was taken for granted that the construction methods and design factors of the new gate would be similar to those used in the chart gates or that the engineer would use his judgment in making suitable allowances for deviations in type of construction. Possibly an example to illustrate the intent of this statement might be in order. Reference is made to the point for the Sepulveda Dam slide (Southern California) gate in Fig. 2(*b*). This is a 6-ft by 9-ft gate with a maximum possible head of only 55 ft, yet its weight is more than 112,000 lb, which makes it the heaviest slide gate of which there is any record. There was nothing in the requirements for this gate which called for special construction. It seems reasonable to believe that, if the designer had then had this chart available to compare the design with previous practice, the plans would have been scrutinized in detail to determine the reasons for the excessive weight. These reasons could easily have been found.

The writer would also like to comment on a few other points raised by Mr. Bowman. Mr. Bowman observes that the function in Eq. 1 used as the abscissa in Fig. 2 for slide gates "appears to be rather complicated for estimating purposes." It was realized that this expression was too complex for a simple slide rule operation. Attention is called to the simple graphical solution of this function in the upper part of Fig. 2, which was developed by the writer for this very reason. It is believed that the complexity of the function is of no moment as long as the result can easily and quickly be obtained graphically, especially when it gives as good results as this one does. Of course, the scale has been reduced in the printing from the original 10½-in. by 12-in. chart so that it is quite small for much practical use. Similar comment applies to Mr. Bowman's remarks relative to the Broome-gate curves.

Mr. Buzzell's comment on a new design for Tainter gates, developed by the Unites States Engineer Corps, is interesting and the writer would appreciate specific information on the particular gates to which he refers. It is noted in this connection that the weight of the Lytle Creek Tainter gate, which was designed by the Los Angeles Office of the U. S. Engineers since the preparation of these charts, is in quite close agreement with the weight which would be predicted by the welded gate curve of Fig. 4. This gate, now under construction, was designed to conform to the then latest Engineer Corps standards, and has inclined side frames as mentioned in Mr. Buzzell's remarks.

Summary.—Most of the data available to the writer have been utilized in the preparation of the paper. This type of material is very difficult to obtain and it is hoped that members of the profession will cooperate to gather information on other types of gates.

As brought out in the foregoing, data in sufficient detail and range on existing gates or finished designs are not available from ordinary sources. Nevertheless, many engineers have information available to them on an individual project with which they are, or have been, connected. The writer would be glad to collect and correlate such data sent to his personal attention. Such an arrangement would soon result in building up a volume of data on a range of gate sizes and types, even though any one contribution in itself would not have much significance.

In closing, the writer wishes to thank the gentlemen participating in the discussion for their interest and their many valuable suggestions.

FRICTION COEFFICIENTS IN A LARGE TUNNEL

By G. H. Hickox,[1] M. ASCE, A. J. Peterka,[2] Assoc. M. ASCE, and R. A. Elder,[3] Jun. ASCE

With Discussion by Messrs. Weston Gavett, W. R. Barrows, Hunter Rouse, Karl R. Kennison, E. J. K. Chapman, Julian Hinds, William P. Creager and Stephen H. Haybrook, G. S. Tapley, J. N. Bradley and S. P. Wing, and G. H. Hickox, A. J. Peterka, and R. A. Elder.

Synopsis

Measurements made to determine friction and roughness coefficients for three different surfaces in the Apalachia Tunnel of the Tennessee Valley Authority are described in this paper. The sections tested were an 18-ft steel pipe coated with bituminous paint, an 18-ft concrete-lined tunnel, and an unlined rock tunnel of 20-ft and 22-ft nominal diameters. Discharges during the tests varied from 975 to 3,210 cu ft per sec.

Methods of reducing the data are described and the results are presented in terms of f and n in the Weisbach and Manning equations, respectively. Also, the surfaces are described in detail and illustrated so that their respective friction and roughness coefficients may be applied to other similar surfaces.

Description of Tunnel

The Apalachia Project of the Tennessee Valley Authority was built primarily as a power project and has been described by H. W. Goodhue, Assoc. M. ASCE, and R. L. Smart and A. A. Meyer,[4] Members, ASCE. The main structures are a comparatively low ponding and diversion dam, a pressure conduit approximately 8.3 miles long, a surge tank, and a powerhouse containing two turbines.

Although the pressure conduit consists mainly of a concrete-lined tunnel 18 ft in diameter, it does have two fairly long reaches of unlined rock which have nominal diameters of 20 ft and 22 ft. Just below the dam there is a comparatively short length of steel pipe 18 ft in diameter. At several other places

PLAN

Fig. 1.—Plan of Test Section of Apalachia Tunnel Showing Details of Lining and Alinement

where sufficient cover for the pressure tunnel is lacking, short lengths of steel pipe of 16-ft and 18-ft diameters are used. The alinement is nearly straight, but topographical considerations necessitated several bends. In general, the grade is quite flat, sloping toward the powerhouse. Fig. 1 shows a plan of the test reach, which is approximately the upper two thirds of the conduit length. All significant features, such as lengths, diameters, types of linings, and alinement are shown.

Piezometers.—During the construction of the conduit seven sets of piezometers were installed at the locations shown in Fig. 1 so that tests could be made to determine the various hydraulic losses.

Each of these installations consisted of a ring of four piezometers spaced at 90° intervals around the conduit and manifolded together so that an average pressure could be obtained. Where the manifold ring was exposed, as on the steel pipe at the dam, the piezometers were provided with cutoff cocks so that the manifold ring could be drained to prevent damage by freezing.

Fig. 1 shows that the piezometers are so placed that friction loss measurements could be obtained on sections containing three types of conduit: 18-ft steel pipe, 18-ft concrete-lined tunnel, and unlined rock tunnel. It was also possible to measure the loss in one of the bends and in the transitions from the 18-ft tunnels to the 16-ft steel pipe.

TYPES OF CONDUIT SURFACES

The types of surfaces on which friction losses were measured varied widely. Since a clear understanding of the characteristics of these surfaces is necessary for intelligent use of the data, they are described in some detail.

Steel Pipe.—The various steel pipe sections were formed of plates rolled to the proper curvature and butt welded. After the pipes were completed, the inner surfaces were covered with bituminous paint, applied hot with swabs. Each application of the swab covered an area approximately 6 in. wide and 2 ft long and deposited a layer of bituminous material approximately $\frac{1}{16}$ in. deep. The cold steel cooled the paint so rapidly that the resulting surface was quite irregular and included ridges and bumps up to $\frac{1}{8}$ in. high. However, the surface of the paint itself was almost glossy. Fig. 2 shows the interior of one of the steel pipes treated in this manner.

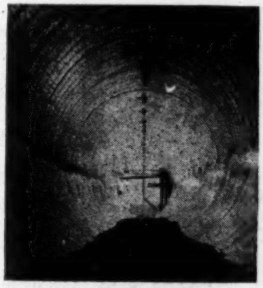

FIG. 2.—INTERIOR OF STEEL PIPE COATED WITH HOT BITUMINOUS PAINT

Between Stations 255+97.50 and 259+17.67 the steel liner was not painted hot because of the lack of ventilation in this section at the time of painting. Instead, the bituminous paint was applied cold in a slightly diluted condition. This produced a smoother surface than that in the other pipe sections.

Concrete Tunnel.—The 18-ft concrete tunnel lining was poured in two stages. An 80° invert section was poured first. The surface of the invert, which was formed by a screed traveling along the top of the longitudinal invert forms, was floated with steel floats immediately after the screed had passed. The quality of the concrete was controlled very carefully so that the best possible surface would result. In addition, concreting was carried on continuously so that no joint irregularities would occur in the invert section.

The arch section was poured against a three-piece steel form, of which the top piece covered a 90° sector and the two side pieces 95° each. Hinged at each joint, these form sections, each 5 ft long, could be collapsed and moved ahead through the other sections. Thus, irregularities due to transverse form joints occurred every 5 ft on the final surface. For convenience in erection, four form sections were kept bolted together as a unit during each change. There is no reason to believe that irregularities at the unit joints are larger than any of the others, because the units were lined up by drift pins in the same manner as were the sections comprising the units. Each piece of each

FIG. 3.—CONCRETE-LINED TUNNEL SECTION AFTER REMOVAL OF STEEL FORMS

FIG. 4.—COMPLETED UNLINED TUNNEL SECTION

section was equipped with an 18-in. by 24-in. inspection door and two or three 2-in. grout pipe holes. Each of these left a slight irregularity on the surface, averaging probably not more than $\frac{1}{32}$ in. high. Some 400 ft of forms were used so that concrete could be placed continuously without resorting to transverse bulkheads.

After the forms were removed, the surface was given a coat of curing compound. This compound disintegrates with time, however, and was probably completely washed off by the time the tests were made. Fig. 3 shows the concrete tunnel lining after the forms were removed and before the curing compound was applied.

FIG. 5.—MAXIMUM, MINIMUM, AND TYPICAL SECTIONS OF UNLINED ROCK TUNNEL

Unlined Rock Tunnel.—Unlined rock tunnel sections are of two nominal diameters, but are otherwise similar. Headings were advanced by shooting drifts 11 ft long; and, although the nominal diameter was approximated at the beginning of each drift, the actual diameter gradually increased away from the heading. In addition, the unusually hard rock broke quite irregularly, as shown in Fig. 4. Maximum, minimum, and typical sections for both the 20-ft-diameter and 22-ft-diameter unlined sections are given in Fig. 5. However, the bottom of the tunnel had not been cleaned out when the cross sections were measured so that the exact shape of the bottom 80° to 90° is unknown. Areas and perimeters have been determined by measuring the known part and assuming the remainder of the cross section to be similar. Characteristics of the unlined sections are summarized in Table 1.

22...	504	368	430.8	23.42	5.855	5.68	0.71

FIELD TESTS

The field observations were made at the same time as the turbine index tests. This procedure was possible because both types of tests required that the turbines be operated over a large range of gate openings with each gate position held constant for a sufficient length of time to allow the flow to become steady.

On January 25, 1944, unit 1 was operated alone. Satisfactory pressure measurements were obtained for each 5% gate position between the 45% and 80% positions. On January 26, both units were operated identically with satisfactory pressure measurements for each 5% gate position between the 25% and 100% positions.

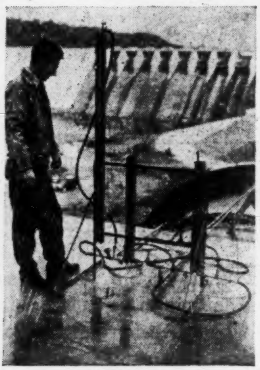

FIG. 6.—OPEN MERCURY MANOMETER (LEFT) AND WATER-AIR DIFFERENTIAL MANOMETERS (RIGHT) AT APALACHIA DAM ADIT

Manometer Installations.—At Apalachia Dam adit, two water-air differential manometers and one open U-tube mercury manometer were used, the last being attached to piezometer C and the others to piezometers A and B, and B and C, respectively.

At Apalachia adit, one water-air differential manometer and one open U-tube mercury manometer were used. In this location the open mercury manometer was connected to piezometer E and the water-air differential manometer to piezometers D and E.

At both Turtletown Creek adit and McFarland adit, single-column 10-ft mercury manometers were used. These manometers, constructed in the shop of the hydraulic laboratory of the Tennessee Valley Authority and carefully calibrated, were made in two sections to facilitate carrying.

FIG. 7.—MANOMETER INSTALLATION (ARROW) ON HILLSIDE AT TURTLETOWN CREEK ADIT

At the Apalachia Dam adit, the pressures were low enough so that the gages could be installed nearly at tunnel level. Fig. 6 shows this installation. It will be noted that each manometer connection was equipped with a blowoff cock so that the piezometer lines could be flushed frequently.

Maximum and minimum pressures at the other three locations were too great to allow the manometers to be installed at tunnel level. Therefore, it was necessary to place them on the hillsides above the tunnel. Fig. 7, which shows the location of the manometer at the Turtletown Creek adit, illustrates the difficulty encountered in finding suitable manometer sites at the proper elevations. Data from all manometers were tied together through the level system established for the tunnel construction.

Connection of the manometers to the tunnel was by $\frac{3}{4}$-in. pipe. The long lines used for most of these connections could have been a source of considerable trouble due to differential temperature effects. Fortunately, however, the tests were conducted on cloudy days and air temperatures were within a few degrees of the water temperature. Thus, it was not necessary to correct for changes in density of the water in the connecting lines.

Observations.—Because each of the four locations was entirely isolated from the others and from the powerhouse, it was necessary to take readings at 1-min intervals continuously throughout the test period to insure a complete record. All observers' watches were carefully compared at the beginning and end of each day's observations and all time readings were corrected to correspond with a master electric clock at the powerhouse. At each location the manometers were operated and read by an experienced member of the hydraulic laboratory's engineering staff.

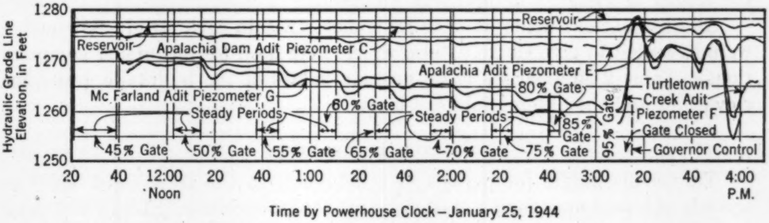

Fig. 8.—Hydraulic Grade Line Elevations for Operation of Turbine Unit 1, Showing Steady Periods for Which Data Were Used in Calculations of Heat Losses

Manometer readings were reduced to elevations of the pressure grade line. These elevations, as well as the differential pressures given by the water-air differential manometers, are shown in Table 2. Reservoir elevations for the test periods were taken from the chart of the headwater recording gage at the dam and are also shown in Table 2.

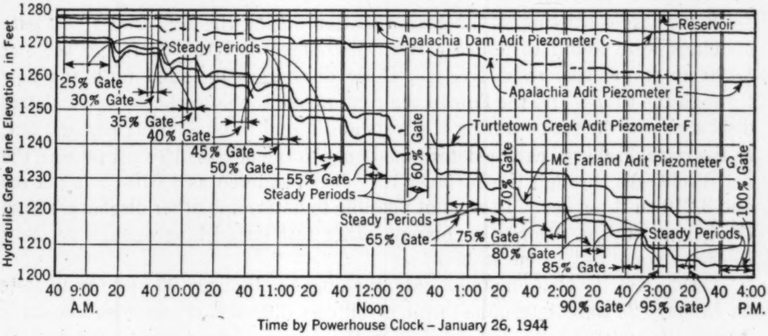

Fig. 9

The records for both days, shown as Fig. 8 and Fig. 9, have numerous breaks in them due to various causes. At some of the sites it was impossible to flush the lines in less than 1 min. Therefore, a break occurred every time this was done. On January 26, rain interfered several times with the recording of measurements, as the data paper became so wet that a legible record could not be kept. A long break occurred in the Turtletown record on January 26 because the top of the mercury column was behind the rubber hose used to connect the two 5-ft gage sections.

Periods during which the turbine wicket gate positions were changed were marked as were also those during which steady flow conditions existed throughout the length of the tunnel. An immediate response in pressure throughout the tunnel to a change in discharge was noted.

All observations made on each manometer within each steady flow period were averaged to give single values, which were used for all further computations. Table 2 summarizes these average values of the hydraulic grade line elevations and the differential head losses.

Tunnel Discharges

Tunnel discharges for periods of steady flow in the river were based on records obtained at a gaging station below the powerhouse. These were supplemented by interpolating discharges based on differential pressures measured on the turbine scroll cases, since steady river flow was only observed at two times during the test period due to the rapidity with which the tests were run. Steady flow conditions existed in the tunnel for an hour or more at gate openings of 25% and 100% on January 26. These periods were long enough so that flow in the river at the gaging station became stable, thus making it possible to determine the river discharges from the gage heights. Discharge measurements made at the station by the United States Geological Survey were carefully examined and replotted to give the best rating curve for the time of the friction measurements.

River stages existing at the gaging station during the 25% and 100% gate openings were found to indicate river discharges of 1,150 cu ft per sec and 3,290 cu ft per sec, respectively. These discharges included both the flow through the tunnel and the flow in the river above the powerhouse. The latter discharge was measured during the tests and found to be 84 cu ft per sec; but, as the river discharge can be determined only to the nearest 10 cu ft per sec, the net discharges through the turbines may be considered as 1,070 cu ft per sec and 3,210 cu ft per sec. It was not possible to determine other discharges from the gaging station records because no other test lasted long enough to allow the river stage to become stable.

Discharges for the remaining gate openings on January 26 and for all tests on January 25 were determined from scroll case differential pressures measured during the index tests. In addition to the differential pressures, the turbine gate openings were recorded in terms of the movement of the servomotor piston that opens the gates. This movement was measured to the nearest $\frac{1}{32}$ in. and is believed reliable.

Known relationships between piston movement, gate opening, discharge, and differential pressure were used to adjust discrepancies in the observed data.

[a] Names of adit where piezometers were located; or of section where loss was measured.

The actual gate opening depends on the movement of the servomotor piston. In turn, the discharge varies with the gate opening, and the differential pressure with the discharge. Thus, the differential pressure should vary smoothly with the observed movement of the servomotor piston.

It is probable that the measurement of piston travel is more accurate than the measurement of differential pressure. Accordingly, the differential pressure for each gate opening was taken from smooth curves drawn through the points determined by the observed relationship between piston movement and differential pressure. Table 3 summarizes, for each gate opening on January 25 and 26, the piston movement, the observed differential pressure, and the adjusted value taken from the smoothed curve.

The known discharge of 3,210 cu ft per sec for both units at 100% gate opening on January 26 was divided between the two units in proportion to their power outputs, which index test data showed to be 39,790 kw and 40,000

kw for units 1 and 2, respectively. Assuming that both units were operating at the same head and efficiency, the corresponding discharges were 1,600 cu ft per sec and 1,610 cu ft per sec. Discharges for each unit at other gate openings were then calculated by assuming discharge to be proportional to the square root of the differential pressure. These values for units 1 and 2 on January 26 are also given in Table 3, which shows the calculated discharge for 25% gate opening to be 1,060 cu ft per sec. This compares favorably with the value of 1,070 cu ft per sec obtained from the rating curve. Discharges for unit 1 on January 25 have been calculated from the same relationship and are also given in Table 3.

REDUCTION OF TEST DATA

The hydraulic grade line elevations and differential pressures given in Table 2, together with the discharge rates in Table 3 and the general data shown in Fig. 1, were sufficient for computation of the various losses in the test sections of the tunnel.

Friction losses for each of the three types of surface were expressed in terms of the friction coefficient f in the Weisbach equation:

$$h_f = f \frac{L}{D} \frac{V^2}{2g} \dots\dots\dots\dots\dots\dots\dots\dots (1)$$

and the results are plotted as a function of Reynolds' number **R**, in which

$$\mathbf{R} = \frac{V D}{\nu} \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

In these equations, L is the length of any test reach; D is the diameter of the pipe; V is the average flow velocity; h_f is the energy loss, in feet, over the length L; and ν is the kinematic viscosity of the flowing water. Since air and water were both very close to 60° F during the tests, the value of ν has been taken throughout the calculations as 1.2×10^{-5}, which is its value at that temperature.

Values of the roughness coefficient n in the Manning equation:

$$V = \frac{1.486}{n} R^{\frac{2}{3}} S^{\frac{1}{2}} \dots\dots\dots\dots (3)$$

were also computed. In this equation, V is the average velocity; R is the hydraulic radius; and S is the slope of the energy grade line. These results are shown on plots of n versus V.

Entrance and bend losses were expressed in terms of the velocity head by the equation:

$$H = C \frac{V^2}{2\,g} \dots\dots\dots\dots (4)$$

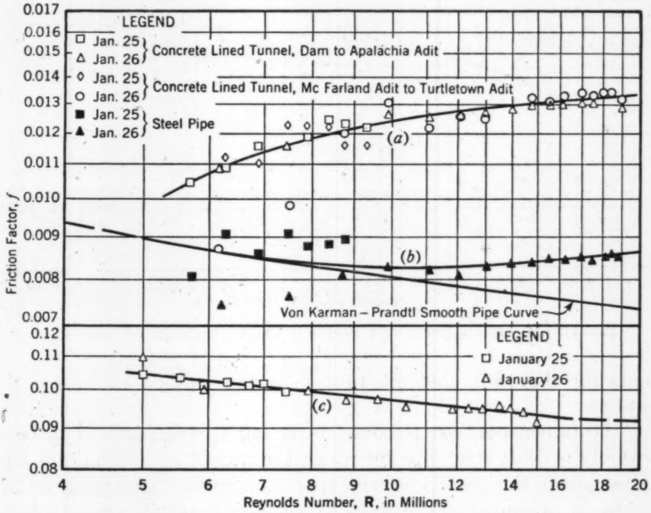

FIG. 10.—PLOT OF FRICTION FACTOR f VERSUS REYNOLDS' NUMBER R
(a) 18-Ft Bituminous-Coated Steel Pipe
(b) 18-Ft Concrete-Lined Tunnel
(c) Unlined Rock Tunnel

in which H, with an appropriate subscript, is the head loss in question; and C, with the same subscript, is the corresponding coefficient.

Losses in the tunnel transitions were expressed in terms of the difference in velocity heads by the equation:

$$H_T = C_T \frac{V^2_1 - V^2_2}{2\,g} \dots\dots\dots\dots (5)$$

In Eq. 5, V_1 and V_2 are the velocities before and after the transition, respectively.

Friction Loss in 18-Ft Steel Pipe.—Friction and roughness coefficients, f and n, for the 18-ft steel pipe were computed by Eqs. 1 and 3 from the discharges given in Table 3, the observed pressure drops given in Col. 7, Table 2, and the dimensions of the test section taken from Fig. 1. These values are given in Table 4 and are plotted as f versus **R** in Fig. 10(*a*) and as n versus V in Fig. 11(*a*).

Preliminary Bend Losses.—The pressure drop measured between piezometers B and C was composed of the loss due to bend 1 and the friction loss in 198 ft of tunnel, of which 120 ft is 18-ft steel pipe and 78 ft is 18-ft concrete-lined tunnel. As both test sections on the 18-ft concrete-lined tunnel contain bends, it was necessary to determine the bend-loss coefficients and the friction coefficients for the 18-ft concrete tunnel by the method of successive approximations.

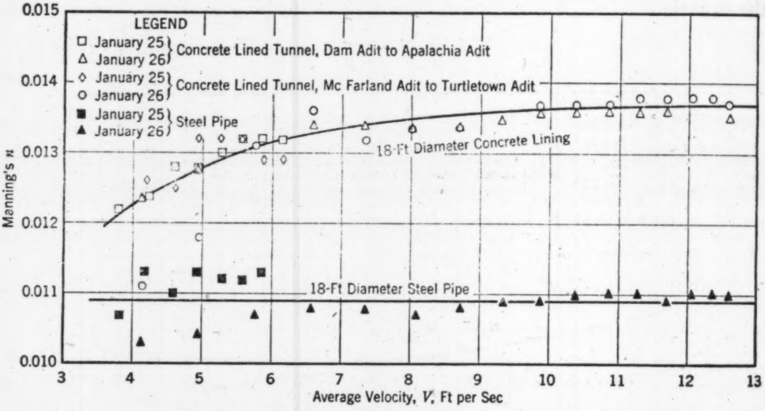

FIG. 11.—MANNING'S ROUGHNESS FACTOR n VERSUS AVERAGE VELOCITY V

First, the tunnel between piezometers B and C was assumed to be composed entirely of 18-ft steel pipe for which the friction coefficient was known. The friction loss in this reach was then approximated by assuming it to be proportional to the measured loss between piezometers A and B. Subtracting this calculated friction loss from the total measured loss gave the loss for bend 1, from which the bend-loss coefficient C_B was computed by Eq. 4. The value of C_B thus determined was applied to bends 2 and 3 between piezometers C and D for determination of n for the concrete pipe. With this coefficient determined, the loss in bend 1 was recalculated. This change in bend loss, however, when applied to bends 2 and 3, did not measurably change f and n as first calculated for the concrete. Table 4 gives the calculated preliminary value of C_B for each rate of discharge; the average preliminary value of C_B for bend 1 is 0.253.

Table 5 lists the six bends included in the test section, together with the deflection angle, the radius, and the diameter of pipe of each. Available information concerning bend losses indicates that C_B varies with the deflection angle and the ratio of bend radius to pipe diameter. Relative values of the coefficient in terms of these variables are given by William P. Creager and Joel D. Justin,[5] Members, ASCE, whose values of K, reflecting the effect of deflection angle, are given in Col. 5. Col. 6 gives values of $\frac{r}{D}$ for each bend and Col. 7 gives the corresponding values of the bend-loss coefficient for a 90° bend. The preliminary values of C_B for bends 1, 2, and 3 are given in Col. 8. For bend 1, this value is found from the calculations of Table 4. For bends 2

[a] Preliminary computations of bend loss for bend 1. [b] From the dam adit to Apalachia adit.

---

[5] "Hydro-electric Handbook," by William P. Creager and Joel D. Justin, John Wiley & Sons, Inc., New York, N. Y., 1927, pp. 119–120.

and 3, the value of C_B is the preliminary value for bend 1 multiplied by the ratios of appropriate factors in Cols. 5 and 7. For example, $C_{B2} = C_{B1} \times \frac{K_2}{K_1} \times \frac{F_2}{F_1} = 0.253 \times \frac{0.311}{0.571} \times \frac{0.45}{0.28} = 0.222$.

Friction Loss in 18-Ft Concrete-Lined Tunnel, Apalachia Dam Adit to Apalachia Adit.—Between Apalachia Dam adit and Apalachia adit, the tunnel is concrete lined, 18 ft in diameter, and contains two bends. Elevations of the hydraulic grade line at piezometers C and E and the differential pressures between piezometers D and E are given in Table 2. Addition of the differentials between piezometers D and E to the hydraulic grade line elevations for E gave the grade line elevations at D; subtraction of these elevations from those at C gave the friction losses between piezometers C and D.

Losses for bends 2 and 3 were calculated by Eq. 4 from the preliminary values of C_B given in Table 5, and values of n and f were calculated from Eqs. 1 and 3. The results of these calculations are summarized in Table 4. Fig. 10(*b*) shows f plotted against R and Fig. 11 gives values of n in terms of V.

[a] For a 90° bend. [b] As reported by William P. Creager and Joel D. Justin,[5] Members, ASCE.

Corrected Bend Losses.—Having determined the roughness coefficients for the concrete-lined tunnel, it was possible to recalculate the loss coefficients for bend 1. This calculation was made by using the average value of n determined for the steel pipe and by taking values of n for the concrete section of the tunnel from a curve drawn through the points determined for that section of the tunnel between Apalachia Dam adit and Apalachia adit. This curve was omitted from Fig. 11 as it differed so slightly from the mean curve shown there that recalculation of the bend losses on the basis of the final curve was unnecessary. From the results of these computations, summarized in Table 6, the average value of C_B for bend 1 was found to be 0.236. Corrected values of C_B for all bends are given in Col. 9, Table 5. These values are within the range commonly used for bend-loss coefficients and they lie between the values given by Messrs. Creager and Justin[5] for "safe" and "probable" values. Col. 10, Table 5, is based on the curve of probable values presented by Messrs. Creager and Justin and is the product of Cols. 5 and 7. These values are less than those based on the measurements at bend 1.

Transition Loss.—The differential manometer between piezometers D and

E at Apalachia adit measured the total head loss due to friction in 96 ft of 18-ft concrete-lined tunnel, 264 ft of steel pipe 16 ft in diameter, and 40 ft of concrete-lined transition sections having an average diameter of 17 ft, and also the loss due to bend 4 and the loss caused by the expansion from the 16-ft diameter to the 18-ft diameter.

[a] For bend 1.

All these losses except that due to the transition can be calculated from data previously obtained. Values of roughness coefficients for the steel pipe and the concrete-lined tunnel were obtained in the same manner as those for the calculation of corrected bend loss. The difference between the total loss and the sum of the calculated friction and bend losses was taken as the loss due to expansion, the loss caused by the contraction being assumed negligible.

The value of the transition-loss coefficient C_T was calculated by Eq. 5.

The computations are summarized in Table 6, the average value of C_T for all tests being 0.027, which is 40% smaller than the value given by H. W. King,[8] Hon. M. ASCE.

Friction Loss in 18-Ft Concrete-Lined Tunnel, Turtletown Creek Adit to McFarland Adit.—Between Turtletown Creek adit and McFarland adit, the tunnel is largely a concrete-lined tunnel 18 ft in diameter like that between Apalachia Dam adit and Apalachia adit. It should, therefore, have the same friction and roughness coefficients. The computations are somewhat more difficult because the test section includes not only 6,944 ft of the 18-ft concrete lining but also 118 ft of steel pipe 18 ft in diameter, 598 ft of steel pipe 16 ft in diameter, 60 ft of concrete transitions having an average diameter of 17 ft, one contraction, two expansions, and bend 6. In addition, the tunnel does not have the same diameter at the two adits so that the measured drop in the hydraulic grade line is not equal to the drop in the energy grade line.

The drop in the energy grade line can be calculated by adding the velocity head at each piezometer to the elevation of the hydraulic grade line at that piezometer and taking the difference of these sums. Thus, if the energy grade line is represented by E and the hydraulic grade line by H, and the Turtletown Creek and McFarland adits by subscripts T and M, respectively, the drop in the energy grade line is $\Delta E = \left(H_T + \frac{V^2_T}{2g}\right) - \left(H_M + \frac{V^2_M}{2g}\right)$. This can be rewritten as $\Delta E = (H_T - H_M) + \left(\frac{V^2_T}{2g} - \frac{V^2_M}{2g}\right) = (H_T - H_M) + \Delta \frac{V^2}{2g}$. The friction loss in the 18-ft concrete-lined section of the tunnel is this value of ΔE less the other losses listed.

Loss in the steel pipe sections was calculated from Eq. 3 using n as 0.0109. Values of n for the concrete transitions with an average diameter of 17 ft were taken from the preliminary curve previously mentioned. Expansion losses were calculated using 0.027 as the value of C_T, and the loss coefficient for bend 6 was taken from Table 5. Contraction loss was neglected. Values of f and n for the 18-ft concrete were calculated from the net loss, using Eqs. 1 and 3. The computations are summarized in Table 7 and the results are plotted in Figs. 10(*b*) and 11.

Friction Loss in Unlined Rock Tunnel.—Between the Turtletown Creek and McFarland adits the tunnel consists of 3,098 ft of unlined rock tunnel 20 ft in nominal diameter, 2,902 ft of unlined rock tunnel 22 ft in nominal diameter, 7,626 ft of 18-ft concrete-lined tunnel, 20 ft of concrete-lined transition averaging 17 ft in diameter, and 369 ft of 16-ft steel pipe. Losses were also caused by bend 5, by the expansions from 18-ft concrete to 20-ft rock and from 20-ft rock to 22-ft rock, and by the contraction from 20-ft rock to 18-ft concrete. The contractions from 22-ft rock to 20-ft rock and from 18-ft concrete to 16-ft steel are so gradual that losses due to them were neglected.

Energy loss between piezometers E and F was not equal to the fall in the hydraulic grade line between the piezometers because of the smaller diameter, with corresponding higher velocity, at piezometer F. The energy loss was determined, however, by adding the difference between velocity heads at piezometers E and F to the elevation of the hydraulic grade line at piezometer F and subtracting the sum from the elevation of the hydraulic grade line at piezometer E. This process is similar to that employed in finding the energy loss between piezometers F and G. The loss in the unlined rock tunnel was found by subtracting from the total energy loss not only the friction losses in the concrete sections 18 ft and 17 ft in diameter and in the 16-ft steel pipe, but also the losses due to bend 5 and the expansions and contractions.

Friction loss in the 18-ft concrete-lined tunnel was computed from Eq. 3 with the n-values taken from the smooth curve shown in Fig. 11. Friction loss due to the 20 ft of transition was also calculated by this method. In the case of the 16-ft steel pipe, however, the loss was computed with $n = 0.0109$, the value determined for the 18-ft steel pipe. Hydraulic loss due to bend 5 was handled in the same manner as was that for bends 2, 3, and 6, the value of C_B for use in Eq. 4 being taken from Table 5.

Loss in the transition from the 18-ft concrete-lined tunnel to the 20-ft unlined tunnel was calculated by Eq. 5, but the value of C_T to be used is open to some question. On the basis of data supplied by Professor King,[6] C_T was estimated at 0.9. Similarly, based on Professor King's data from the same source and on the value of 0.027 for C_T for the expansion from the 16-ft pipe to the 18-ft concrete tunnel, C_T for the expansion from the 20-ft to the 22-ft rock section was estimated at 0.05.

At the entrance to the 18-ft lined tunnel, the concrete lining has a 9-in. chamfer, as shown in Fig. 1, detail D. Tests on concrete box culverts with a similar beveled entrance[7] indicate that the loss at entrance may be expressed by Eq. 5 with a coefficient of 0.15.

It was not possible to determine roughness coefficients for the 20-ft and 22-ft unlined tunnels separately. However, values of *n* and *f* were computed from Eqs. 3 and 1, assuming that the same values apply equally to both sections. Values of *n* are plotted in Fig. 12 against the average velocity for the two sections. In Fig. 10(*c*), *f* is plotted against a value of **R** based on the average diameters and areas of the two sections. Calculations of these factors are summarized in Table 8. Col. 5, Table 8, includes the bend loss, contraction loss, and expansion losses, all of which were calculated by expressing all velocities in terms of the velocity in the 18-ft tunnel and using that velocity for the calculations.

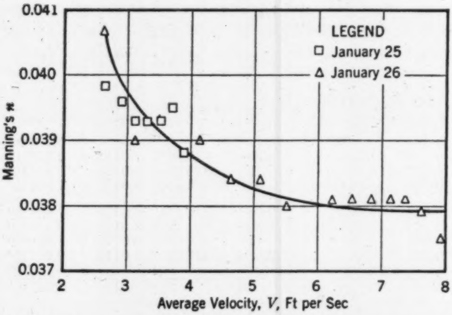

FIG. 12.—MANNING'S ROUGHNESS FACTOR *n* VERSUS AVERAGE VELOCITY *V* FOR UNLINED ROCK TUNNEL

In making the computations of *f* and *n*, the diameter was taken as that of a circle whose area was equivalent to the average area of the section. The hydraulic radius used was one fourth of the equivalent diameter. This assumption is not quite correct because of the irregularity of the tunnel cross sections. For example, the average hydraulic radii of the 20-ft and 22-ft tunnels as measured on the cross sections are actually 5.36 ft and 5.60 ft instead of 5.465 ft and 5.855 ft, respectively. Thus, use of these values in Eq. 1 produces values 2.3% smaller than those given in Table 8. Similarly, when used in Eq. 3, these values give *n*-values 1.5% smaller than those in Table 8. The differences are small, however; and, in view of the uncertainty of actual tunnel shapes (which depend on the character of rock and the manner in which it breaks, as well as on the care taken in measuring the irregular sections), it is believed better to use the simpler assumption of an equivalent circular area and the corresponding hydraulic radius.

SUMMARY

Tests on the Apalachia tunnel were made at discharges between 975 cu ft per sec and 3,210 cu ft per sec. Friction and roughness coefficients were de-

[a] Based on average equivalent diameter of 22.64 ft.

termined for three widely different types of surfaces, including steel coated with bituminous paint, concrete placed against steel forms, and unlined rock. Discharges were based on a rating curve established by current meter measurements supported and supplemented by observations of turbine scroll case differential pressures.

Values of f for the bituminous-coated steel pipe, at values of R below 8×10^6, agree with the curve suggested by Theodor von Kármán,[8,9] M. ASCE, and L. Prandtl[10] for smooth pipe. For greater values of R, the value of f departs from the smooth pipe curve but increases very little in actual value. The average values of f and n are about 0.0085 and 0.0109, respectively.

Values of f and n for the concrete surface placed against steel forms increase with increasing values of V and R, whereas values of f and n for the unlined rock tunnel decrease with increasing R.

[10] "Neue Ergebnisse der Turbulenzforschung," by L. Prandtl, *Zeitschrift des Vereines Deutscher Ingenieure*, No. 5, 1933.

Bend and transition losses were approximated to enable more accurate calculation of the friction losses in the tunnel. These losses were not recalculated after the final determination of friction loss had been made; but the change, if any, would have been very small. Since these losses are a relatively small part of the total loss, the effect of a small change in the roughness coefficient used in determining them would change them only slightly and the final effect on the friction coefficients for the tunnel surfaces would be insignificant. The coefficients determined are within the range of commonly accepted values.

The data from these tests offer an opportunity to check the validity of the von Kármán equation relating friction coefficient, pipe diameter, and size of roughness. The equation, based on J. Nikuradse's[11,12] experiments on small pipes lined with sand, is

$$\frac{1}{\sqrt{f}} = 1.74 + 2 \log \frac{r}{k} \quad \text{.....................} \quad (6)$$

in which f is the friction coefficient; r is the radius of the pipe; and k is the diameter of the sand grains composing the surface. The equation is applicable only to the region of complete turbulence in which f remains constant with increasing **R**. Although this condition was not quite reached in the tests, the constant value of f may be estimated by inspection of Fig. 10. Table 9 lists the estimated values of f and r for each type of tunnel, together with the corresponding values of $\frac{r}{k}$ and k.

TABLE 9.—COMPUTATION OF SURFACE ROUGHNESS

Tunnel surface (1)	Friction coefficient, f (2)	Pipe radius (ft) (3)	Ratio, $\frac{r}{k}$ (4)	Grain diameter, k (in.) (5)
18-ft steel......	0.0087	9.0	30,900	0.0035
18-ft concrete..	0.0135	9.0	2,690	0.04
22.6-ft rock....	0.091	11.3	6.17	22.0

Calculated values of k are in fair agreement with what would be expected after an inspection of the respective surfaces. The interior of the steel pipe was almost glassy smooth except for the irregularities caused by the method of application. The concrete lining was slightly grainy. Estimates of the mean sand grain diameter, based on visual inspection, varied from 0.03 in. to 0.06 in. The value of 0.04 is within this range. No accurate estimate of average roughness for the unlined rock can be made, but the value of 22 in. does not seem out of line after examination of Figs. 4 and 5. The agreement is the more remarkable when the difference in size between Mr. Nikuradse's apparatus and the Apalachia tunnel is considered.

DISCUSSION

Weston Gavett,[13] Assoc. M. ASCE.—Friction coefficients for large tunnels with three types of wall surface such as described are of great interest.

Apparently the piezometers were located with difficulty, for in some instances several types and sizes of tunnel with bends and transitions are included between piezometers, requiring successive approximations to arrive at the coefficient for each part.

Figs. 11 and 12, showing the relation of Manning's n to V, indicate a straight line for the 18-ft diameter steel pipe but show curves for the 18-ft diameter concrete tunnel and the unlined rock tunnel. A straight line shows that the exponent x in the equation $H_f = C\ V^x$ is 2.00, whereas a curve indicates that x is greater or less than 2.00. As the friction loss for the 18-ft steel pipe, for which $x = 2.00$, was obtained in a straight run between points A and B with no other types, sizes, or bends to complicate the computations, the question arises as to whether the values of x for the 18-ft concrete tunnel and the unlined rock tunnel are, in fact, more and less, respectively, than 2, or whether the variations are due to the assumptions made in arriving at the coefficients.

TABLE 10.—Values of x in $H_f = C\ V^x$

Tunnel section	Friction Loss		x
	Table	Column	
(1)	(2)	(3)	(4)
A-B	2	7	2.00
B-C	2	8	2.09
D-E	2	9	2.01
18-ft concrete	8	2	2.18
Unlined rock	8	6	1.89

TABLE 11.—Computed Roughness Height for Various Conduits

Type of conduit	Length of sections (ft)	Diameter (in.)	Age (yr)	Roughness height, k (in.)
(1)	(2)	(3)	(4)	(5)
Concrete, lock joint	12	51	6.7	0.008
Steel, riveted	7½	72	17.0	0.55
Steel, riveted	7½	72	23.0	0.77
Steel, riveted	7	48	27.4	0.37
Steel, riveted	7	48	39.2	0.894
Steel, riveted	7	42	27.4	0.23–0.40
Steel, riveted	7	42	43.8	0.85
Steel, lock bar	30	72	4.0	0.18
Steel, lock bar	30	74	0.6–9.6	0.028–0.056

By computation, the writer obtained the values of x shown in Table 10, using figures for Q, in cubic feet per second, from Table 3, Cols. 4 and 13, and friction losses from other data in the paper as shown in Cols. 2 and 3, Table 10. It will be noted that the values of x vary only slightly from 2 for the observed data in sections A-B, B-C, and D-E.

Of special interest is the finding that Eq. 6, derived from experiments with 2.5-cm, 5-cm, and 10-cm pipes, gives plausible results for the roughness height k for the 18-ft to 22-ft diameter tunnels. Use of the same equation to compute the roughness height in pipes described elsewhere[14,15] gave the results shown in Table 11. The Nikuradse[11,12] sand size appears to be a practical standard for evaluating wall roughness, comparing different types of pipe, and indicating the growth of roughness height with age. Obviously, many types of roughness are not similar to uniform sand; but some standard is desirable, and any form of roughness may be referred to Nikuradse's sand as an equivalent sand size as was done by H. Schlichting[16] for various forms of artificial roughness.

[15] Discussion by Weston Gavett of "Trends in Coefficients of Large Pressure Pipes," by Charles H. Capen, *ibid.*, April, 1942, p. 524.

W. R. Barrows,[17] Assoc. M. ASCE.—A part of the Apalachia tunnel was left unlined after an economic investigation had indicated that such a move would be wise. During the course of this investigation, it became necessary to estimate the probable friction loss in the unlined part. A search of the literature produced very little information. To make matters worse, the published data reported widely varying coefficients of friction for apparently similar conditions and gave no clue as to the probable value for the problem at hand. At this point the Aluminum Company of America made available data on the unlined tunnel of its Nantahala project. From these data the value of n in the Manning formula was estimated to be 0.037 for the unlined tunnel. This value compares favorably with the values determined by precise measurements in the Apalachia tunnel and was computed for velocities ranging from 2.18 to 4.28 ft per sec.

The Nantahala tunnel had been recently completed in a rock formation similar to the rock in which the Apalachia tunnel was driven. When it was unwatered after completion of the unit test, it was inspected by a party of engineers familiar with the Apalachia tunnel, who agreed that, in so far as could be observed, there was no difference in either the surface roughness or the manner the rock broke out in the two tunnels. The estimated coefficient for the Nantahala tunnel is slightly lower than that determined for the Apalachia tunnel. The difference could easily have resulted from the fact that the minor losses in the Nantahala tunnel had to be estimated.

Unlined parts of the Nantahala tunnel were driven to three different sections with nominal dimensions of 12 ft wide by 12 ft high, 14 ft wide by 13 ft high, and 13 ft wide by 14 ft high, the theoretical section in each case having an arched roof with a radius equal to half the width and a flat floor connected to the spring line of the arch by vertical sides. Cross sections of the completed tunnel were available and from them the average area and the wetted perimeter of the different sections were determined. The discharge was determined from unit efficiency tests, and the head loss between the forebay and the surge tank was measured.

The experimental values for the coefficient of friction of an unlined rock tunnel presented by Messrs. Hickox, Peterka, and Elder are based on the measured properties of the actual section "adjusted to equivalent circular sections." This point deserves emphasis. The engineer when considering reported values of n for excavations which may deviate considerably from the desired dimensions should assure himself that the values were determined in such a way as to make them applicable to his problem. For instance, assume that the coefficient of friction of an unlined tunnel 12 ft in diameter was determined using the theoretical properties of the section instead of the actual. Such a value applied to a tunnel 30 ft in diameter would result in an estimated head loss equal to approximately two thirds of the actual head loss, assuming equal overbreak. However, the values reported by the authors should be applicable in similar rock tunnels over a wide range of sections.

[17] Civ. Engr., Albuquerque, N. Mex.

Hunter Rouse,[18] M. ASCE.—Test results that extend the existing range of measured data are welcome in any field of engineering. To the best knowledge of the writer, the resistance measurements presented by the authors of this factual paper go well beyond the available information in two respects. First, the Reynolds numbers are nearly a full logarithmic cycle higher than those of all but a few isolated measurements on large conduits. Second, the absolute roughness of one series far exceeds that of boundary surfaces generally considered in the roughness category. With this apparent two-directional enlargement of the resistance field, several checks upon the matter at once suggest themselves. Are the new results in accord with present knowledge of this problem? If not, do these results indicate errors in present knowledge, or is such knowledge sufficiently sound to disclose inaccuracies in either the data or the authors' analysis?

In 1942 the writer showed[19] that the best available resistance measurements for a wide variety of new and old commercial pipe approximated the transition curve of C. F. Colebrook:[20]

$$\frac{1}{\sqrt{f}} - 2\log\frac{r}{k} = 1.74 - 2\log\left(1 + 18.7\,\frac{r/k}{\mathbf{R}\sqrt{f}}\right) \qquad \text{. . . . . (7)}$$

On the basis of this analysis, the writer prepared a general resistance diagram[19,21] permitting solution for either V or h_f for (presumably) the flow of any fluid at any speed through any size of conduit having a surface comparable to any one of those for which data were analyzed. In this diagram an asphalted surface was listed as having an equivalent sand roughness of $k = 0.005$ in. and a concrete surface of $k = 0.1$ to 0.01 in. The authors' values for the asphalted and concrete linings were 0.0035 in. and 0.04 in., respectively. The writer's diagram included no relative roughness values higher than $k/r = 1/10$, however, for two reasons: First, the effective diameter of a very rough conduit is difficult to define, both practically and theoretically; second, boundary irregularities having a greater relative magnitude than approximately one tenth of the radius begin to represent cross-sectional constrictions rather than surface roughness and cannot significantly be discussed in the same terms. The maximum value listed in this paper is about one sixth.

[20] "Turbulent Flow in Pipes, with Particular Reference to the Transition Region Between the Smooth and Rough Pipe Laws," by C. F. Colebrook, *Journal*, Inst. C. E., London, Vol. 11, 1938–1939, p. 133.

[21] "Elementary Mechanics of Fluids," by Hunter Rouse, John Wiley & Sons, Inc., New York, N. Y., 1946, p. 211.

The authors restrict their interpretation of the surface-resistance measurements to two primary features—the variation of f with **R**, and the variation of n with **R**. The former, with Fig. 10 the corresponding exhibit, shows little of the actual relationship of the three series to existing generalized treatments; nevertheless, the resulting values of k for the assumed limits of the apparent transition curves are tabulated. Portrayal of n as a function of **R**, furthermore, is hardly consistent with either the true significance of n as a roughness parameter or with the authors' evaluation of k, for most assuredly showing how k (neither more nor less a roughness parameter than n) varied with **R** was not considered.

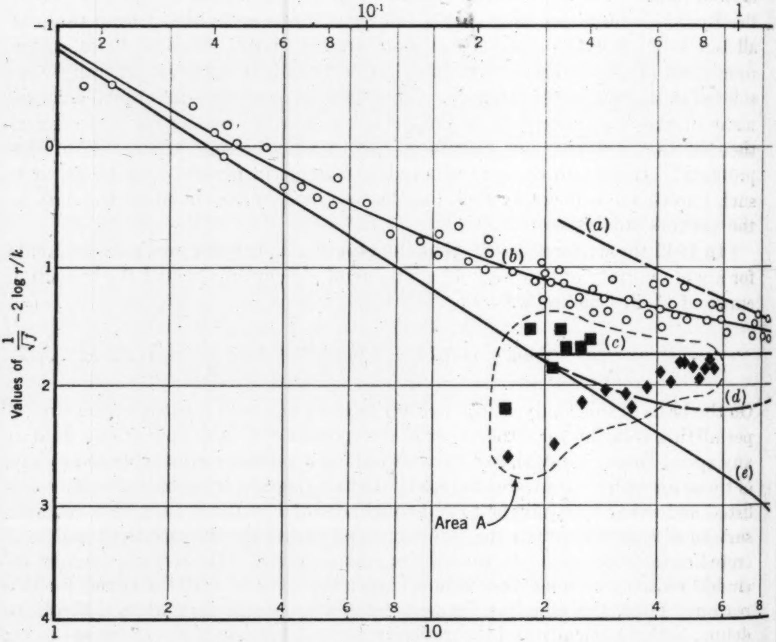

Fig. 13.—Comparison of Apalachia Tunnel

As has long appeared evident,[22] whether the resistance of a conduit boundary is dependent on or independent of **R** is governed by whether the zone of laminar flow at the boundary (that is, the laminar sublayer, for which the nominal thickness δ' is equal to $65.6\, r/\mathrm{R}\sqrt{f}$) encloses and thus renders the surface irregularities ineffective, or is itself disrupted and thus rendered ineffective by the irregularities. In a word, whether the wall behavior is smooth or rough depends on whether the ratio k/δ' is, respectively, much less or much greater than unity. This ratio is evidently proportional to the quantity $(\mathrm{R}\sqrt{f})/(r/k)$. A plot using this parameter for the abscissa scale and the quantity $1/\sqrt{f} - 2 \log r/k$ for the ordinate scale in effect reduces all resistance data to the same common denominator of relative viscosity-versus-roughness action. J. Nikuradse[12] first used this method in correlating his tests on uniform sand roughness, which resulted in the single function for all his data shown by

curve (*d*) of Fig. 13. Extending this study to the conditions of nonuniform sanded surfaces, C. F. Colebrook and C. M. White[23] obtained a gradual displacement of the transition function with increasing nonuniformity; curve (*a*),

---

[23] "Experiments with Fluid-Friction in Roughened Pipes," by C. F. Colebrook and C. M. White, *Proceedings*, Royal Soc. of London, Vol. 161, 1937.

Fig. 13, represents the limiting one of their series. Since most natural roughnesses are essentially nonuniform, it is reasonable that the transition curve for such surfaces should lie between these limits and yet begin at a far lower value of k/δ' than that for uniform surface irregularities; this condition is satisfied by C. F. Colebrook's function shown in Fig. 13 by curve (*b*).

Data previously analyzed by the writer[19] and reproduced in Fig. 13 include new and old pipes varying from 2 in. to 72½ in. in diameter and fabricated of such materials as galvanized iron, wrought iron, cast iron, tarred cast iron, spiral-riveted steel, and wood stave. The three series of the authors' data are likewise reproduced, using the values of r/k given in Tables 4, 7, and 8. It is at once evident that the zone covered by any one series is very small compared with that encompassed by all three; also evident is the departure of the data from the trend of the general transition between smooth and rough boundary behavior. In fact, the data for the bituminous-coated steel pipe (area A), when reduced to the proportions of this plot, no longer indicate a significant trend, and the centroid of this area is well below the general function. A trend of the data for the concrete-lined tunnel (area B) is more apparent, but is not in agreement with any of the earlier functions; the centroid is likewise low. Finally, the data for the unlined rock tunnel (area C) are so far beyond the range of viscous action (note that k is some six thousand times the computed magnitude of δ') that the slight downward trend probably has no significance.

From this comparison it may be concluded that the authors' method of evaluating the relative and absolute roughness is generally unreliable. If the centroid of the unlined tunnel data, with a value of $f = 0.099$, is used to determine the relative roughness from the limiting ordinate 1.74 of the roughness function (curve (*c*), Fig. 13), this will be found to be $r/k = 5.3$, for which $k = 26$ in., as compared with the authors' values of $r/k = 6.17$ and $k = 22$ in. If the centroid of the concrete lining data ($f = 0.0123$) is likewise used, it will be found that $r/k = 4{,}300$ and $k = 0.025$ in., in distinction to the authors' values of $r/k = 2{,}690$ and $k = 0.04$ in. Since the bituminous lining data, on the other hand, lie well within the zone of viscous influence, it is necessary either to locate the centroid on a general resistance diagram (such as that prepared by the writer from the Colebrook function[19,21]) and read r/k directly thereon, or to solve Eq. 7 for the same conditions by the process of trial and error. The result will be $r/k = 170{,}000$, for which $k = 0.00063$ in. These values differ considerably from the authors' selection of $r/k = 30{,}900$ and $k = 0.0035$ in. There is a comparable difference between this value of 0.00063 in. for the 18-ft bituminous-lined steel pipe and the average of 0.005 in. previously determined[20] for asphalted cast-iron pipe varying from 4 in. to 5 ft in diameter, which may be attributable to the effect of pipe joints and methods of surface application.

Although the discrepancies between the authors' and the writer's calculations are small in two of the three cases, it is the general method rather than the numerical results which the writer seeks to emphasize. In no way, however, is it sought to disparage contributions of this nature. Variations such as those indicated by the authors' data have been the rule rather than the exception, even in apparently well-controlled laboratory experiments. Although one cannot expect to duplicate laboratory results under field conditions with respect to either accuracy or over-all range of Reynolds numbers, field corroboration of laboratory analyses are fully as essential as are final acceptance tests for any hydraulic design. The authors are therefore to be heartily commended for their effort to provide several links in the necessary chain of field evidence. The particular merit of the paper as a whole is twofold: First, it gives a clear indication of the desirability of preparing for prototype tests of this nature during the design of every large installation. Second, it gives an equally clear indication of the degree of accuracy which may be expected in predicting the performance of a conduit; surely the use of more than two significant digits is still quite futile.

Karl R. Kennison,[24] M. ASCE.—Much valuable information on coefficients of flow in large diameter tunnels has been assembled in this paper. It occurs to the writer that it will be interesting and instructive to compare this information with that obtained in actual operation over a period of years on the Quabbin Aqueduct tunnel built by the Metropolitan District Water Supply Commission,[25, 26, 27, 28] in Massachusetts. The great length of this tunnel, 24.6 miles, and the uniformity of operating conditions over long intervals of time obviously contribute much to the accuracy of the data and the precision with which the results can be computed. For example, since the filling of Quabbin Reservoir was started late in 1939, the aqueduct has been used for free discharge into Wachusett Reservoir in the following quantities:

Period	Million gal
September 17 to October 28, 1941	20,426
August 6 to September 7, 1943	17,020
June 13 to September 11, 1944	25,425
June 27 to September 22, 1945	22,008
August 26 to September 13, 1946	10,745
January 27 to February 11, 1947	9,660

The tunnel is operated as a pressure tunnel. It was constructed as a horseshoe-shaped grade tunnel, since the internal water pressure is less than the external pressure resulting from the normal ground-water level. This is not strictly true for a short distance at the Wachusett Reservoir end, where a length of 500 ft next to uptake shaft 1 was constructed as a circular pressure tunnel 12 ft 9 in. in diameter, with the lining grouted against the ledge to prevent leakage from the tunnel under the full head of Quabbin Reservoir. This head is effective throughout the entire length of the tunnel as far as the outlet control gates at the top of shaft 1. Another section, 200 ft long at the extreme westerly end next to the Quabbin intake shaft (shaft 12), was similarly constructed as a circular pressure tunnel to prevent excessive leakage from the reservoir into the tunnel whenever the latter is unwatered for inspection purposes by inserting stop logs at shaft 12. With these two exceptions, the horseshoe section is maintained throughout the entire length of 129,413 ft between downtake shaft 12 and uptake shaft 1. These lengths of circular tunnel represent a small percentage of the total and furthermore have the same cross-sectional area. Hence, the fact that these end sections have a slightly greater hydraulic radius can be neglected.

[27] "Boston Metropolitan Water Supply Extension," by Karl R. Kennison, *Journal*, New England Water Works Assn., June, 1934, p. 147.

[28] "Ware River Intake Shaft and Diversion Works," by Karl R. Kennison, *Civil Engineering*, August, 1934, p. 388.

The width of the tunnel is 11 ft 0 in. between vertical side walls; the height is 12 ft 9 in. from invert to crown. The cross-sectional area is 127.6 sq ft, and the hydraulic radius is 3.03 ft. Flow is unobstructed except as follows:

(*a*) The downtake waterway in shaft 12 is about 115 ft deep and is crossed by numerous struts spanning the openings in which stop logs and screens are placed. Ordinarily water is drawn from the upper intake, which permits free entrance from the reservoir for a depth of nearly 50 ft from the surface. Water drawn from the lower intake must rise through an uptake shaft before turning to drop into the downtake shaft.

(*b*) Shaft 11-A is an uptake shaft for diverting flood flows from the Ware River into Quabbin Reservoir; hence, there is a large opening in the crown.

(*c*) At the bottom of construction shafts 11, 10, 7, 6, 5, and 3 there is a sizable rectangular opening in the crown and a large sump in the invert.

(*d*) At the bottom of shaft 9 there is a central pier 18 in. wide, in addition to large openings in the crown for access and for placing emergency stop logs in the two 4-ft 9-in. bays, and in addition to the invert sump. There are also two low racks 4 ft 6 in. high in each of the two bays for the purpose of catching any debris that may roll along the invert. These racks are constructed of ½-in. flats, 3 in. on centers. They are placed there merely because the access to this point is convenient because of gravity drainage into Wachusett Reservoir. The net cross-sectional area may well be taken as from about 110 to 115 sq ft.

(*e*) At a point between shaft 9 and shaft 8, there is a 2-ft-wide central pier, which was left after the removal of a heavy steel bulkhead behind which the Quabbin end of the tunnel was constructed while the Wachusett end was first operated for diversions from the Ware River directly to Wachusett Reservoir. The net waterway area is 102.1 sq ft.

(*f*) At shaft 8, a downtake shaft for Ware River floods, there is a considerable enlargement in the area as well as a large sump in the invert crossed by a narrow footbridge.

(*g*) At the bottom of shaft 4, there is a central pier 18 in. wide and the shaft otherwise resembles shaft 9. The net waterway area is 108.5 sq ft. No racks are placed there.

(*h*) At shaft 2, an uptake shaft leading to a spillway at the surface, there is a large opening in the crown as well as the sump in the invert.

(*i*) Shaft 1, the uptake shaft to Wachusett Reservoir, contains a 144-in. by 90-in. venturi meter, by which all the flows are measured. At the top, a branch extends horizontally through two 6-ft control valves in series and discharges under water into a stilling pool through a 5-ft 5½-in.-diameter end nozzle with a waterway area of 23.4 sq ft. The nozzle crown is several feet beneath the surface. Under all the high velocity conditions considered in this discussion, the water is pushed ahead in large eddies, which flow back around the nozzle in such a manner that the static head is practically zero at the nozzle crown (El. 388.2).

By the summer of 1943, Quabbin Reservoir had filled to within 30 ft of the flow line and a continuous draft was made for about a month under conditions of steady uniform flow. On September 3 of that year, fifteen readings were taken, at 1-min intervals, of the water level in a well connected to the bottom of shaft 12. The average level was El. 494.16; the maximum departure from the mean was 0.35 ft. It was estimated that 0.72 ft should be added to this pressure gradient to obtain the true energy gradient, allowing for velocity head and some downstream loss on account of the bend.

On the same day, about 1 hour earlier, ten readings were taken, at 1-min intervals, of the water level in shaft 9. The average level was El. 466.29, and the maximum departure from the mean was 0.09 ft. It was estimated that the true energy gradient, including velocity head, was 467.29. Hence, the loss of head in the 47,098 ft between shafts 12 and 9 was 27.59 ft, which is estimated to be reduced to about 27.3 ft by miscellaneous minor losses occurring at the previously described shaft bottoms en route. Hence, the slope of the hydraulic gradient was 0.580 per thousand.

Four hours earlier on the same day fifteen readings were taken, at 1-min intervals, of the water level in shaft 2. The average level was El. 423.57, and the maximum departure from the mean was 0.20 ft. It was estimated that the true energy gradient, including velocity head, was 424.29. Hence, the loss of head in the 72,413 ft between shafts 9 and 2 was 43.00 ft, which is estimated to be reduced to about 42.0 ft by miscellaneous minor losses occurring past the pier between shafts 9 and 8, and at the other shaft bottoms, including somewhat less than full recovery of velocity head at the downstream end of the piers at shafts 9 and 4. Hence, the slope of the hydraulic gradient was 0.580 per thousand, the same as that in the other stretch upstream. Continuing this same slope for the remaining 9,902 ft to the bottom of uptake shaft 1, the computed energy gradient at that point was El. 418.54, and the difference or loss from this point to the crown of the nozzle in the stilling chamber, El. 388.2, was 30.3 ft. Of this total, 21.4 ft represented velocity head at the discharge end, leaving about 8.9 ft for all the miscellaneous losses in the uptake shaft, including those of the meter and valves. This loss, in feet, equals 0.0000282

[a] Average surface elevation of Quabbin Reservoir. [b] Difference in elevation between Quabbin Reservoir surface and outlet (388.2).

mgd^2, which has been checked by the writer on a number of other occasions as entirely reasonable.

In writing a convenient expression of the loss as a function of the rate of flow, the use of the exponent 2 is justified because of the narrow range within which the rate fluctuates. The loss in getting into the tunnel from Quabbin Reservoir and in the downtake to the bottom of shaft 12 is estimated from excellent data to be 0.0000100 mgd^2 with draft from the upper intake (0.0000160 mgd^2 with draft from the lower intake). The losses are summarized as follows:

Type of head loss	Head, in ft/mgd^2
Reservoir to bottom of shaft 12	0.0000100
Past shaft bottoms and piers	0.0000041
Bottom of shaft 1 to exit	0.0000282
Total miscellaneous	0.0000423
Velocity head at exit	0.0000680
	0.0001103
Friction	0.000235
	0.000345

In confirmation of the previous reference to the inherent accuracy and precision caused by the great length of the tunnel, note that it takes as much as 11% uncertainty in the determination of miscellaneous losses to correspond to 1% difference in the rate of flow. Based on this fairly accurate determination of these miscellaneous losses in terms of the rate of flow, the data for all the long runs have been tabulated and used to determine the probable coefficient, as shown in Table 12. The change in reservoir elevation during any run is so small and at so uniform a rate that no appreciable error is introduced in observing it. The same is true of the steadiness of the rate of flow. Although infiltration of as much as 3 mgd has been noted just after unwatering of the tunnel, leakage under actual operating conditions at full head is considered negligible.

The losses in Col. 6, Table 12, are for drafts from the upper intake in the case of the last two runs, in 1946 and 1947, and from the lower intake in the previous years. In the case of run 2, however, the upper intake was also open providing free access and approximately the same head loss conditions as normal draft from the upper intake at the later high reservoir levels. Col. 12 is based on depth observations in the reservoir in front of the intake.

For convenience, the data in Col. 13 were read from the writer's diagram and those in Col. 14 from the Hazen-Williams slide rule.

The writer has noted, in studying these data, that there appears to be a slight improvement in the coefficient immediately following a long period of flushing out at these high velocities. It should also be pointed out that there is a tendency for air to enter aqueducts of this type and to be carried along the crown. This results in an appreciable lubricating effect, the actual hydraulic radius being somewhat greater than the theoretical and the roughness being actually somewhat greater than indicated by using the theoretical radius. Such differences, however, are very slight.

E. J. K. CHAPMAN,[29] Assoc. M. ASCE.—The results published in this paper are of considerable value and the authors are to be commended for their careful and analytical presentation of the facts. One set of results is of particular interest in that it discloses certain surprising features which would not normally have been expecteed. These are the data given for the 18-ft-diameter concrete-lined tunnel. In the section between the Apalachia Dam adit and the Apalachia adit, the results indicate a variation in Manning's n from 0.0122 to 0.0136 as the velocities increase from 3.8 ft per sec to 12.6 ft per sec. This variation in n is large and seems much greater than could have been anticipated, especially in view of the careful manner in which the tests were conducted. Manning's formula has been well tested in the past in many large tunnels and has proved reliable, and the values of n determined for any given tunnel are usually more consistent. In addition to the variations of n, the top value of 0.0136 is considerably higher than would have been expected from the descriptions of the concrete surfaces given in the paper. In fact, in the section between Turtletown Creek and McFarland adit, a value of 0.0138 was reached and maintained over a fair range of velocity.

It is interesting to note that the value taken for a design basis[4] was 0.0130 and it might well have been hoped that a better value than this would be obtained, especially before the tunnel had seen any service.

The writer is closely associated with James Williamson, who has done much work on the underlying causes of frictional resistance created by turbulent flow in pipes.[30] In the manuscript of an unpublished paper, Mr. Williamson touches on the special conditions occurring in very large pipes with very high *R*/*k*-ratios. He shows how pipes with *R*/*k*-ratios greater than 2,000 can be expected to develop spiral flow which may be of the stable or continuing form, where the pitch is independent of the velocity. In such cases the frictional resistance is expected to be higher than that given by calculations based on normal axial flow.

---

[29] Cons. Engr., Glasgow, Scotland.

[30] "Considerations on Flow in Large Pipes, Conduits, Tunnels, Bends, and Siphons," by James Williamson, *Journal*, Inst. C. E., London, April, 1939, p. 451.

The Apalachia 18-ft-diameter concrete-lined tunnel has an *R*/*k*-ratio of 2,690, or possibly higher. This ratio brings the tunnel into the spiral flow region, and a further unusual feature of the tunnel is that the section is circular, which would allow spiral flow to develop and continue, whereas the more usual horseshoe shape would tend to maintain axial flow.

From these considerations, the writer feels that the probable explanation of the surprisingly high value of Manning's *n* is due to the fact that spiral flow has developed, especially at the higher velocities.

It is noted from the description of the design of the project[30] that the associated Ocoee No. 3 project included a horseshoe-shaped tunnel of somewhat smaller diameter than the Apalachia tunnel. Presumably the workmanship and finish of the concrete surfaces were similar in the two projects. If so, the Ocoee tunnel, in view of its smaller *R*/*k*-ratio in conjunction with its horseshoe section, would probably not present conditions for spiral flow. Thus, frictional loss would be expected to give a more constant and generally lower value of Manning's *n*.

The authors do not publish any data on Ocoee No. 3 in their paper, but possibly some tests were made even if these consisted only of recording the surge tank water levels at steady flows, from which, with suitable allowances, a calculation could be made of the whole loss from reservoir to surge tank and a value of *n* could be determined. If so, it would be extremely interesting to discover if the writer's supposition is borne out by an apparently lower value of *n*.

Probably the only positive method of determining whether spiral flow does occur at Apalachia would be to make pitometer traverses on two or more diameters of the 18-ft pipe and plot the velocity distribution. The velocity contours would clearly indicate whether flow is symmetrical across the whole diameter or not. A suitable place to install appliances for taking these traverses appears to be at the 16-ft-diameter steel pipe crossing over Turtletown Creek. Unfortunately the contraction from 18-ft to 16-ft diameter a short distance upstream will apply an energy effort causing reversion toward uniform velocity, and one could expect at this place only a slight residual indication of spiral flow. Better results would be obtained if it were possible to make the measurements on an 18-ft-diameter section.

It is not often that an opportunity occurs to check a large-scale effect which cannot be determined by laboratory experiment, but the writer feels that such an opportunity exists in the two tunnels referred to and strongly urges that, in the interest of hydraulics, the hydraulic engineers of the Tennessee Valley Authority should re-examine the test results for the two tunnels and make further experiments, if practicable, to determine the effect of spiral flow on resistance to flow.

The pertinent points are:

(1) Does Ocoee No. 3 tunnel, with presumably similar surface conditions to those in the Apalachia tunnel, show a lower coefficient *n* by the Manning formula?

(2) Does spiral flow occur in the Apalachia tunnel and not in the Ocoee No. 3 tunnel?

JULIAN HINDS,[31] M. ASCE.—In this carefully conducted series of experiments, the authors have invaded a size range for circular conduits flowing full on which very little research has been done previously. The results deserve careful study and frank discussion by all engineers interested in the development of better pipe flow data.

Because of the complexity of the layout, the precise allocation of losses to particular reaches of line is not simple, but the complexities are fully presented and the method of allocation is explained in detail. The considerable lengths of the various reaches contributed to dependability.

It is noted that the reduced data are compared both with a "conventional" formula (Manning) and the more recent Reynolds number formulas. This comparison is particularly appropriate because of the efforts being made to unify practice and theory in pipe line design.

The earliest and most fundamental of the formulas used for computing resistance to flow in pipe lines are those proposed by Chézy and Darcy. These formulas are not independent, but are transposable, either into the other. Any table or diagram for finding the coefficients in one of them can be made to yield the coefficients for the other simultaneously. Any difference in regard to convenience of use is inconsequential. The Darcy equation has the esthetic virtue of being nondimensional, for which reason it is preferred in mathematical discussions. Auxiliary methods are required for finding the coefficients in each of these equations.

Supplementing these two basic equations are the conventional Kutter, Manning, Williams-Hazen, Scobey, and other formulas. The Kutter formula is used for finding the Chézy coefficients; and, although it is primarily adapted to open channels, at times it is applied to pipes. The Williams-Hazen and the Scobey formulas are exponential in form and are considered applicable only to pipes. The Manning formula also is exponential and usually is so employed, but is occasionally used for determining the Chézy coefficient—for both open and closed conduits.

All these formulas are empirical, applicable to water only, and may be confidently adopted only within the range of experimental verification. Much work has been done on the development of rational flow formulas for the flow of all fluids in all pipes. Definite progress has been made, but complete coordination between laboratory and field experiments as well as between theory and designing office practice has not been accomplished.[32] If the new formulas are to be applicable to all kinds of fluids, it is essential that they take into account the effect of viscosity. This effect is introduced through the Reynolds number, **R**. (All nomenclature is identical with that used by the authors unless otherwise noted.) The dimensionless factor, *f*, in the Darcy formula (Eq. 1) is used as the other variable; hence, these new equations will be referred to as the $(f-\mathbf{R})$-equations or formulas.

---

[31] Gen. Mgr. and Chf. Engr., The Met. Water Dist. of Southern California, Los Angeles, Calif.

[32] "Comparison of Formulas for Pipe Flow," by Julian Hinds, *Journal*, A.W.W.A., November, 1946, p. 1226.

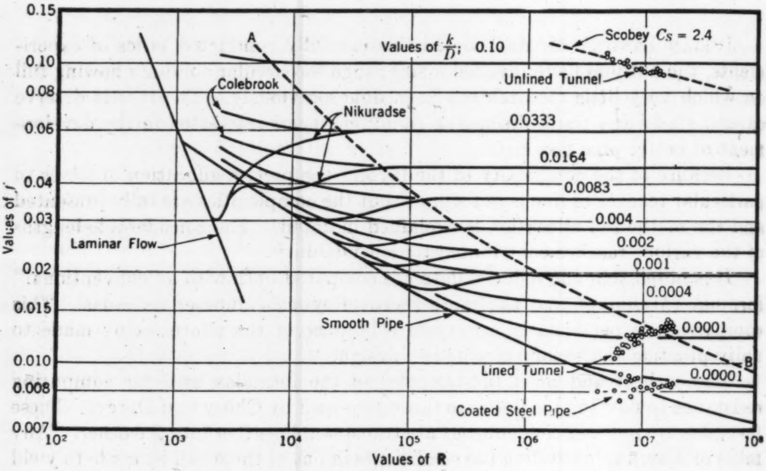

FIG. 14

The relation of these equations to each other, to the authors' data, and to one important collection of previously published data, is illustrated in Fig. 14. This group of curves covers the full range of pipe flow conditions up to $\mathbf{R} = 100{,}000{,}000$, passing from laminar flow on the left through a transition zone to a zone of complete turbulence in the upper right-hand part of Fig. 14. Laminar flow has no connection with the data reported in this paper and need not be discussed.

There are at present three $(f-\mathbf{R})$-equations within the turbulent range bidding for acceptance, each in its particular field. The most thoroughly substantiated of these is the smooth pipe formula credited by the authors to Theodor von Kármán, M. ASCE, and Ludwig Prandtl:

$$\frac{1}{\sqrt{f}} = 2.0 \log \mathbf{R} \sqrt{f} - 0.80 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

The accuracy of Eq. 8 for the flow of water or air through glass or drawn brass pipe was experimentally substantiated by T. D. Stanton and T. F. Pannell for values of **R** up to 500,000.[33] Its conformity to flow in larger pipes and in other types of surfaces has been reasonably well substantiated by others. In 1939 C. F. Colebrook published a diagram showing the applicability of this equation to cast-iron pipe from 4 in. to 60 in. in diameter, provided with spun cement and bituminous linings; he also showed its applicability to an 18-ft concrete-lined tunnel.[20]

---

[33] "Similarity of Motion in Relation to Surface Friction of Fluids," by T. D. Stanton and T. F. Pannell, *Transactions*, Royal Soc. of London A, Vol. 214, 1914, p. 199.

Eq. 8 is presumed to apply to all fluids and is doubtless accurate for actually smooth surfaces beyond all practical requirements. As will subsequently appear, flow in even moderately roughened pipes seems to follow this curve for limited values of **R**.

The smooth pipe curve, Eq. 8, plats as a single line in Fig. 14. It thus serves merely as a boundary for an unlimited multitude of possible flow conditions for which other formulas are required. Eq. 6, likewise reasonably well established, is applicable to flow conditions in the zone of complete turbulence, the upper right-hand part of Fig. 14.

Data substantiating the applicability of this equation to smooth pipes roughened by uniform sand grains glued to the interior surface were published by J. Nikuradse in 1933.[34,35] The results of these experiments classified as to the ratio of sand grain size (k) to pipe diameter (D) are shown in Fig. 14. (The Nikuradse data were transferred to Fig. 14 photostatically. The results are accurate enough for present purposes, but not necessarily exact.) It will be noted that the plotted points follow the smooth pipe curve for varying distances, depending on the relative roughness (k/D), then pull away, continuing downward for a distance and finally rising to a constant value of f. Beyond this point the ($f-\mathbf{R}$)-curve for any specific value of k/D is horizontal. Eq. 6 gives the vertical distribution of the horizontal parts of these lines.

The points at which the platted data assume horizontal directions are not sharply defined, but are approximately delineated by curve A–B, Fig. 14, the equation of which is

$$\frac{1}{\sqrt{f}} = \frac{\mathbf{R}}{200} \times \frac{k}{D} \qquad (9)$$

The region to the right of, and above, this line constitutes the zone of complete turbulence. Within this zone, viscosity has no effect on flow and, for a given pipe, values of Darcy's f and Chézy's C are constant; they are the same for gas, water, gasoline, hot or cold crude oil, or any other fluid. Within the range of applicability of Eq. 6, a diagram of the complicated form of Fig. 14 is unnecessary. Values of both f and C can be taken from a simple diagram or table.

Unfortunately, a large percentage of the flow problems encountered in practice do not fall within this range, but lie in the transition zone. If it could be shown that all rough pipe flows follow the form of Mr. Nikuradse's experimental data, it would be on the side of safety (although not necessarily economical) to ignore the dip shown by him in the transition zone. All rough pipe for all purposes then could be designed in accordance with Eq. 6, except for small values of **R** for which the smooth pipe formula, Eq. 8, controls.

---

[34] "Gesetzmässigkeiten der turbulenten Strömung in glatten Röhren," by J. Nikuradse, *Zeitschrift*, Verein Deutscher Ingenieure, Band 77, 1933, p. 48.

[35] "The Mechanics of Turbulent Flow," by Boris A. Bahkmeteff, Princeton Univ. Press, Princeton, N. J., 1941, p. 32.

However, other experimenters have found that pipes with natural roughness follow a different law in the transition zone. There appears to be a continuous upcurve toward the left, rather than the dip found for the sand-roughened pipe. After analyzing available data, Mr. Colebook proposed a formula covering flow both in the transition zone and in the zone of complete turbulence:[20]

$$\frac{1}{\sqrt{f}} = -2 \log \left(\frac{k/D}{3.7} + \frac{2.51}{\mathbf{R} \sqrt{f}} \right) \qquad (10)$$

Eq. 10 is asymptotic to the smooth pipe curve on the left (in Fig. 14) and to the Nikuradse curves on the right, and is offered by its proponents as a universal rough-pipe flow formula. It is not as formidable as it appears to be. In fact, it is readily adaptable to presentation by diagrams.[36] The chief difficulties with Eq. 10 are lack of final assurance of correctness within the transition zone and lack of an established set of values for k. The relation of the Colebrook curve to the Nikuradse data is shown in Fig. 14. It is not convenient to show data supporting the Colebook equation on this diagram.

The $(f-\mathbf{R})$-equations purport to be at least partly rational and are supported by laboratory experiments. The conventional formulas are empirical and depend for support largely on field tests. Field tests cannot be made with laboratory precision, but a multiplicity of comparisons should show a common trend. To date this has not been demonstrated to be true. Curves based on field experiments frequently cut sharply across theoretical curves, a fact that needs explanation.

The authors' data are platted in Fig. 14 to show their general relation to the $(f-\mathbf{R})$-equations. This platting does not replace, but supplements, the original platting in Fig. 10. Points for the tar-lined steel pipe conform to the smooth pipe curve out to $\mathbf{R} = 10{,}000{,}000$. These points lie too far from the zone of complete turbulence to give a definite indication of the final value of k. If it is assumed that an extension of these experiments would follow the Colebrook trend, then a value of k/D somewhat less than 0.00001 might be anticipated or, say, a value of k less than 0.0002 ft. On the other hand, if it is anticipated that these points will follow the Nikuradse trend, rising to a maximum of 0.00002 or 0.00003 in the vicinity of the line A–B, the value of k would be about 0.0004 ft. The authors arrived at a value of 0.0035 in. or about 0.0003 ft.

These data do not justify the drawing of a conclusion as to the precise value of k for this type of pipe, but they do illustrate the necessity for determining whether flow in such pipe follows the Nikuradse or the Colebrook trend.

The points for the cement-lined tunnel are more consistent within themselves than those for the steel pipe. They cross the curve A–B and appear to level off at about $k/D = 0.0002$ or, say, at a value of k somewhat less than 0.004 ft, which conforms to the authors' value of $k = 0.04$ in. It will be noted that these data definitely follow the Nikuradse rather than the Colebrook trend. If repeatedly confirmed by other field experiments, this fact may have a profound influence on the final selection of a flow formula. However, it will be noted from Fig. 11 that these data also are at distinct variance with the Manning formula, which suggests that a critical review of why these points fall as they do may add something to the over-all understanding of the problem.

---

[36] "Friction Factors for Pipe Flow," by Lewis F. Moody, *Transactions*, A.S.M.E., Vol. 66, 1944, p. 671.

The points for the unlined tunnel are more consistent among themselves than would be expected under the circumstances. They are platted in the upper right-hand corner of Fig. 14 and are far within the zone of complete turbulence. Consequently, they might be expected to lie on a horizontal line; actually, they are distinctly inclined. Their combined center of gravity lies slightly below the $k/D = 0.10$ line as determined by Eq. 10 or 6. The corresponding value of k approximates the authors' estimated value of 22 in. Also, as revealed by Fig. 12, these points show a definite trend away from a constant Manning's n. Strangely, they conform excellently to the Scobey steel pipe formula for a coefficient $C_s = 2.4$. Of course, this value of C_s is entirely outside the range for which Mr. Scobey's formula was proposed and tested and the Scobey formula has no analytical correlation with the rough pipe law; hence, this conformity contributes nothing to the solution of the general problem. Again, a critical examination of why these platted points fail to follow the expected trend should add to the general understanding of the resistance to flow in pipes.

It is hoped that the ideas expressed herein may help in the ultimate evaluation of the results of these and future tests.

William P. Creager,[37] M. ASCE, and Stephen H. Haybrook,[38] Jun. ASCE.—Some excellent experiments to determine the friction-loss coefficients in several types of conduits have been described by the authors. The writers desire to discuss the test results as applied to rock-lined tunnels, about which there is, relatively, a dearth of information.

The writers have advocated that, for consistency of records, tests on open conduit losses be tabulated by the Kutter formula and tests on closed conduit losses by the Hazen-Williams formula for general use where special formulas, such as the Scobey formula, have not been devised for special types of conduits.

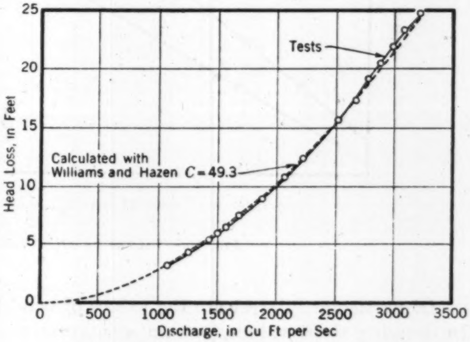

Fig. 15.—Head Losses in Unlined Rock Tunnel

With this in mind, the writers have tabulated in Fig. 15, by a full line, the relation between discharge and losses determined by tests for the Apalachia unlined rock tunnel; and also, by a dotted line, the same data calculated from the Hazen-Williams formula:

---

[37] Cons. Engr., Buffalo, N. Y.

[38] Engr., Justin and Courtney, Philadelphia, Pa.

$$v = 1.32\, C\, R^{0.63}\, S^{0.54} \qquad \text{(11)}$$

using a C-value of 49.3.

The deviation in loss is only 2.5% and the corresponding deviation in C is only about 1.5%. Based on similar comparisons for other unlined rock tunnels, the rock surface trimming in the Apalachia tunnel was well done, it being the opinion of the writers that a Hazen-Williams $C = 50$ is about the best which can be expected and that $C = 45$ is a safe value for average conditions.

G. S. TAPLEY,[39] Assoc. M. ASCE.—The authors are to be commended on their success in determining values of roughness coefficients under complicated conditions for the various types of surface of the structure examined; the values of coefficients obtained confirm, for very large-sized structures, the existing ideas as to the magnitude of such coefficients. The application of Eq. 6 to determine the measure of wall roughness, as shown in Table 9, is interesting.

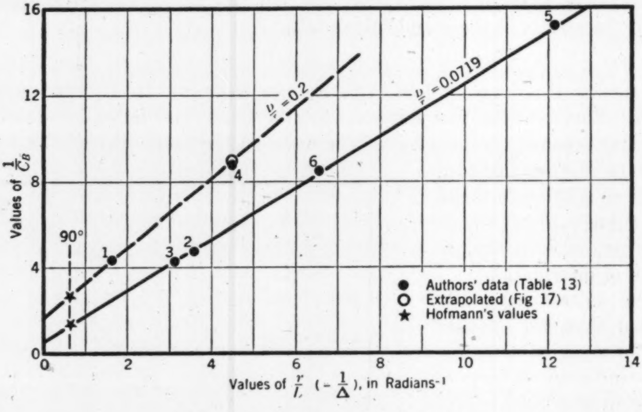

FIG. 16.—VALUES OF $1/C_B$ VERSUS $1/\Delta$

Of particular interest are the values of bend-loss coefficient, C_B, in Table 5. In deriving these values, certain assumptions were made in the preliminary calculations. Perhaps the effect of these assumptions is mirrored to some extent in the final results; for example, the authors' application of Fig. 67 of W. P. Creager and J. D. Justin,[6] Members, ASCE, tacitly assumes that the minimum value of C_B corresponds to $r/D = 5$, and their application of Fig. 68 from the same reference may predetermine the manner of variation of C_B with the central angle. In so far as the authors' final results on bend loss may be considered independent of the assumptions, they furnish a basis for developing data to cover a considerable range of design conditions as shown hereinafter. Data, so developed, can be applied in design practice with less risk of error, perhaps, than can existing data.

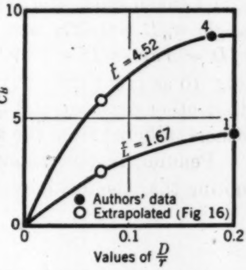

FIG. 17.—VALUES OF $1/C_B$ VERSUS D/r

With reference to Fig. 16, it may be noted that points representing bends 2, 3, 5, and 6 fall along a straight line representing $r/D = 13.9$. For $r/D = 5$, only one point (bend 1) was available. Bend 4, however, has a value of $r/D = 5.63$, and by extrapolating a short distance in Fig. 17, another point representing $r/D = 5$ and $1/\Delta = 4.52$ was obtained—thus furnishing two points through which the locus representing $r/D = 5$ was drawn. Here, $1/\Delta$, of course, equals r/L, where L is the length of curve and Δ is in radians. Calculations are shown in Table 13.

By passing curves through the origin and points representing the data in Fig. 16, Fig. 17 was constructed with maximum points at $D/r = 0.2$ ($r/D = 5$). Passing the curves through the origin in Fig. 17 is equivalent to the assumption that C_B is infinite when Δ is constant and r is infinite while D is finite; L, also, is then infinite.

TABLE 13.—COMPUTATION OF BEND-LOSS ELEMENTS

Bend No. (1)	Deflection angle, Δ (degrees) (2)	r/D (3)	C_B (4)	$\Delta = L/r$ (radians) (5)	$\frac{1}{\Delta} = \frac{r}{L}$ (6)	D/r (7)	$1/C_B$ (8)
1	34.26	5.00	0.236	0.598	1.67	0.200	4.24
2	15.72	13.9	0.207	0.274	3.65	0.0719	4.83

5	4.70	13.9	0.066	0.082	12.2	0.0719	15.2
6	8.72	13.9	0.119	0.152	6.58	0.0719	8.41
....[a]	90.0	5.0	0.40	1.57	0.637	....	2.50
....[a]	90.0	13.9	0.86	1.57	0.637	....	1.16

[a] "Der Verlust in 90°—Rohrkrümmern mit gleichbleibendem Kreisquerschnitt," by Albert Hofmann, *Mitteilungen*, Hydraulischen Instituts der Technischen Hochschule, München, Heft 3, 1929.

On the other hand, it may be noted in Fig. 16 that, when L is very great, although r/D is finite, C_B is not infinite; in fact, the intercepts on the axis of ordinates are $1/C_B = 0.5$ and $1/C_B = 1.5$, from which $C_B = 2$ and 0.667, respectively (for $r/D = 13.9$ and 5, respectively). In this case C_B has a maximum value depending on the value of r/D. The implication is that for a very long curve of very long radius (but finite pipe diameter) C_B is infinite; whereas, for a very long curve of finite radius and finite pipe diameter (such as in a coil of many loops) the coefficient has a finite value depending on r/D. This seems to suggest that the velocity distribution becomes adjusted to the curvature in the latter case, but continues to be disturbed in the former.

Since the authors' data covered central angles up to only a little less than 35°, it was desired to obtain confirmation of the data in Fig. 16 in the region of larger central angles. A. Hofmann's plotting[40] of the Williams, Hubbell, and Fenkell data referring to a 30-in.-diameter pipe curve with a 90° central angle ($r/L = 0.637$) was used by the writer to calculate values of $1/C_B$ for $r/D = 5$ and $r/D = 13.9$. The calculated values plotted exactly on the loci in Fig. 16 as previously derived from the authors' data. It was found, however, that other experimental data such as that of Balch, Davis, Brightmore, and others, differed from the authors' data considerably.

Pending further confirmation of the data in Fig. 16, it might be worth noting that the loci may be represented by

$$\frac{1}{C_B} = c_1 + c_2 \frac{1}{\Delta} \text{.......................} (12)$$

in which c_1 and c_2 are functions of r/D, and represent, respectively, the intercepts on the axis of ordinates and the slopes of the loci.

The straight-line equation (Eq. 12) can also be represented by the locus of an equilateral hyperbola whose coordinates are Δ and C_B and which has asymptotes at $C_B = 1/c_1$ and $\Delta = \frac{-c_2}{c_1}$. Only that section of the locus for which coordinates are positive is, of course, real. The data are plotted in hyperbolic form in Fig. 18. That the curves pass through the origin in Fig. 18 follows from the fact that the head loss due to the bend (and, therefore, C_B) must be zero when L is zero.

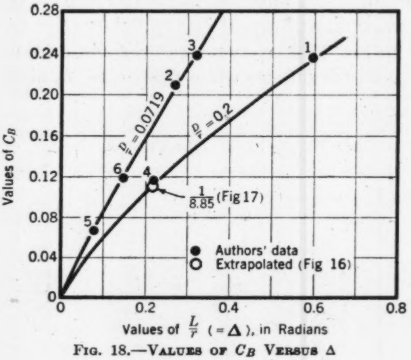

FIG. 18.—VALUES OF C_B VERSUS Δ

Although the authors' development of data on loss of head in bends was auxiliary to the main purpose of their paper, it is believed that the data have some merit as a basis for design material, in a form such as Fig. 16, to which additional lines can be added by the process already described. Needless to say, further confirmation by other experimental data is indicated.

J. N. BRADLEY,[41] ASSOC. M. ASCE, AND S. P. WING,[42] M. ASCE.—The authors and others concerned are to be commended on the meticulous manner in which the planning and the testing were performed on the hydraulic features of the Apalachia Tunnel. In making field tests the usual procedure is to assign to the job a man who is not especially trained in hydraulic testing, with in-

Description and literary reference

(8)

Curve 1. Smooth cement surface; discharge rated by a current meter placed in the tailrace; about 10% of the line located on a small degree of curvature ($r/D = 30$). About 5% subtracted from the over-all measured losses as an estimate of entrance losses. The writers estimate that the plotted losses are about 1% greater than normal. This was a reliable test. ("Correnti Uniformi entro grandi condotte e grandi canali, Milano," by Giuliode Marchi, Milan, Italy, 1932–1936; Library Data File, U.S.B.R., 91–241.)

Curve 2. Smooth surface resulting from use of steel forms; discharge rated by Gibson method. The section measured was straight. The velocities are probably 3% in error. Combining all errors, the friction factor was probably not more than 4% in error. (*Transactions*, ASCE, Vol. 101, 1936, p. 1409; also Library Data File, U.S.B.R., 91–241.)

Curve 3. Pre-cast in steel forms 6 ft long; discharge rated by color movement, current meter, and Cipoletti weir. All joints were carefully calked on the inside. The alinement was straight. There was a gentle vertical bend near the inlet and one near the outlet (*Bulletin No. 852*, by Fred C. Scobey, U.S.D.A., Washington, D. C., 1924, p. 38.)

Curve 4. Lining and the joints smooth; discharge rated by pitot tube. The alinement of the first section was nearly straight and there was a gentle sinuous curve, vertically, in the second section. This pipe was pre-cast in 12-ft oiled steel forms. (*Engineering News-Record*, April 29, 1926, p. 678.)

Curve 5. These experiments were reported by Bazin to be "perfect in bore." The alinement was straight and the results indicate an unusually smooth pipe. (*Bulletin No. 852*, U.S.D.A., Washington, D.C., 1924, p. 79.)

Curve 6. Lining finished with a brush coat. The finish coat wore off on the bottom but brush marks were still visible on the sides. The approach and the alinement were straight. The inlet was rounded. The readings were taken during flood flows, the discharge being rated by current meter. (*Transactions*, ASCE, Vol. 93, 1929, p. 1588.)

Curve 7. Lining finished with a brush coat. The finish coat wore off on the bottom but brush marks were still visible on the sides. The alinement was straight, the approach curved, and the inlet rounded. The readings were taken during flood flows, the discharge being rated by current meter. (References same as for curve 6.)

Curve 8. Tests by E. Kemler involving observations on 1,500 to 2,000 diameters of brass pipe 0.103 in. to 5.0 in. in diameter. The Nikuradse tests, indicated as plotted points (curve 11, Fig. 19), were included in the data that produced the Kemler curves. (*Transactions*, A.S.M.E., Hydraulics Section, Vol. 55, 1933, p. 7–32.)

Curve 9. Hand-troweled cement finish; discharge rated by current meter placed in the tailrace.

DATA ON LARGE CONCRETE PIPE

Description and literary reference
(8)

There were seven horizontal curves and two large vertical curves. The tests are reliable. (Reference same as for curve 1.)

Curve 10. Some rough spots remained on the surface after the steel forms were removed. This was a poor test, no account being taken of the change in size and shape of the cross section. The alinement was irregular, with six horizontal bends and two vertical bends. The estimated error in the results is ±15%. (Letter dated March 5, 1931, from the Pacific Gas and Electric Company, San Francisco, Calif.)

Curve 11. Smooth pipe; the plotted points designated curve 11 in Fig. 19 denote tests by J. Nikuradse on brass pipe from 0.033 in. in diameter to 3.28 in. in diameter. The equation through these points is good for extrapolation from $R = 30^6$ to 10^8. (*Forschungsheft 356*, Verein Deutscher Ingenieure, 1932, p. 30.)

Curve 12. Steel forms were used and the concrete was rubbed with carborundum brick. The discharge was rated by color movement. The line included five bends on 800-ft radii, with short tangents between. This is equivalent to a curve length of 3,060 ft and a radius of 1,665 ft ($r/D = 92$). The bend loss (±5%) and surge tank losses were not considered. The data used were taken from a curve passing through forty-two observations. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 83; supplemented by correspondence with the Ontario Power Company in June, 1931, and April, 1935, including a map and a profile.)

Curve 13. Hand-troweled cement finish; discharge rated by current meter placed in the tailrace. This was a very reliable test. The pipe was straight, free from bends and entrance losses, and was equipped with three excellent mercury monometers. The line was built in 1917. (References same as for curve 1.)

Curve 14. Smooth cement surface; generator rating of discharge. It is reported that losses were high because of underestimated intake losses and poor location of the lower piezometer. The writers estimate that these factors make the plotted points ±7% high. (References same as for curve 1.)

Curve 15. On this test oiled forms were used, and a neat cement brush coat. The lining was not smooth. The pipe was probably new at the time of the test and the discharge was rated by a weir below the plant. Surge chamber losses were neglected. The regained velocity head loss h_v was assumed equal to the entrance losses. The invert was placed by hand without forms and it presented a rather rough, uneven appearance. (*Proceedings*, June, 1923, Convention, Pacific Coast Electrical Assn., p. 139; *Engineering News-Record*, October 11, 1923, p. 598; and Library Data File, U.S.B.R., 91-241.)

Curve 16. Surface originally smooth, had become somewhat eroded in 4 years. Discharge was rated by color movement. The line was pre-cast in 4-ft lengths in oiled steel forms. Joints were smooth. The water flowing in this line contains sharp basalt particles which have eroded the bottom of the intake like a sandblast. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 51). The water enters the pipe in a very turbulent state and the erosion extends 150 ft from the intake. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 36; also drawing No. 33.19(*b*) in the Denver office of U.S.B.R.)

Curve 17. Use of steel forms in place have resulted in rough joints but with a smooth surface between joints. The line contains a sharp 90° bend and two slight vertical bends in the reach measured. About nineteen diameters upstream there is the last of two bends and constrictions resulting from repair work. The exit head loss was ignored and the results are not consistent. The concrete joints protrude as much as 0.15 ft in places. The effect of the bends was not considered in the computations. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 81; *Transactions*, ASCE, Vol. 73, September, 1911, pp. 399 and 460; "Catskill Water Supply of New York," by Lazarus White, John Wiley & Sons., Inc., New York, N. Y., 1913, pp. 66 and 73; and *Engineering Record*, January 1, 1910, p. 26; September 17, 1910, p. 312; March 11, 1911, p. 279; and February 28, 1914, p. 240.)

Curve 18. Surface polished. Friction values taken from curve prepared by E. W. Spies. ("Turbulente Stromungon in geraden und gekrummten glotten Rohrleitungen bei hohen Reynolds'schen Zahlen," by Romano Gregorig, Dipl. Masch-Ingenieure, Eidgenossichen Technischen Hochschule in Zurich, No. 695, 1933., D. F. 91-26.)

Curve 19. Pre-cast in oiled steel forms with 12-ft lengths. The joints were smooth and carefully laid. Discharge was rated by venturi meter. In the first test there were twenty-nine bends; in the second, the line was slightly sinuous; and, in the third, the line was nearly straight. (*Engineering News-Record*, May 28, 1925, p. 897.)

Curve 20. Smooth surface; discharge rated by color movement. The line was quite straight in horizontal alinement. Vertical curves were long and gentle. The reach includes five 6-in. valves and three manholes. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 35.)

Curve 21. Smooth surface. Sections pre-cast in 6-ft steel forms. Discharge was rated by color movement. The alinement was straight. The reach includes eight 6-in. valves, two 6-in. blowoffs, and four 12-in. by 14-in. manholes. The inside surface was painted with a rich cement grout. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 41.)

Curve 22. Smooth surface; discharge rated by water meter. The conduit in the concrete was formed by a 36.5-ft length of smooth straight rubber hose. (*Technical Memorandum No. 339*, U.S.B.R., Denver, Colo., June 15, 1933.)

Curve 23. Sections pre-cast in oiled steel forms, 4 ft long, steam cured; discharge rated by color movement. The surface is reported as "unusually smooth" but for about half the line is curved gently and no allowance has been made for this curvature in the computations. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 39.)

Curve 24. Surface formed by troweled gunite. (References same as for curve 18.)

Curve 25. Use of steel forms in place has resulted in rough joints but with a smooth surface between joints. The line contains one sharp 90° bend in the reach measured. The concrete was poured against oiled steel forms but the joints were not smoothed. (*Bulletin No. 852*, U.S.D.A., Washington, D. C., 1924, p. 82; *Engineering Record*, April 2, 1910, p. 460.)

Curve 26. Smooth steel forms were used by the Tennessee Valley Authority (TVA) on the Apalachia Tunnel. Discharge was rated by current meter. The tunnel consists of three types of lining—concrete, steel, and unlined rock. The concrete section contains four long radius bends in the test section. The entire tunnel has a total of six bends.

Curve 27. The solid line marked "curve 27" in Fig. 19(*b*) was plotted from experimental data.

Curve 28. This curve in Fig. 19(*b*) represents the von Kármán-Nikuradse equation: $1/f^{0.5} = 0.8 + 2 \log(R f^{0.5})$.

Curve 29. Extrapolated from data for the 13-ft steel penstock tests at Boulder Dam, introducing the value of $f = 0.0177$ in the formula: $\frac{1}{f^{0.5}} = -2 \log \left(\frac{K}{7.4\,r} + \frac{2.51}{R\,f^{0.5}} \right)$. (*Transactions*, ASCE, Vol. 109, 1944, p. 59.) This formula was derived by C. F. Colebrook and C. M. White to cover the transition from smooth pipe to rough pipe ($K/r = 0.00134$).

structions to acquire help in the vicinity and to perform a definite series of tests in the shortest possible time. As a result, instrument taps are placed in the most convenient points along the pipe rather than in the more significant locations, and difficulties are often encountered with the work performed by the untrained personnel. Information resulting from the tests is too often questionable and is at times contradictory. Tests on prototype structures are a bountiful investment when performed with care and a thorough understanding of the problem involved.

In the case of the Apalachia Tunnel tests, pressure taps were installed in significant locations along the tunnel at the time of construction and well-trained personnel performed the test work and analyzed the data. The results should be very dependable.

The writers and others of the Bureau of Reclamation have collected and compiled test data on friction coefficients for large pipe lines for a number of years. It is felt that some of this information should be of value to the engineering profession as a whole. For example, data showing the relation of the friction coefficient to Reynolds' number are presented in Fig. 19. The data contained in Fig. 19 represent results from concrete pipe to 18 ft in diameter, velocities as high as 42 ft per sec, and Reynolds' numbers approaching 30,000,000.

As each curve in Fig. 19 is numbered, by referring to Table 14, information can be found concerning the diameter, velocity, length, age of pipe, character of surface, and estimated reliability of each test. Also listed in Table 14 are the references to published papers and bulletins on original work from which the information in Fig. 19 was obtained. For the sake of clarity, the actual test points have been omitted. In most cases these did not fall directly on the line as drawn but fell to both sides with considerable variation in some cases. The lines represent average values.

Superimposed in Fig. 19(*a*) are the results of the Nikuradse laboratory tests on smooth brass pipe and on brass pipe artificially roughened with sand; the Kemler boundary of tests on smooth brass pipe; and a line representing the von Kármán and Nikuradse equation for friction coefficients in smooth pipes for large Reynolds' numbers. Also included in Fig. 19 (designated as curve 26) are the results on the concrete-lined section of the Apalachia Tunnel tests. These were obtained from Fig. 10(*a*).

In looking over this graphical presentation of nearly all the apparently reliable hydraulic friction tests of pressure conduits surfaced with concrete and including pipes from 1 in. to 18 ft in diameter, one is first impressed by the wide range of coefficients found at any given Reynolds' number. For example, at a Reynolds' number of 10,000,000, the coefficient varied from 0.008 in the Ontario Power Company test (curve 12) to about 0.0125 in the Apalachia tests (curve 26)—a range of about 25% from the mean value. Whether this variation represented a real difference in the character of the concrete surfaces in the two cases or whether it represented errors in the measurement of hydraulic losses or in computations made to allow for bend or entrance effects is not known. The concrete surface of the Ontario conduit is known to have been exceptionally smooth, but without a quantitative measure of the roughness, such as has been developed by mechanical engineers to measure the smoothness of bearings, it would appear useless to speculate on the reasons for the differences shown. In the circumstances, it would appear necessary for hydraulic engineers, in their computations, to allow for the extreme range of possible friction coefficients. Since this is an economically wasteful procedure, the need for the development of some quantitative laboratory methods of measuring roughness seems evident.

The second feature of the curves in Fig. 19 is the general upward slope of the lines showing the results of tests of individual pipes. An upward slope means that friction losses are increasing at a greater rate than the square of the velocity. This is in accord with the Colebrook and White[43] transition law for the change between smooth and rough surfaces and is indicated in Fig. 19 by the family of $\frac{K}{r}$-curves. Apparently in the larger pipe and at the economic velocities usual in hydraulic design, most flow falls within the transition classification. The plotted data should serve as a warning that, where large diversion tunnels are to be designed to function at high velocities, friction losses may prove to be greater than would be anticipated from low velocity tests. The writers would appreciate comments from the authors on this characteristic of the data presented in the paper.

G. H. HICKOX,[44] M. ASCE, AND A. J. PETERKA[45] AND R. A. ELDER,[46] ASSOC. MEMBERS, ASCE.—The interest shown in this paper, as evidenced by the questions asked, the criticisms made, and the new data presented, is gratifying to the authors.

Mr. Barrows raises an important point when he emphasizes the authors' use of "equivalent circular sections." This method of computation was chosen because it provided a simple relationship between cross-sectional area and hydraulic radius. Although the actual hydraulic radius was a trifle smaller than that obtained by assuming an equivalent circular area, the amount of the difference is small and depends on the variability of the overbreak. The irregularities of overbreak can scarcely be known in advance, but some estimate of the average diameter is always available. Lacking other knowledge, the designer will assume an ideal section for his calculations and will thus utilize the data in the same manner as for the calculations of the paper. It follows that the actual areas, including overbreak, should be used instead of the nominal area. Failure to observe this precaution may result in considerable error. Thus, the designer must estimate the probable overbreak for the particular rock he is working in, and for this particular type of excavation, and must add this overbreak to the nominal diameter.

Messrs. Bradley and Wing are to be commended for the data of Fig. 19 and the accompanying descriptions of tunnel surfaces. This chart, in a much more complete form, was available to the authors, by courtesy of the Bureau of Reclamation, before the Apalachia tunnel tests were made. It is unfortunate that limitations of space prevented showing the experimental points in Fig. 19 and it should be noted that many of the curves presented are supported by scattered data. It was in part the uncertainty caused by these scattered results and by the conflicting nature of the curves that prompted the tests reported in this paper.

[43] "Turbulent Flow in Pipes, with Particular Reference to the Transition Region Between the Smooth and Rough Pipe Laws," by C. F. Colebrook, *Journal*, Inst. C. E., London, Vol. 11, 1938–1939, pp. 133–136.

[44] Associate Director, Eng. Experiment Station, Univ. of Tennessee, Knoxville, Tenn.

[45] Hydr. Engr., Hydr. Laboratory, Bureau of Reclamation, Denver, Colo.

[46] Associate Hydr. Engr., TVA Hydr. Laboratory, Norris Tenn.

The authors are indebted to Mr. Hinds for his clear understanding and elucidation of the practical problems surrounding the use of the (f − **R**)-equation for fluid resistance. The nature of the transition region still seems to be very imperfectly understood and much additional work remains to be done, both in laboratories and in the field, before the differences between the Nikuradse and the Colebrook types of transition are fully understood. It seems significant that, although the Apalachia tests were carefully made, they do not conform to either the Nikuradse or the Colebrook type of transition. In the meantime, designers should be aware of the possibilities implied by the data, as suggested by Messrs. Bradley and Wing, and should design with caution.

The tests on the unlined rock tunnel seem to indicate that in spite of the apparent good results the Nikuradse equation for f in terms of k/r for the completely turbulent region may break down for large values of k/r by the introduction of other effects as indicated by Professor Rouse. His suggestion that perhaps the irregularities of the tunnel wall constituted constrictions of the flow area is certainly worth consideration. The unlined rock tunnel was a succession of enlargements and constrictions caused by the method of driving it. The tunnel was at approximately its nominal diameter at each heading, and enlarged gradually to the next heading, with a very irregular surface as described in the paper and shown in Fig. 4. There seems to be little relationship between the size of the projecting rocks and the thickness δ' of the turbulent boundary layer. Perhaps the agreement with the Nikuradse equation is only fortuitous.

Mr. Chapman's suggestion that spiral flow may account for the high value of f in the concrete-lined tunnel is interesting. The cost of preparing for, and conducting, tests to investigate this point would be high because of the size of the conduit, the pressures in it, and its relative inaccessibility. No comparable data are available for the Ocoee No. 3 tunnel.

Mr. Gavett remarked on the successive approximations required by the piezometer locations. The location of the piezometers was a compromise between a complete set of pressure measurements such as might have been made in the laboratory and the practicalities of the field situation. Extensive installations are expensive and it was necessary to set up as few as would yield usable results. Observations were also a matter of serious consideration. The locations were isolated and access was over roads distinctly mountainous in character, some of which had been closed to public use and were no longer being maintained. The distance by such roads was several miles between points less than 7,000 ft apart along the tunnel. The distribution of personnel and equipment to these sites and the reading of gages at 1-min intervals for a continuous 8-hr period in rainy midwinter weather presented difficulties not encountered in the laboratory. Under these conditions it seemed much more reasonable to make a number of approximations than to obtain complete data.

With regard to Mr. Gavett's question about the exponent x in the equation $H_f = C\ V^x$, most of the available data indicate that x is 2 when the Reynolds number is large enough so that complete turbulence exists. For the part of the roughness curve lying on the smooth pipe curve, the exponent is less than 2. In the transition from "smooth" to "rough" flow, it may be either less than or greater than 2, depending on conditions that do not seem to be well understood. J. Nikuradse found a section of the transition from smooth pipe flow to complete turbulence where x was greater than 2. C. F. Colebrook found, however, that for commercial pipe x was everywhere less than 2 in the transition zone. In this field more data are needed, for unfortunately most flow occurs in the transition region, where knowledge of friction factors is least certain. This point is well brought out by Mr. Hinds in his excellent discussion.

The variation of Manning's n with velocity, mentioned by Messrs. Chapman and Hinds, is inherent in the equation whenever the frictional resistance does not vary with the square of the velocity. As a matter of fact, variation with the square of the velocity seldom occurs except for fully developed turbulence, which is beyond the range of most practical applications. Figs. 14 and 19 show the type of variation that may be expected. The surprising feature is not that Manning's equation does not fit these data, but that its inadequacy had not been discovered long ago.

It is hoped that, by the presentation of the data, use of the (f — **R**)-relationship for tunnel friction calculations may be stimulated. The empirical equations of Manning, Scobey, Kutter, and Hazen-Williams are useful within the region of experiment, but there is considerable doubt that the coefficients are characteristic of the surfaces. These equations (except Kutter's) are exponentials and plot as straight lines on logarithmic paper. Consequently, the particular value of the exponent of S (or V, depending on the form of the equation) can be correct only for a relatively small range of velocities as indicated by the curves of Figs. 14 and 19.

The authors do not quite agree with Professor Rouse in his interpretation of the test results. His position appears to be that the Apalachia tunnel data should conform to the curves of Fig. 13. Curve (d) of this figure was obtained from Nikuradse's data on uniformly sanded surfaces, and curve (b), from Colebrook's data on certain commercial surfaces. Mr. Colebrook and C. M. White showed that the transition curve depended on the character of the surface. The authors see no reason why the data presented by them should conform to any of the transition curves previously published. Of far greater significance is the fact that, in all cases, the data for each type of surface tend unmistakably to approach the line representing a value of $\frac{1}{\sqrt{f}} - 2 \log \frac{r}{k} = 1.74$. The scattering of the data for the asphalt-lined tunnel at low Reynolds numbers is accounted for by the fact that the measured head losses were very small. The squares (Fig. 13) represent a maximum head loss of 0.123 ft; and the first four diamonds, a maximum head loss of 0.144 ft. The losses for the concrete-lined tunnel varied from 0.88 ft to 12.58 ft; and for the unlined rock, from 3.13 ft to 24.78 ft. These data scatter much less. The only inconsistency in them is that they lie outside the range limited by the curves of Fig. 13. This is not unexpected because the surfaces tested probably differed from those represented in Fig. 13.

Since the data for all surfaces approach a value of 1.74 for $\frac{1}{\sqrt{f}} - 2 \log \frac{r}{k}$ as the Reynolds number increases, it seems clearly logical to estimate the apparent constant value of f in Fig. 10 for use in calculating k by Eq. 6. The results thus obtained are those of Table 9. There seems to be no more significance in the centroid of "Areas" A, B, and C of Fig. 13, as used by Professor Rouse, than in a centroid of Nikuradse's test data. Further, the similarity in the values of k for the asphalted surface, determined by Mr. Colebrook and the authors as 0.005 in. and 0.0035 in., respectively, cannot be ignored. Professor Rouse's value of $k = 0.00063$ in. needs explanation.

The authors believe that the test data have significance but not necessarily that described by the Colebrook transition function. These data have been presented in the hope that study of the transition region will be stimulated and that an explanation will eventually be evolved which will include the apparent deviations of the present contribution.

Professor Rouse's remarks concerning portrayal of Manning's n as a function of the Reynolds number appear irrelevant. At no point in the paper was n shown in that relationship except in the tables, where it might equally have been considered to be a function of gate opening or head loss. In spite of the fact that leading hydraulicians are turning toward the representation of surface roughness and frictional resistance in terms of f and the Reynolds number, there are still a great many designers who prefer to use empirical relationships such as Scobey's and Manning's equations. It was for this reason that Manning's n was shown as a function of velocity in Figs. 11 and 12. These plots show clearly that Manning's n is not a constant function of the surface and that is the reason they were included. It is true that the velocity for each tunnel is proportional to the Reynolds number. However, those engineers who still use Manning's equation, and for whose benefit Figs. 11 and 12 were included, are not likely to interpret the data in terms of the Reynolds number in spite of the proportionality that exists.

Mr. Tapley's discussion of bend losses is interesting and points out the extremely unsatisfactory state of knowledge in this field. In the tests made by the authors, the only independent determination of bend loss was at bend 1. Losses at the other bends were calculated in Table 5 by application of the data given by Mr. Creager and Joel D. Justin,[5] M. ASCE, in their Figs. 67 and 68. This procedure was followed to provide as good an estimate as possible of the loss chargeable to friction. The determination of bend loss is one of the weak points in the paper, but fortunately the bend losses were relatively small and errors in their determination were consequently unimportant. In addition to the discussion by Mr. Tapley, it might be pointed out that tests by Albert Hofmann[40] also indicated that the bend loss was materially affected by the surface roughness of the bend, the bends with the rougher surfaces, surprisingly enough, having the lower bend-loss coefficients. This serves further to emphasize the need for definitive experimentation in this field.

The data presented by Mr. Kennison have been converted to terms of f and the Reynolds number as listed in Table 15. In making these calculations

TABLE 15.—CONVERSION OF DATA FROM TABLE 12

Line[a] No.	Q (cu ft per sec)	V (ft per sec)	s ($\times 10^3$)	f	Temperature (degrees C)	R ($\times 10^{-6}$)
1......	869.9	6.81	0.580	0.0103	17	7.43
2......	925	7.25	0.619	0.0096	17	7.91

the cross section was assumed to be an equivalent circle with the given area of 127.6 sq ft. The values of f are unusually close to the smooth pipe curve and it would be of interest to know the condition of this surface. The points are plotted in Fig. 20.

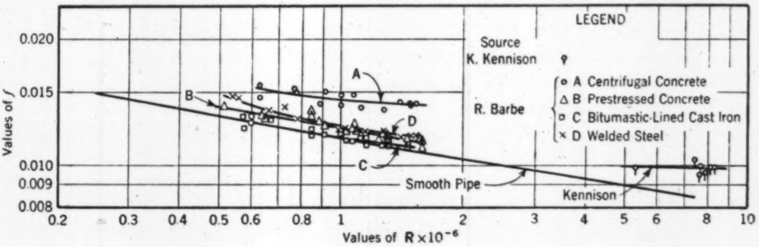

FIG. 20.—FRICTION FACTOR VERSUS THE REYNOLDS NUMBER FOR DATA OF K. KENNISON, M. ASCE, AND R. BARBE

Additional data on surface roughness of commercial pipes have recently been published,[47] and, in the belief that they have not come to the attention of the profession generally, are presented here for convenience of reference. The pipes were all 800 mm (31.5 in.) in nominal diameter and the test length was 200 m (656 ft). The results are shown in Fig. 20, together with the curve for smooth pipe flow. The surfaces are as follows:

A. Centrifugal concrete, of good average quality (new); 4-m (13.06-ft) lengths, with male and female ends, joined with aquarium cement, afterward smoothed on the inside, making a perfectly smooth joint.

B. Pre-stressed concrete (Freyssinet system); 6-m (19.85-ft) lengths with an inside surface formed during manufacture by very smooth helicoidal bands

---

[47] "La Mesure dans un Laboratoire des pertes de charge de conduits industrielles," by R. Barbe, *La Houille Blanche*, Mai-Juin, 1947, pp. 191–203.

48 mm wide with a pitch of 15 m. The bands were very smooth but were separated by fairly rough grooves about 5 mm wide and 1 mm deep. The joints were made by placing the sections end to end and sealing them with flexible rubber rings.

C. Cast iron with smooth bitumastic coating applied by a centrifugal process (new); 5-m (16.4-ft) lengths, very smooth joints, bell and spigot, with poured lead seal, smoothed inside.

D. Welded steel (new); 6-m (19.85-ft) lengths, each length composed of three sheets welded end to end and rolled. There were one longitudinal and two transverse welds in relief on the interior or each section. The joints were the same as for surface *B*.

It will be noted that the bitumastic-lined cast iron is the smoothest, and agrees very closely with the smooth pipe curve.

The authors wish to extend their sincere thanks to all who took the trouble to read and comment on a paper which, after all, merely added to the many conflicting data already existing without offering any explanation.

ANALYSIS OF STEPPED-COLUMN MILL BENTS

By Daniel S. Ling,[1] M. ASCE

With Discussion by Messrs. Ralph E. Spaulding, E. I. Fiesenheiser, Walter J. Gray, L. J. Mensch, Arthur R. Graves, Erik Sollid, A. Floris, Charles W. Dohn, and Daniel S. Ling.

Synopsis

The "moment-distribution" technique is applied to the analysis of stepped-column mill bents, in this paper. Curves for obtaining the necessary distribution coefficients and the fixed-end moments are included. The method permits evaluating the relative resistance, to horizontal forces, of columns having different stiffnesses due to length, size, or other factors. Several examples of two-column and three-column bents are included to describe the method fully.

Although this method will require more time than that of obtaining moments from an assumed point of contraflexure, the additional time would seem to be justified, because of the difficulty in estimating the location of such a point of contraflexure accurately for stepped columns.

I. Introduction

In the design of mill buildings, especially where the crane clearances require considerable height, the horizontal forces from wind and crane thrust are important factors. In short buildings, it is simple enough to transmit these forces to the ground through a bracing system to the braced end bents of the building. However, with the trend toward larger and larger industrial buildings, the length increases so that one or more expansion joints are required; and horizontal forces must be resisted by each individual bent. Often, as a result, the bending stresses in the columns become greater than the direct stresses, and the "column" essentially becomes more of a vertical beam than a column from the standpoint of stress analysis.

The simple and more familiar method of analysis for such "columns" is to determine the bending moments from an assumed point of contraflexure. With a column of constant section from top to bottom, the location of this point can be assumed with reasonable accuracy under any set of assumptions regarding the base and top fixations. However, for a column supporting a crane runway,

---

Note.—Published in October, 1947, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate of Paul S. Calkins, Cons. Engr., Detroit, Mich.

a "stepped section" is considerably more economical, in most cases. Immediately, the question arises as to the location of the point of contraflexure; inaccuracy as to this assumption may cause considerable error in the final result.

It is hoped that this paper will present a more satisfactory method for the analysis of stepped-column mill bents. The loadings given in the examples are used as illustrations of the method, and not as recommendations. Admittedly, these loadings are not the nearest approach to the probable applied conditions, but they do illustrate the various types of design loads as used by designers.

The method of successive approximations, or so-called "moment distribution," is used without explanation, to determine the true end moments, since this method is probably familiar to most engineers and can be found in various textbooks and reference books.

In particular, the writer has used a set of unpublished mimeographed notes, by L. C. Maugh, Assoc. M. ASCE, entitled "The Analysis of Continuous Framed Structures," as a reference in preparing this material. The discussion of the basic theory is given briefly herein as Example 1. For a more detailed discussion of the theory, reference can be made to "Statically Indeterminate Structures,"[2] also by Professor Maugh.

II. General Conditions and Design Assumptions

With the increasing necessity for the greatest economy in the use of steel and the resultant use of higher working stresses, it has been more than ever important to eliminate as many uncertainties as possible in structural design. Since these columns are essentially beams, they should be treated as such. The analysis of a beam of variable moment of inertia is generally understood; it is not difficult, although the work involved does require considerable time and is somewhat tedious. The writer used this general method, with good results, on several industrial buildings erected during World War II. To save time in the analysis of beams of variable moment of inertia, a series of curves is presented which reduces the work to that required for a continuous beam of two spans with the translation of one joint. By the well-known method of successive approximations introduced by Hardy Cross, M. ASCE,[3] the analysis is not a lengthy problem.

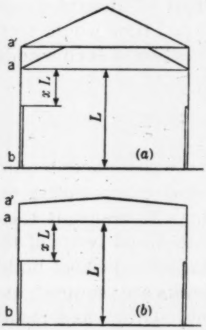

Fig. 1

As with any design problem, certain assumptions must be made to simplify the problem and to save time. Some of these assumptions are known to be erroneous. However, the error involved is so small as to be safely ignored. In this method of analysis the following assumptions were made (see Fig. 1):

a. Hooke's law applies.

b. The principle of superposition applies.

[2] "Statically Indeterminate Structures," by L. C. Maugh, John Wiley & Sons, Inc., New York, N. Y., 1946.

[3] *Transactions*, ASCE, Vol. 96, 1932, p. 1.

c. In the deflection of a bent, point a and point a′ move the same amount—that is, point a′ is always directly above point a. (Unless the truss is subject to considerable deflection, this is a safe assumption.)

d. The column is simply supported at points a and a′—that is, the truss or knee brace connections create no effective fixity at these individual points. Since the column is usually quite rigid in relation to the truss or knee brace members, this is a safe assumption.

e. Both columns deflect the same amount—that is, any change in length of roof trusses caused by horizontal forces is too small to be significant.

f. The relation between the moments of inertia of the upper and lower parts of the column is known. (This relation can be approximated readily and quite closely after some experience; but if the preliminary design indicates too large an error the analysis can be corrected quickly with a new ratio of moments.)

(It can be argued that, in effect, the column is fixed at the top. If points a and a′ are close together, it is true that there can be little deflection between these points; but, if this distance is larger, the deflection may be considerable. Assumption *d* is more general and therefore safer than the assumption of full fixity at point a.)

The explanation of such a design method is shown more readily by examples, and this device will be used in this paper. For greater ease in illustrating the principles of the method, the following loading conditions were used in the examples although it is realized that this procedure does not represent true wind action:

(1) Beam bending in a column, from wind, occurs entirely in the windward column;

(2) Wind force is assumed uniformly distributed over the entire length of a column; and

(3) Horizontal force from a crane is applied entirely to one column of a bent.

Symbols and Notation.—The letter symbols in this paper are defined where they first appear, in the text or by illustration, and are assembled for convenience of reference in Appendix I.

III. ILLUSTRATIVE EXAMPLE

Example 1.—Consider a column of a symmetrical bent similar to those in Fig. 1 and fixed at the base. If I is the moment of inertia of the main section of the column and I_o is that of the smaller (reference) section above the step, let $I/I_o = 8$ and $x = 0.3$. The general slope-deflection equations, for moments in a beam (ab, Fig. 1) with a variable moment of inertia, are:

$$M_{ab} = \frac{E\,I_o}{L}\left[C_1\,\theta_a + C_2\,\theta_b - (C_1 + C_2)\,\frac{\Delta}{L}\right] + M_{f,ab} \ldots\ldots\ldots (1a)$$

and

$$M_{ba} = \frac{E\,I_o}{L}\left[C_2\,\theta_a + C_3\,\theta_b - (C_2 + C_3)\,\frac{\Delta}{L}\right] + M_{f,ba} \ldots\ldots\ldots (1b)$$

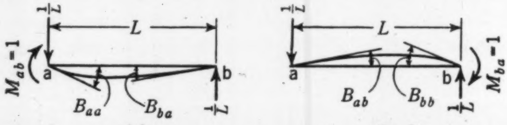
In Eqs. 1, E is the modulus of elasticity; C is the slope-deflection coefficient; θ is the angular rotation, with subscripts a or b denoting point of rotation; Δ is the relative displacement of one end of the beam to the other end; M_f is the fixed-end moment; M_{ab} equals moment in joint a of member ab; and M_{ba} equals moment at joint b of member ab. If the beam is hinged at point a, moment M_{ab} is zero. Solving for θ_a in Eq. 1a and substituting in Eq. 1b:

$$M_{ba} = \frac{E\,I_o}{L}\left(C_3 - \frac{C_2^2}{C_1}\right)\left(\theta_b - \frac{\Delta}{L}\right) + M_{f,ba} - \frac{C_2}{C_1} M_{f,ab} \ldots\ldots (2a)$$

Similarly, if the beam is hinged at point b:

$$M_{ab} = \frac{E\,I_o}{L}\left(C_1 - \frac{C_2^2}{C_3}\right)\left(\theta_a - \frac{\Delta}{L}\right) + M_{f,ab} - \frac{C_2}{C_3} M_{f,ba} \ldots\ldots (2b)$$

The relation between the end rotations and the end moments can be determined by obtaining B_{aa} and B_{ba}, the angles of rotation at joints a and b, respectively, caused in each case by a unit moment at joint a; and B_{ab} and B_{bb}, the angles of rotation at joints a and b, respectively, caused by a unit moment at joint b (Fig. 2). For any end moments M_{ab} and M_{ba}, then:



(a) (b)

FIG. 2

$$M_{ab} = \frac{B_{bb}}{\beta}\,\theta_a + \frac{B_{ba}}{\beta}\,\theta_b \ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

and

$$M_{ba} = \frac{B_{ba}}{\beta}\,\theta_a + \frac{B_{aa}}{\beta}\,\theta_b \ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

in which

$$\beta = B_{aa}\,B_{bb} - B_{ba}^2 \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Comparing Eqs. 3 with Eqs. 1, with $\frac{E\,I_o}{L} = K_o$:

$$C_1\,K_o = \frac{B_{bb}}{\beta} \ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

$$C_2\,K_o = \frac{B_{ba}}{\beta} \ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

and

$$C_3\,K_o = \frac{B_{aa}}{\beta} \ldots\ldots\ldots\ldots\ldots\ldots (5c)$$

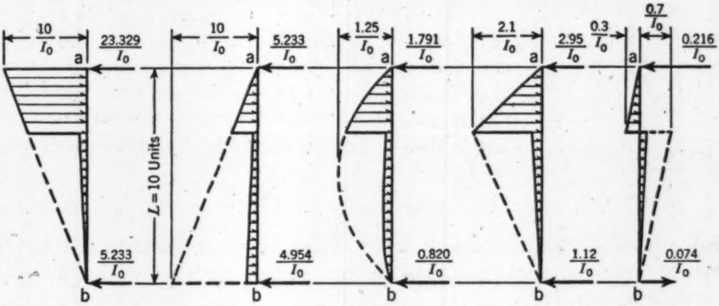
In Eqs. 5, $\Delta = 0$ and fixed-end moments are temporarily ignored. Having determined the coefficients, the fixed-end moments can be determined for any applied loads by computing the angular rotations α_a and α_b of the end tangents of the beam considered simply supported. The fixed-end moment must prevent any rotation of the end tangents; therefore,

$$M_{f,ab} = C_1 K_o (-\alpha_a) + C_2 K_o (-\alpha_b) \ldots\ldots\ldots\ldots (6a)$$

and

$$M_{f,ba} = C_2 K_o (-\alpha_a) + C_3 K_o (-\alpha_b) \ldots\ldots\ldots\ldots (6b)$$

The angles in Eqs. 5 can readily be determined by the conjugate beam method, by determining the reactions of a beam loaded with the $\frac{M}{I}$-diagram (since E is constant). Figs. 3(*a*) and 3(*b*) illustrate the use of that method for this example. An end moment of ten units is applied at end a and the length L is divided into ten units. For the $\frac{M}{I}$-diagram applied as a load the reaction at end a is $23.329/I_o$, and at end b it is $5.233/I_o$. Since these values are for an end moment of ten units and a length of ten units, the end rotation B_{aa} at end a is $\frac{23.329}{100} \times \frac{L}{I_o}$ or $0.23329 \frac{L}{I_o}$; and the rotation B_{ba} at end b is $0.05233 \frac{L}{I_o}$. In the same way, by applying an end moment of ten units at end b it is found that $B_{ab} = 0.05233 \frac{L}{I_o}$ and $B_{bb} = 0.04954 \frac{L}{I_o}$. Substituting these values in Eq. 4: $\beta = \frac{0.23329}{K_o} \times \frac{0.04954}{K_o} - \left(\frac{0.05233}{K_o}\right)^2 = \frac{0.00881}{(K_o)^2}$. Then (see Eq. 5*a*) $C_1 K_o = \frac{0.04954}{K_o} \times \frac{(K_o)^2}{0.00881}$. The stiffness ratio K_o cancels and $C_1 = 5.63$. Likewise $C_2 = \frac{0.05233}{0.00881} = 5.95$; and $C_3 = \frac{0.23329}{0.00881} = 26.50$. The carry-over factor from end a to end b is $\frac{C_2}{C_1} = \frac{5.95}{5.63} = 1.06$; and from end b to end a the carry-over factor $\frac{C_2}{C_3} = \frac{5.95}{26.50} = 0.22$. Substituting these values in Eqs. 6:



(*a*) (*b*) (*c*) (*d*) (*e*)

FIG. 3

$$M_{f,ab} = K_o (-5.63\, \alpha_a - 5.95\, \alpha_b) \ldots\ldots\ldots\ldots (7a)$$

and

$$M_{f,ba} = K_o\,(-\,5.95\,\alpha_a - 26.50\,\alpha_b) \qquad \text{(7b)}$$

As shown in Fig. 4, the loadings on this column which produce bending are of three types—a uniform load of 0.5 kips per ft, a concentrated load (at the change in section) of 8 kips, and an eccentric load of 120 kips. The upper load of 32 kips will also produce some bending, particularly in the upper section; however, this will not be especially severe, since it is near the center line of the lower section. In this example, clockwise resisting moments are designated "plus (+)" and counter-clockwise resisting moments, "minus (−)"; the number within a box indicates the ratio of the moment distributed to that side of joint; the number at an arrow between joints indicates the "carry-over" to the adjacent joint in the direction of the arrow; and, at the completion of single distribution at a joint, a single line is drawn under the numbers and after the final distribution (unbalanced factor of negligible size) a double line is drawn under the numbers and a summation is made.

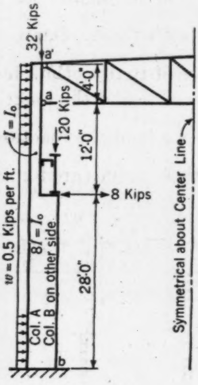


FIG. 4

Fig. 3(c) shows the $\frac{M}{I}$-diagram for a unit uniform load applied to a beam of length L. As before, the end reactions give the end rotations or, in this case, angles α_a and α_b. Substituting the values of the end reactions in Eqs. 7:

$$M_{f,ab} = 0.0516\,W\,L \qquad \text{(8a)}$$

For $W = 20$ kips and $L = 40$ ft, Eq. 8a yields $M_{f,ab} = 0.0516 \times 20 \times 40 = 41.3$ ft-kips; and $M_{f,ba} = 0.1126\,W\,L = 0.1126 \times 20 \times 40 = 90.1$ ft-kips.

Fig. 3(d) shows the $\frac{M}{I}$-diagram for a unit load applied 0.3 L from end a; thus:

$$M_{f,ab} = 0.0994\,P\,L \qquad \text{(8b)}$$

For $P = 8$ kips and $L = 40$ ft, Eq. 8b yields $M_{f,ab} = 0.0994 \times 8 \times 40 = 31.8$ ft-kips and $M_{f,ba} = -\,0.1210\,P\,L = -\,0.1210 \times 8 \times 40 = -\,38.7$ ft-kips.

For a unit moment applied 0.3 L from end a, Fig. 3(e) shows the $\frac{M}{I}$-diagram. Again substituting in Eq. 7:

$$M_{f,ab} = +\,0.166\,M_x \qquad \text{(8c)}$$

For $M_x = 120$ ft-kips Eq. 8c yields $M_{f,ab} = 0.166 \times 120 = +\,19.9$ ft-kips and $M_{f,ba} = +\,0.325\,M_x = +\,39.0$ ft-kips.

For the column under consideration—with $C_1 = 5.63$; $C_2 = 5.95$; and $C_3 = 26.50$—the carry-over ratios from points a to b and from points b to a, respectively, are: $\frac{C_2}{C_3} = \frac{5.95}{26.50} = 0.22$; and $\frac{C_2}{C_1} = \frac{5.95}{5.63} = 1.06$. Computations for the distribution factors r at point a, Fig. 4, are shown in Table 1; and fixed-end moments for the several types of load are shown in Table 2. The unbalanced moments at end a are distributed as shown in Fig. 5(a), assuming full fixity at the base; and the shear H_b is computed as $\frac{0.5 \times 40}{2} + \frac{97.0 - 34.8}{40} = 11.56 \leftarrow$ kips.

(a) UNBALANCED MOMENTS AT POINT a

(b) CONCENTRATED LOAD OF 8 KIPS

FIG. 5.—DISTRIBUTION OF MOMENTS, EXAMPLE 1

In a like manner distributing the fixed-end moments (in ft-kips) for the 8-kip concentrated load produces: $M_{ba} = -44.1$, $M_{ab} = +26.7$, $M_{aa'} = 26.7$ and (in kips) $H_b = 2.84$. For the 120-kip eccentric load: $M_{ba} = +35.6$, $M_{ab} = +16.7$, and $M_{aa'} = -16.7$. If only 60% fixity is assumed at point b the procedure is similar (see Fig. 5); and H_b becomes $10.0 + \frac{59.0 - 42.1}{40} = 10.42 \leftarrow$ kips.

TABLE 1.—DISTRIBUTION FACTORS, r, AT POINT a, FIG. 4

Member	C	K	$C\,K$	r
ab......	5.63	$I_e/40$	$0.141\ I_e$	0.16
aa′......	3.00	$I_e/4$	$0.750\ I_e$	0.84
Σ........	....	....	$0.891\ I_e$	....

The horizontal forces, of course, cause a translation of the top of the column in relation to the base or, conversely (since by assumption c—points a and a′ move the same amount), point b moves some distance Δ in relation to points a and a′. This translation, naturally, causes additional end moments in the column. These moments are not readily determined directly but can be obtained easily as follows:

TABLE 2.—FIXED-END MOMENTS, EXAMPLE 1, IN FOOT-KIPS

Loading	$M_{f\ aa'}$	$M_{f,ab}$	$M_{f,ba}$
Uniformly Distributed:			
0.5 kips per ft..........	$0.5 \times 4^2/8 = 1.0$	41.3	−90.1
Point Loads:			
8 kips concentrated...	....	31.8	−38.7
120 kips eccentric......	....	19.9	39.0

Assume a value of $E\,\Delta$; in this case, assume $E\,\Delta = 40$ units. From Eqs. 1 the end moments for this translation, only, are:

$$M_{f,ab} = K\left[(C_1 + C_2)\frac{E\,\Delta}{L}\right] = (5.63 + 5.95)\frac{40}{40} = 11.58 \text{ ft-kips } (K = 1)$$

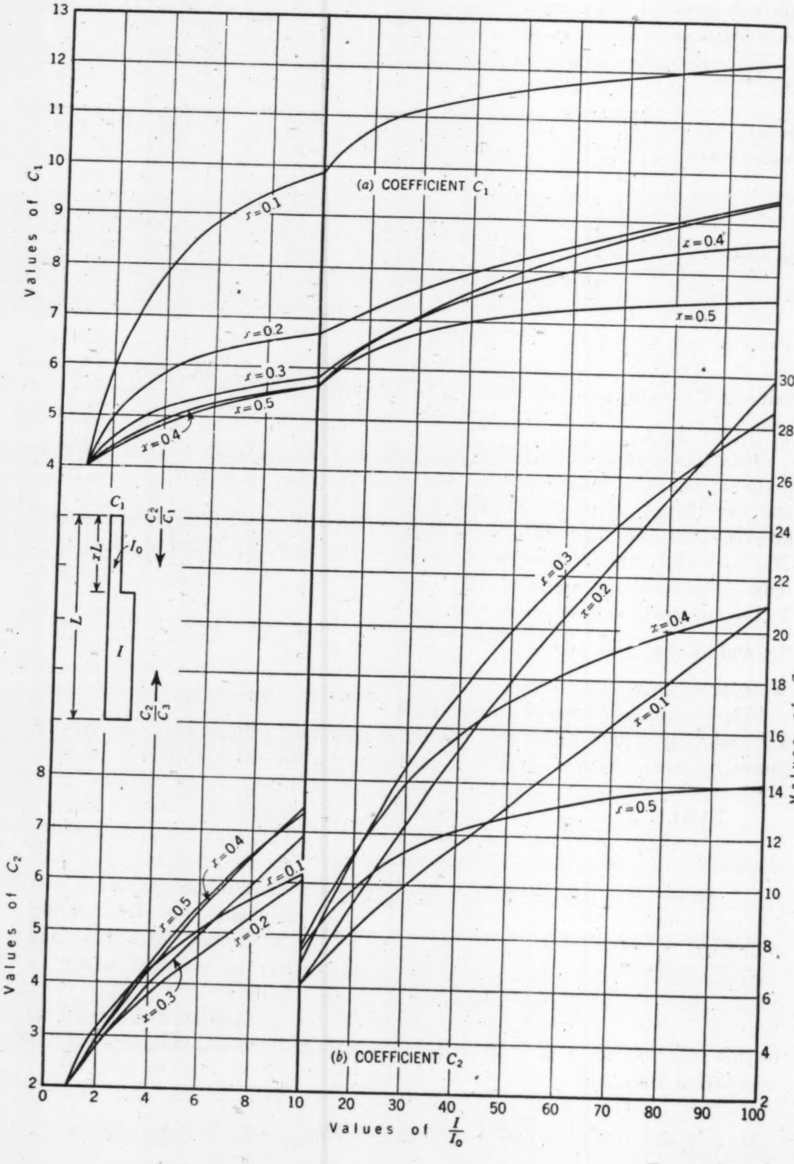

FIG. 6.—CURVES OF

and

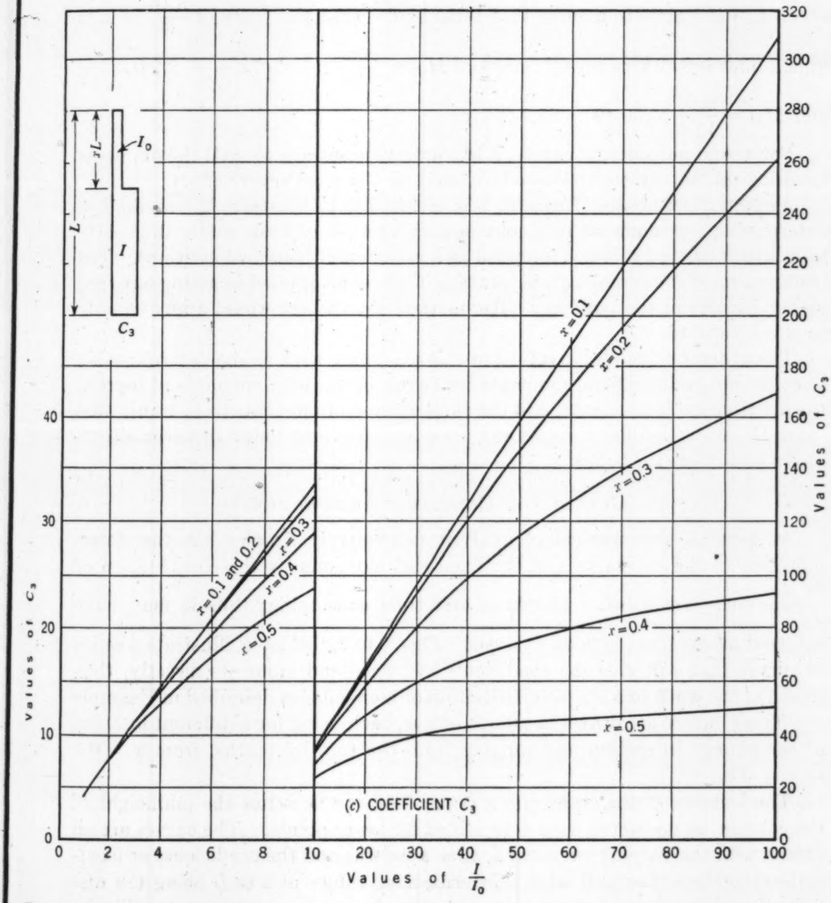
$$M_{f,ba} = K\left[(C_2 + C_3)\frac{E\,\Delta}{L}\right] = (5.95 + 26.50)\,\frac{40}{40} = 32.45 \text{ ft-kips.}$$

By distribution, as before, the final moments, in foot-kips, become:

$$M_{ab} = -11.58 + 0.16 \times 11.58 = -9.73$$
$$M_{ba} = -32.45 + 1.06 \times 0.16 \times 11.58 = -30.49$$

and, in kips:

$$H_b = \frac{30.49 + 9.73}{40} = 1.01$$



(c) COEFFICIENT C_3

Distribution Coefficients

For the uniform horizontal load on the column, and with no translation considered, it was shown that the shear at point b on the windward column was 11.56 kips. Since the total force assumed acting on the column was 22 kips a force of $22 - 11.56 = 10.44$ kips is the force creating deflection in the bent. Assuming that both columns resist this deflection equally, the force resisted by each column is 5.22 kips. Then the end moment M_{ab} for this 5.22 kips is $\frac{5.22}{1.01} \times -9.73 = -50.5$ ft-kips and M_{ba} is $\frac{5.22}{1.01} \times -30.49 = -157.6$ ft-kips.

For the 8-kip concentrated load the force causing bent deflection is $8 - 2.84 = 5.16$ kips. Since the crane thrust is spread to adjacent bents by the roof bracing, it is logical to assume that three bents resist this force or $\frac{5.16}{3} = 1.72$ kips. This is 0.86 kips per column; and $M_{ab} = \frac{0.86}{1.01} \times -9.73 = -8.2$ ft-kips; and $M_{ba} = \frac{0.86}{1.01} \times 30.49 = 25.7$ ft-kips.

For design purposes, of course, it is now only necessary to total the moments from logical loading conditions which produce the most severe effect.

As stated previously, Example 1 is given only to illustrate the method of determining the moments in a column from any set of loads under the conditions assumed, and it is not intended as a criterion of loading conditions. For instance, most codes require a percentage of the wind applied as acting outward on the lee side of the building. The method shown here would apply equally to this condition.

The general principles involved in this example—such as the determination of constants and fixed-end moments for beams of variable moments of inertia, the distribution of moments, and the computation of moments from translation—are no doubt familiar to most engineers and are to be found in various textbooks and reference books.

IV. Curves for Constants and Moments

In general, this method of analysis is relatively simple; but the determination of the constants and the fixed-end moments by the construction of $\frac{M}{I}$-diagrams is somewhat laborious and time consuming; thus it may have deterred others from such an analysis. Figs. 6 to 9, inclusive, illustrate a series of curves that will give the coefficients and fixed-end moments directly, thus reducing the work to a simple distribution of moments, as described in Example 1. These curves are drawn in groups of five, each being for a different location of the change in section and ranging from the top, by tenths, from $x = 0.1$ to $x = 0.5$.

The location of the crane girder is not likely to be below the midheight of the column, so no curves were determined for lower points. The curves are all drawn with the varying values of I/I_o as abscissas and the coefficients or fixed-end moments as the ordinates. Intermediate values of x ($x\,L$ being the distance from the top of column section to the change in section) can readily be

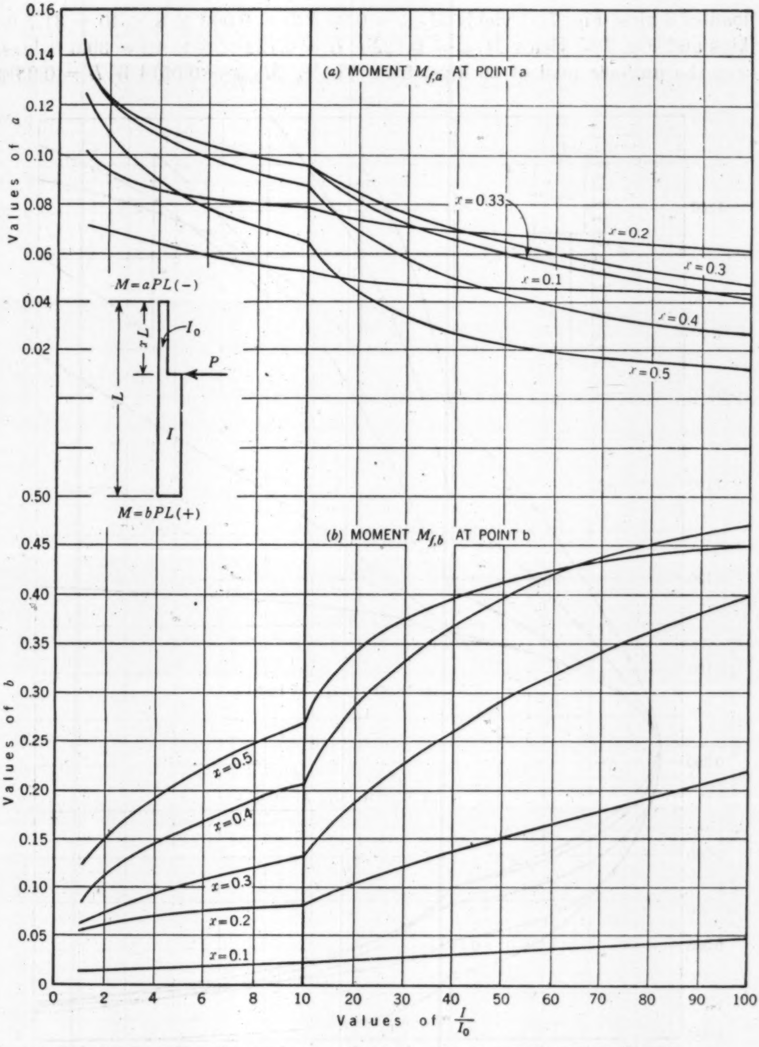


FIG. 7.—FIXED-END MOMENTS FOR A FORCE APPLIED AT THE CHANGE OF SECTION

interpolated. In two of the series of curves (Figs. 7(*a*) and 9(*a*)) it was found desirable to add a curve for $x = 0.33$.

Example 2. Use of Curves.—For the known values of $I/I_o = 8$ and $x = 0.3$, Fig. 6 reveals that $C_1 = 5.65$, $C_2 = 5.95$, and $C_3 = 26.5$. Thus, the "carry-over" from point a to point b $= \frac{5.95}{5.65} = 1.05$. Similarly, for the horizontal load of 8 kips, Fig. 7(*a*) yields $M_{f,ab} = 0.99\ P\ L = 0.099 \times 8 \times 40 = 31.7$ ft-kips and Fig. 7(*b*) yields $M_{f,ba} = 0.122\ P\ L = 0.122 \times 8 \times 40 = 39.0$ ft-kips. For the uniform load of 20 kips, from Fig. 8, $M_{f,ab} = 0.0514\ W\ L = 0.0514$

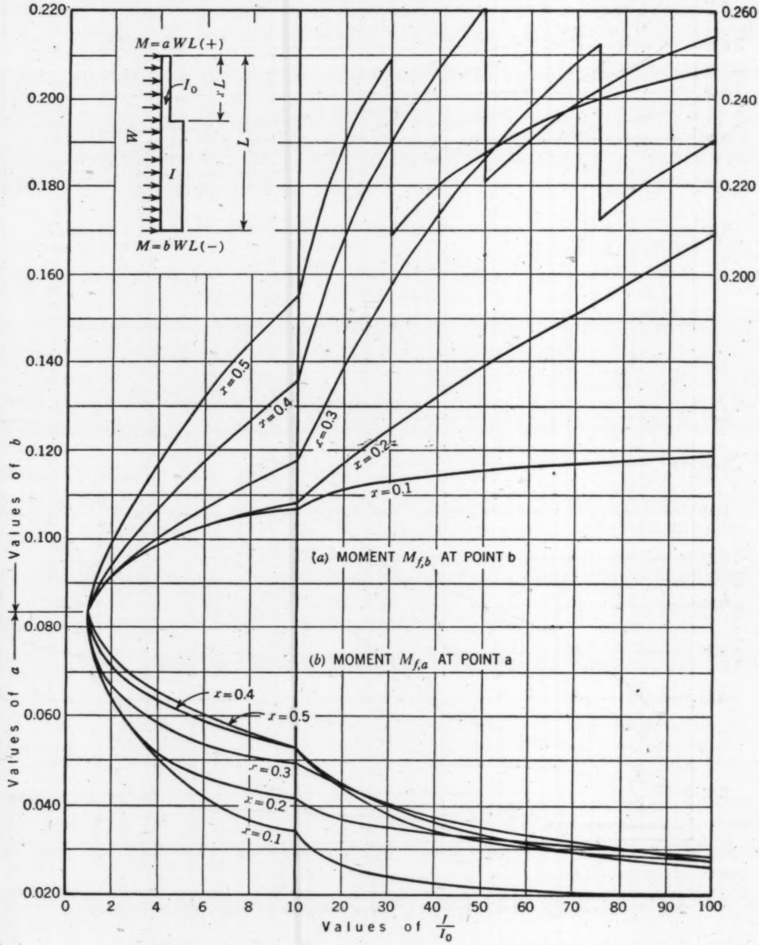

FIG. 8.—FIXED-END MOMENTS FOR UNIFORMLY DISTRIBUTED HORIZONTAL LOAD

$\times 20 \times 40 = 41.1$ ft-kips and $M_{f,ba} = 0.1125\ W\ L = 0.1125 \times 20 \times 40 = 90.0$ ft-kips. For the applied moment of 120 ft-kips from Fig. 9, $M_{f,ab} = 0.167\ M_1 = 0.167 \times 120 = 20.0$ ft-kips and $M_{f,ba} = 0.323\ M_1 = 0.323 \times 120 = 38.8$

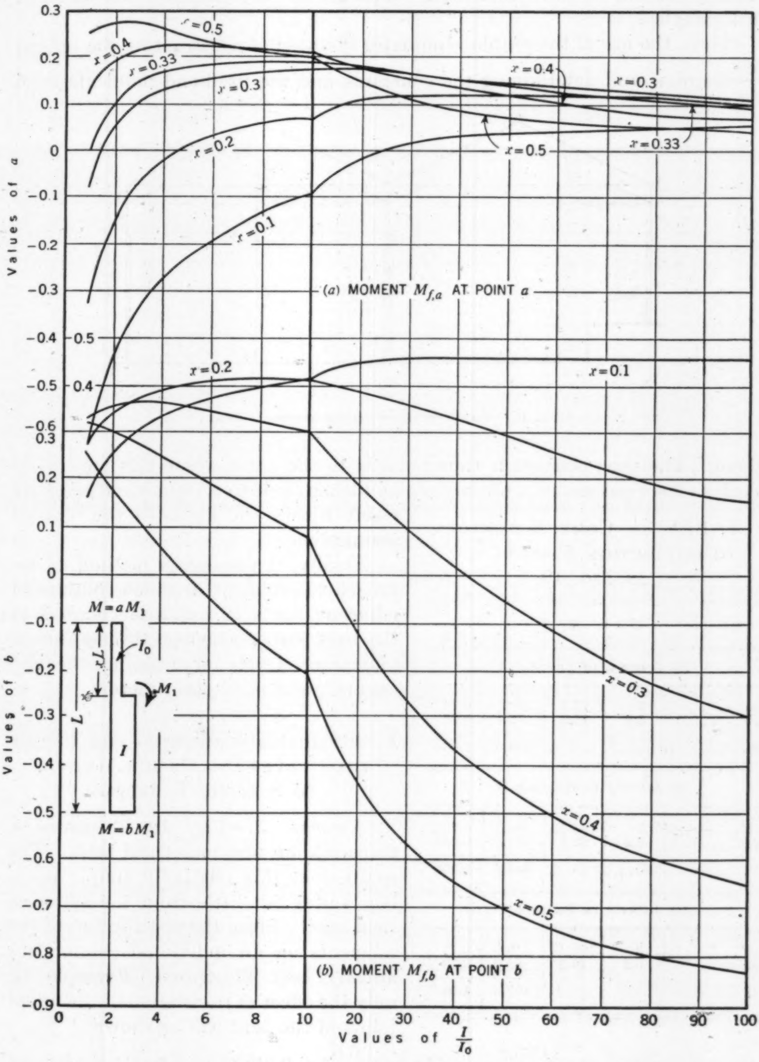

FIG. 9.—FIXED-END MOMENTS FOR A MOMENT COUPLE (AN ECCENTRIC LOAD) APPLIED AT THE CHANGE OF SECTION

ft-kips. It will be noted that these values are all very close to those obtained in Example 2.

Thus, the use of the graphs eliminates the need of constructing the several $\frac{M}{I}$-diagrams and determining the constants and the fixed-end moments from them. The time element is thus reduced to the point where this method of analysis becomes entirely practicable and lends itself to a logical and accurate result within the limits of the original assumption.

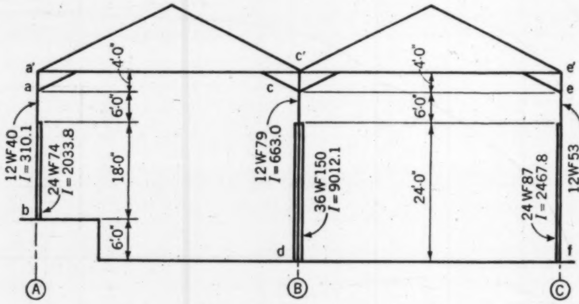

FIG. 10.—THREE-COLUMN UNSYMMETRICAL BENT

Finally, it presents a method of approach to problems in which columns in adjacent bents or opposite columns in the bent are of varying stiffness due to mezzanine levels of framing, heavier column section, or other factors.

V. APPLICATIONS SHOWING THE USE OF THE CURVES AND DESIGN METHOD TO SPECIFIC PROBLEMS

Example 3.—Fig. 10 illustrates a three-column unsymmetrical bent. The solution of this relatively simple problem varies but little from the symmetrical bent. Since the distribution of the moments on an individual column has already been illustrated (Example 1), only the effect of translation of the upper joints of the bent will be shown.

For line A: $\frac{I}{I_o} = \frac{2,033.8}{310.1} = 6.55$; $x = \frac{6.0}{24.0} = 0.25$; $C_1 = 5.9$; $C_2 = 5.0$; and $C_3 = 22.0$ (from Fig. 6). Carry-over ratios are: $\frac{5}{22.0} = 0.23$ and $\frac{5}{5.9} = 0.85$.

Also, $K_{aa'} = \frac{310}{4} = 77.5$; $K_{ab} = \frac{310}{24} = 12.9$; and the distribution factors are computed as in Table 3(*a*). For $E\,\Delta = 10$:

$$M_{f,ab} = \frac{(5.9 + 5.0) \times 12.9 \times 10}{24} = 58.5 \text{ ft-kips}$$

and

$$M_{f,ba} = \frac{(5.0 + 22.0) \times 12.9 \times 10}{24} = 145.0 \text{ ft-kips}$$

(*a*) SECTION A (*b*) SECTION B (*c*) SECTION C

Fig. 11.—Distribution of Moments, Example 3, Fig. 10

These values of fixed-end moment are distributed as in Fig. 11(*a*), with the result that the shear at point b is computed as $\frac{132.6 + 43.9}{24} = 7.35$ kips.

For line B: $\frac{I}{I_o} = \frac{9{,}012.1}{6{,}630} = 13.6$; $x = \frac{6.0}{30.0} = 0.2$; $C_1 = 6.9$; $C_2 = 7.2$; and $C_3 = 44.5$. Carry-over ratios are: $\frac{7.2}{44.5} = 0.16$ and $\frac{7.2}{6.9} = 1.04$. Also, $K_{cc'} = \frac{663}{4} = 165.75$; $K_{cd} = \frac{663}{30} = 22.1$; and the distribution factors are computed as in Table 3(*b*). For $E\,\Delta = 10$:

$$M_{f,cd} = \frac{(6.9 + 7.2) \times 22.1 \times 10}{30} = 103.8 \text{ ft-kips}$$

and

$$M_{f,dc} = \frac{(7.2 + 44.5) \times 22.1 \times 10}{30} = 381.0 \text{ ft-kips}$$

As for line A, these values of fixed-end moment are distributed in Fig. 11(*b*), the resulting shear at point d being $\frac{356.1 + 79.4}{30} = 14.53$ kips.

For line C: $\frac{I}{I_o} = \frac{2{,}467.8}{426.2} = 5.8$; $x = 0.2$; $C_1 = 6.2$; $C_2 = 4.4$; and $C_3 = 20.0$. Carry-over ratios are: $\frac{4.4}{20.0} = 0.22$ and $\frac{4.4}{6.2} = 0.71$. Also, $K_{ee'} = \frac{426.2}{4} = 106.55$; $K_{ef} = \frac{426.2}{30} = 14.2$; and the distribution factors are computed as in Table 3(*c*).

For $E\,\Delta = 10$:

$$M_{f,ef} = \frac{(6.2 + 4.4) \times 14.2 \times 10}{30} = 50.2 \text{ ft-kips}$$

and

$$M_{f,fe} = \frac{(4.4 + 20.0) \times 14.2 \times 10}{30} = 115.4 \text{ ft-kips}$$

These values of fixed-end moment are distributed as in Fig. 11(*c*), the shear at point f being $\frac{107.4 + 39.2}{30} = 4.89$ kips.

From the foregoing it is then evident that column line A takes $\frac{7.35}{7.35 + 14.53 + 4.89} = 27.5\%$ of the thrust from bent sidesway; line B takes $\frac{14.53}{7.35 + 14.53 + 4.89} = 54.3\%$; and line C takes $\frac{4.89}{7.35 + 14.53 + 4.89} = 18.3\%$.

Example 4.—Fig. 12(*a*) shows a simple bent with a shed roof lean-to on one side. The lean-to columns are relatively small and, assuming hinged bases, they provide no horizontal stiffness to the bent. However, since joint e can move only horizontally (the column prevents vertical translation) the stiffness of the lean-to roof truss insures that although joints c and d can deflect horizontally, they deflect the same distance. Thus, the column translation (E-line) in this case, will be a combination of two types as shown in Figs. 12(*b*) and 12(*c*), and the total stiffness of these columns is much increased.

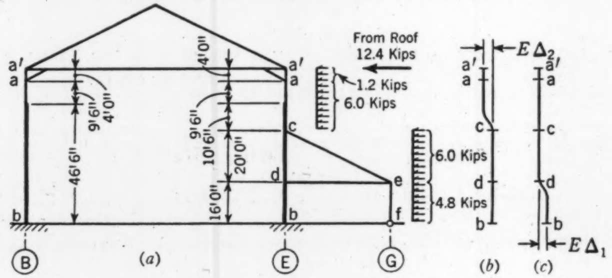

FIG. 12.—SIMPLE BENT WITH LEAN-TO

A somewhat different method is required to analyze this bent. First, assuming that $E\,\Delta_2 = 0$, assign an arbitrary value to $E\,\Delta_1$ and distribute the moments produced. Then express the shears in terms of $E\,\Delta_1$, or since E is a constant, it can be dropped. Next, with $E\,\Delta_1 = 0$, assign a value to $E\,\Delta_2$, distribute the moments, and express the shears in terms of Δ_2. The total shear in the column between any two joints is the sum of these two shear terms. Thus knowing the force system which produces translation, equations can be set up for the solution of Δ_1 and Δ_2. However, since column B also offers resistance to this force system, the method used in Example 1 must be applied. For horizontal forces acting only on column B, the shears in column E produced by translation are the same between points a and c and between points d and b. Assume any value for this shear, and solve for Δ_1 and Δ_2. Then the total deflection at point a is the sum of these for this particular shear. Since the tops of columns B and E move the same amount (assumption *e*), determine the shear in the B columns for the same Δ-value and the relative stiffness of the two lines of columns is proportionate to these shears.

TABLE 4.—COMPUTATION OF DISTRIBUTION FACTORS *r* FOR COLUMN B, FIG. 12

Member	*C*	*K*	*C K*	*r*
aa'.........	3	107.5	322.5	0.85
ab.........	7.3	7.7	56.2	0.15
Σ..........	....	....	787.7	1.00

To apply the foregoing to a numerical example, first consider column B, Fig. 2, with: $I_o = 430; I = 3{,}130; \frac{I}{I_o} = 7.3;$ and $x = \frac{9.5}{56} = 0.17$. From Fig. 6: $C_1 = 7.3$; $C_2 = 5.2$; $C_3 = 24.5$; and the carry-over factor is $\frac{5.2}{7.3} = 0.71$. Also, $K_{aa'} = \frac{430}{4} = 107.5$; $K_{ab} = \frac{430}{56} = 7.7$; and the distribution factors are computed as in Table 4. For $E\,\Delta = 10$:

$$M_{f,ab} = \frac{10\,K_o\,(C_1 + C_2)}{L}$$

$$= \frac{10 \times 7.7\,(7.3 + 5.2)}{56} = 17.2 \text{ ft-kips}$$

and

$$M_{f,ba} = \frac{10\,K_o\,(C_2 + C_3)}{L}$$

$$= \frac{10 \times 7.7\,(5.2 + 24.5)}{56} = 40.8 \text{ ft-kips}$$

These values of fixed-end moment are distributed as in Fig. 13, the shear at point b, Fig. 12, being $\frac{39.0 + 14.6}{56} = 0.96$ kips.

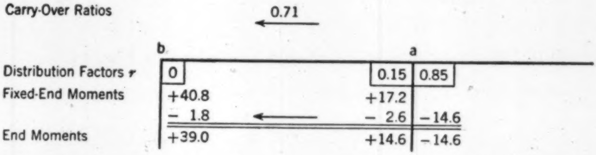

FIG. 13.—DISTRIBUTION OF MOMENTS IN COLUMN B, FIG. 12 (EXAMPLE 4)

For E line: Assume I_o and I the same as for column B, with $I/I_o = 7.3$. Furthermore: $x = \frac{9.5}{20} = 0.475$; and (see Fig. 6) $C_1 = 5.3$; $C_2 = 6.1$; and

$C_3 = 20.0$. Carry-over ratios are: $\frac{6.1}{5.3} = 1.15$; and $\frac{6.1}{20} = 0.305$. Finally: $K_{aa'} = 107.5$; $K_{ac} = \frac{430}{20} = 21.5$; $K_{cd} = \frac{3{,}130}{20} = 156.5$; and $K_{db} = \frac{3{,}130}{16} = 195.6$. Distribution factors are computed as in Table 5.

For $E\,\Delta_1 = 1$:

$$M_{f,bd} = M_{f,db} = \frac{6\,K\,E\,\Delta}{L} = \frac{6 \times 195.6 \times 1}{16} = 73.4 \text{ ft-kips}$$

and, for $E\,\Delta_2 = 1$:

$$M_{f,ac} = \frac{(C_1 + C_2)\,K\,E\,\Delta}{L} = \frac{(5.3 + 6.1) \times 21.5 \times 1}{20} = 12.3 \text{ ft-kips}$$

and

$$M_{f,ca} = \frac{(C_2 + C_3)\,K\,E\,\Delta}{L} = \frac{(6.1 + 20.0) \times 21.5 \times 1}{20} = 28.0 \text{ ft-kips}$$

These values of fixed-end moment are distributed as in Fig. 14.

FIG. 14.—DISTRIBUTION OF MOMENTS IN COLUMN E, FIG. 12 (EXAMPLE 4)

Assume that $E\,\Delta_1 + E\,\Delta_2$ is caused by forces which produce shears in lengths ac and db each equal to 1 kip (forces at points a and a′ total 1 kip and reaction at point b equals 1 kip) then:

$$5.08\,\Delta_1 + 0.41\,\Delta_2 = 1 \dots\dots\dots\dots\dots\dots\dots (9a)$$

and

$$0.42\,\Delta_1 + 1.04\,\Delta_2 = 1 \quad \text{.................... (9b)}$$

Multiplying Eq. 9b by $\frac{5.08}{0.42}$, it becomes:

$$5.08\,\Delta_1 + 12.58\,\Delta_2 = 12.1 \quad \text{.................. (9c)}$$

Solving Eqs. 9a and 9c simultaneously: $\Delta_2 = 0.913$; and $\Delta_1 = 0.124$. Consequently, $\Delta_1 + \Delta_2 = 1.037$.

Since both columns are assumed to deflect the same amount at the top, Δ for column B would be 1.037 to correspond to the foregoing values. The total shear is distributed in the bent as follows:

Deflection	Computation	Shear	
Column B....................	$\frac{0.96}{10} \times 1.037$		0.100
Column E:			
$\Delta_1 = 0.124$.............	5.08×0.124	0.63	
$\Delta_2 = 0.913$.............	0.41×0.913	0.37	
$\Delta_1 + \Delta_2 = 1.037$.............	....		1.00
Total shear in bent..........	....		1.10

Column E then resists $\frac{1.00}{1.10}$ or 91% of the horizontal thrust and column B resists $\frac{0.10}{1.10}$ or 9%.

FIG. 15.—MOMENTS IN COLUMN E WHEN HORIZONTAL FORCES ACT ON COLUMNS E AND G

When the horizontal forces act on columns E and G, however, the shear between points a and c and between points d and b is no longer equal, and the relative values of Δ_1 and Δ_2 change. The first step, as in previous examples, is the distribution of the moments from forces acting between joints, with all joints held against translation (see Fig. 15).

As a first step in the solution of the auxiliary force system, assume that all resistance to translation is taken by the E-line columns. The force system on the E-line columns then consists of forces at joints a, a′, c, and d equal and opposite to the reactions determined in Fig. 15 plus forces applied directly to the joints such as wind forces on the roof. Since the base of column G is hinged, half the uniform load of 4.8 kips, shown acting on it, is assumed to go to base f and half to the top point e. This half at point e plus the 6 kips acting on the lean-to roof are distributed between points c and d on column E, Fig. 12. Without another set of calculations (translating points c and d, distributing the moments produced, and determining the shears) the exact distribution between these two joints is not known, but such distribution is not needed for the present problem; only the shear is needed between points d and b, and between points a and c. The shear between points a and c is $5.19 - 1.17 = 4.02$ kips plus 12.4 kips from the roof, or a total of 16.42 kips. The shear between points d and b is increased by $3.88 - 1.07 + 6.0 + \frac{4.8}{2}$, or 27.63 kips. Since there is no relative translation between joints c and d the shear is not needed.

To determine the relative values of Δ_1 and Δ_2, set up formulas similar to Eqs. 9, except that the shear values are different:

$$5.08\,\Delta_1 + 0.41\,\Delta_2 = 27.63 \qquad (10a)$$

and

$$0.42\,\Delta_1 + 1.04\,\Delta_2 = 16.42 \qquad (10b)$$

Multiplying Eq. 10*b* by $\frac{5.08}{0.42}$, it becomes:

$$5.08\,\Delta_1 + 12.59\,\Delta_2 = 198.8 \qquad (10c)$$

As in Eqs. 9, solve Eqs. 10*a* and 10*c* simultaneously, and determine: $\Delta_2 = 14.05$; and $\Delta_1 = 4.30$. Consequently, $\Delta_1 + \Delta_2 = 18.35$.

For a Δ-value on the B-line columns of 18.35 units, the shear would be $\frac{18.35}{10} \times 0.96$ or 1.76 kips. The E-line columns thus would take $\frac{27.63}{27.63 + 1.76} = 94.2\%$ of the thrust and the B-line columns only 5.8%.

VI. CONCLUSION

Although most of the examples in this paper are not complete they show the general procedure for the various cases. As with any method of design for indeterminate structures, the ability to make a relative close initial estimate of the members required is very helpful and saves repeated computations. This ability, of course, comes largely with experience and observation.

Although the types of problems described in this paper by no means exhausts the variations that are likely to occur in practice, it is felt that a practical approach to other forms of bents should not be found difficult.

The method of analysis probably is not original, although not commonly used. However, without the use of the curves presented herein, the solution would be quite time consuming. Although this method of solution with the curves will require more time than that of assuming a point of contraflexure and solving as a statically determinate structure, the greater assurance of a reasonably accurate analysis should justify this extra time.

ACKNOWLEDGMENT

Figs. 6 to 9 were prepared by the writer for his own use in structural design and were original in form and development. L. T. Evans, Assoc. M. ASCE, in the revised edition of "Rigid Frames,"[4] has similar curves for all but the uniform load condition. His curves do not, however, cover the range of those presented. It appears that the curves by Mr. Evans were developed somewhat earlier than those presented herein.

The paper is based on data assembled and presented as a thesis[5] to the University of Michigan, Ann Arbor, Mich., in 1943, in partial fulfilment of the requirements for the professional degree of Civil Engineer.

APPENDIX I. NOTATION

The following letter symbols, used in the paper and in its discussion, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

a = a nondimensional coefficient of end moment at the top of a stepped column (see Fig. 7);

B = angle of rotation caused by a unit torque; thus—B_{ab} = rotation at joint a caused by a unit torque applied at joint b;

b = a nondimensional coefficient of end moment at the bottom of a stepped column (see Fig. 7);

C = a coefficient, with suitable subscript, used in slope-deflection equations; thus:

  C_1 = the distribution coefficient for point a for given values of I/I_o and x in Fig. 6(a);

  C_2 = the coefficient (see Fig. 6(b)) which, with C_1 or C_3, gives the carry-over ratio (the carry-over ratio from point a to point b is C_2/C_1 and from point b to point a, is C_2/C_3);

  C_3 = the distribution coefficient for point b, the bottom of the column, for given values of I/I_o and x in Fig. 6(c);

E = modulus of elasticity;

I = moment of inertia of a column section, the moment of inertia for the reference section (the upper and smaller section of a stepped column) being designated I_o;

---

[4] "Rigid Frames," by L. T. Evans, Edwards Bros., Ann Arbor, Mich., 1938.

[5] "Analysis of Mill Bents with Stepped Columns by the Method of Successive Approximations," by Daniel S. Ling, thesis presented to the Univ. of Michigan, Ann Arbor, in 1943, in partial fulfilment of the requirements for the professional degree of Civil Engineer.

K = stiffness ratio $E\,I/L$ used in moment distribution, the stiffness ratio of the upper and smaller section of a stepped column being designated $K_o = E\,I_o/L$:

L = length of member;

M = bending moment; the subscript f denotes "fixed end"; other subscripts refer to a designated joint and span—that is, in general, $M_{f,ba}$ equals fixed-end moment at joint b in member ab;

P = a point load or concentrated load;

r = distribution factor;

W = total weight, force, or pressure;

w = weight, force, or pressure per linear foot;

x = a ratio of length;

α = angular rotation of the end tangents of a deformed beam, considered simply supported;

β = a substitution constant, function of the unit rotation B;

Δ = linear displacement of one end of a beam with respect to the other end; and

θ = angular rotation of a beam.

DISCUSSION

Ralph E. Spaulding,[6] M. ASCE.—Any clear-cut rapid method of determining the stresses in stepped-column mill bents is of interest to the designing engineer. The author is to be complimented on his derivation of such a method; however, the writer differs with Mr. Ling in his application of Fig. 4 to this method. These differences involve: (1) Determination of x for $x\,L$; and (2) point of application of the horizontal thrust from the bridge crane.

(1) When analyzing any member of discontinuous cross section in bending (such as stepped-back columns), it must be recognized that the effective moment of inertia does not change abruptly when the cross section so changes, even in the case of a symmetrical column, such as the author's column B, Fig. 10. The larger value of I is not effective right up to the junction with the smaller cross section. There is a transition period between the end of the smaller cross section and some point farther along in the larger cross section.

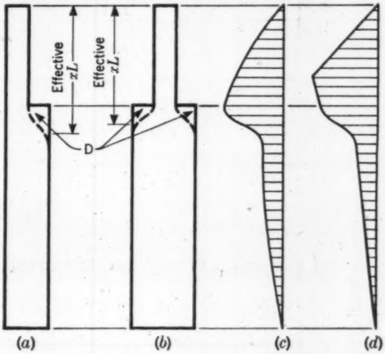

Fig. 16

Referring to Figs. 16(*a*) and 16(*b*), when stepped-back members are subjected to bending, photoelastic and strain gage tests reveal that adjacent to the smaller part of the member, the corners D, of the wider part of the member are "dead areas." The effective cross section for $\frac{M}{E\,I}$-analysis approximately follows the dotted lines. Much time may be saved in computations by using only two moments of inertia for the entire length of the member (such as the author's values of I and I_o); but to do this without introducing undue inaccuracy, it is necessary to make a scientific guess as to the proper value of the effective length $x\,L$. It is always greater than the net length of the smaller section; and, comparatively, it is much greater for the eccentric column (Fig. 16(*a*)) than for the concentric column (Fig. 16(*b*)). The $\frac{M}{I}$-diagram for unit uniform load would be as shown in Fig. 16(*c*) instead of Fig. 3(*c*). This does not in any way detract from the value of the author's curve sheets—as long as the proper effective value of distance $x\,L$ is used.

(2) The effective point of application of the side thrust from a bridge crane is at the level of the top of the crane rail. Assuming that the height of the crane

---

[6] Cons. Engr., Jacksonville, Fla.

beam and the crane rail in Fig. 4 is 2 ft, the applied load of 8 kips would be 10 ft from point a instead of 12 ft. The $\frac{M}{I}$-diagram for this case would be as indicated in Fig. 16(*d*) rather than as shown in Fig. 3(*d*).

E. I. FIESENHEISER,[7] M. ASCE.—The use of moment distribution and the balancing of shear produced by sidesway provide a convenient solution for stresses in the mill building bent. An alternative method for determining the

fixed-end moments in the stepped column involves only shear and moment distribution for the stepped member itself. This method is convenient and does not require the use of moment diagrams. Since it may be of interest to some engineers, it is presented herein.

The procedure is to assume the stepped column to be a combination of two separate members. Fixed-end moments due to loads on the separate members are first computed and balanced, and the resulting unbalanced shear (or joint restraint), acting at the junction of the two members, is then calculated. The shear is balanced by application of an equal and opposite force at this joint.

Fig. 20

In calculating the effect of the applied force the joint is allowed to deflect without rotation. In this case the applied moments must be proportional to I/L^2 for the two segments of the stepped column and then balanced. Shears are computed and balanced by use of the proper correction factor. To obtain the final fixed-end moments, the moments caused by the loads acting on the separate members and those due to the shear balance are added.

The alternative method is illustrated by the calculations shown in Figs. 17, 18, 19, and 20. These calculations are made for the problem in Example 1, in which the ratio of moments of inertia is given as 8 to 1. Since only relative values are significant, moments of inertia of 96 and 12 are assumed. Figs. 17 and 18 show the calculation of the fixed-end moments for a wind load of 0.5 kips per ft on the 40-ft column. Fig. 19 shows the fixed-end moment computation for the effect of the 8-kip force due to crane thrust; and Fig. 20, the effect of the applied moment of 120 ft-kips at the joint.

It is noted that the fixed-end moments calculated by this method compare reasonably well with those calculated by the author. The use of moment diagrams and the procedure of dividing the member into many segments is unnecessary.

Walter J. Gray,[8] **Jun. ASCE.**—The sets of factors presented in this paper permit rapid analysis of the examples. However, they are not sufficiently complete for general use. Additional curves should be presented to show:

1. Fixed-end moments for concentrated side loads at other positions than at crane level, permitting a direct solution of the case of shed roof thrust as shown in Fig. 12.

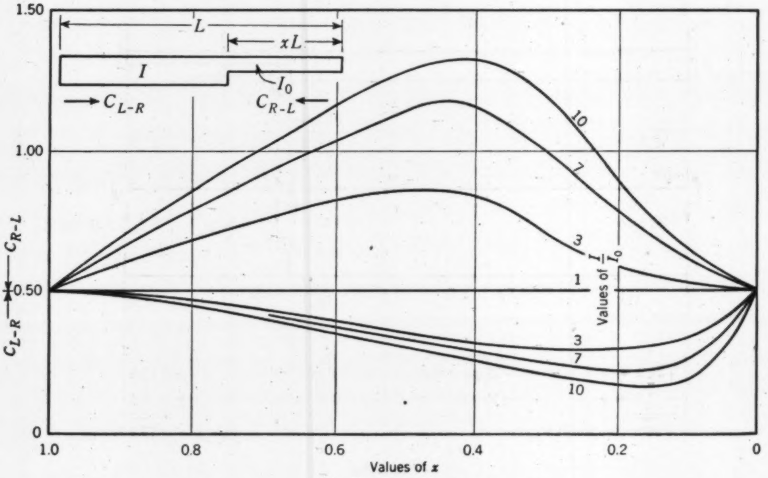

Fig. 21.—Carry-Over Factors for Stepped Member

2. Distribution factors, permitting a direct evaluation of the effects of truss restraint and lower floor restraint.

---

[8] Civ. Engr., Public Utilities Comm., City of San Francisco, San Francisco, Calif.

3. Fixed-end moments, indicating the effects of eccentric application of loads on the column, although these might be approximated from fixed-end moments for concentrated side loads at positions other than at crane level.

The carry-over factor curves should be redrawn to give a direct reading in one set of curves, thus avoiding the use of two factors. Fig. 21 is such a set of direct reading carry-over factor curves with a limiting value of $I/I_o = 10$, as given in an unpublished paper written by the writer in 1942 on "Analysis of Stepped Crane Columns by Moment Distribution," which is on file in the Engineering Societies Library at New York, N. Y. Values were calculated by the column analogy[9] procedure of Hardy Cross, Hon. M. ASCE.

The design of the stepped column is not complete, however, even though the combined stresses due to maximum moments and thrusts are computed, since they must be compared with the allowable combined stress in a stepped column. This latter value requires consideration of the slenderness ratio of the column before an allowable axial stress value can be determined. Thomas C. Shedd,[10] M. ASCE, suggests using an "equivalent" slenderness ratio of $L_1/R_1 + L_2/R_2$.

L. J. **Mensch**,[11] M. ASCE.—There was a dearth of technical literature on the analysis of mill bents by the theory of elasticity until about 1913 when a treatise appeared on the subject[12] in full panoply by W. Gehler, which showed the analysis of each of the bents in Fig. 22 for nearly ten loading conditions. Simple working formulas, clearly arranged, were given for each case—formulas not equaled by later authors in the ease of arrangement. This enabled engineers to design such bents in a very short time. A number of writers refigured some of the cases.[13,14,15] Had the author compared his results with any of those in the references suggested, he would have found his assumptions incorrect, as the moments at the foot of the columns are only one half the correct amount.

[14] "The Structural Engineers Handbook; Data for the Design and Construction of Steel Bridges and Buildings," by Miles S. Ketchum, McGraw-Hill Book Co., Inc., New York, N. Y., 3d Ed., 1924.

[15] "Rahmen Formeln," by Adolf Kleinlogel, W. Ernst und Sohn, Berlin, Vol. 8, 1939.

It is true that no formulas are available for bents with stepped columns and that the theory of elasticity would require the solution of a structure three times indeterminate complicated by the presence of a roof truss; this is a task even beyond the capacity of a large engineering organization, when it has to design perhaps five bents each for five loading conditions.

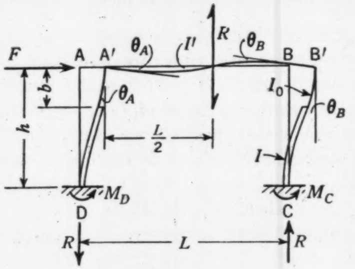

FIG. 23

Many years ago the writer stumbled on a solution that gives values within a small percentage of the theoretical results. It is based on the fact that the truss is from two times to ten times stiffer than the columns, and on the fundamental loading condition by a horizontal force at the top of one column. A symmetrical bent will deform as shown in Fig. 23. By inspection,

$$\theta_A = \theta_B \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

$$M_A = R\frac{L}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

$$AA' = BB' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

$$M_D = M_C = h\frac{F}{2} - R\frac{L}{2} = \frac{F\,h}{2} - M_A \ldots\ldots\ldots\ldots (14)$$

and

$$F\,h = M_D + M_C + R\,L = 2\,M_D + R\,L \ldots\ldots\ldots\ldots (15)$$

From Eqs. 14 and 15 it will be seen that if R or M_A were known, all other unknown quantities could be computed. This can be effected by expressing θ_A twice—once by the deformation of the truss, and once by the deformation of column AD.

Assuming the truss to have parallel chords and the moment of inertia, I',

$$\theta_A = \frac{R\,L^2}{12\,E\,I'} = \frac{M_A\,L}{6\,E\,I'} \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

From the column deformation for a uniform column section,

$$\theta_A = \int_0^h \frac{M\,dx}{E\,I} = \frac{\frac{x\,F}{2}\,dx - M_A\,dx}{E\,I} = \frac{\frac{F\,h^2}{4} - M_A\,h}{E\,I} \ldots\ldots (17a)$$

For stepped columns the column deformation is

$$\theta_A = \int_0^b \frac{\frac{F}{2}\,x\,dx - M_A\,dx}{E\,I_0} + \int_b^h \frac{\frac{F}{2}\,x\,dx - M_A\,dx}{E\,I} \ldots\ldots\ldots (17b)$$

Four particular combinations of values for stepped columns will be considered, as follows:

Combination	Values of I/I_0	Values of b
1	5	$h/3$
2	5	$h/4$
3	10	$h/3$
4	10	$h/4$

For these combinations, respectively,

$$\theta_A = \frac{13}{36}\frac{F\,h^2}{E\,I} - \frac{7}{3}\frac{M_A\,h}{E\,I} \tag{18a}$$

$$\theta_A = \frac{10}{32}\frac{F\,h^2}{E\,I} - 2\,\frac{M_A\,h}{E\,I} \tag{18b}$$

$$\theta_A = \frac{1}{2}\frac{F\,h^2}{E\,I} - 4\,\frac{M_A\,h}{E\,I} \tag{18c}$$

and

$$\theta_A = \frac{25}{64}\frac{F\,h^2}{E\,I} - \frac{13}{4}\frac{M_A\,h}{E\,I} \tag{18d}$$

Denoting $I'/L \div I/h$ by n, and eliminating θ_A by combining Eq. 16 with Eqs. 17*a* and 18, for a column of uniform section,

$$M_A = \frac{F\,h}{4}\left(\frac{6\,n}{1 + 6\,n}\right) = 0.242\,F\,h \tag{19}$$

For the four combinations of I/I_0 and b previously given,

$$M_A = \frac{13}{84}\,F\,h\left(\frac{14\,n}{1 + 14\,n}\right) = 0.1525\,F\,h \tag{20a}$$

$$M_A = \frac{5}{32}\,F\,h\left(\frac{12\,n}{1 + 12\,n}\right) = 0.1535\,F\,h \tag{20b}$$

$$M_A = \frac{1}{8}\,F\,h\left(\frac{24\,n}{1 + 24\,n}\right) = 0.124\,F\,h \tag{20c}$$

and

$$M_A = \frac{25}{208}\,F\,h\left(\frac{19.5\,n}{1 + 19.5\,n}\right) = 0.1185\,F\,h \tag{20d}$$

Inasmuch as n generally has a value of 5 or more, the fraction containing n in Eqs. 19 and 20 is nearly equal to 1; the approximate values were determined for $n = 5$. By Eq. 14, it can easily be proved that, for uniform columns,

$$M_D = 0.258\,F\,h \tag{21}$$

and for the four combinations of I/I_0 and b previously given,

$$M_D = 0.3475\,F\,h \tag{22a}$$

$$M_D = 0.3465\,F\,h \tag{22b}$$

$$M_D = 0.376\,F\,h \tag{22c}$$

and

$$M_D = 0.3815\,F\,h \tag{22d}$$

The results given by Eqs. 21 and 22 enable solution for other loading conditions, as follows:

Assume a column of uniform section to be affected by a horizontal wind load, w, per linear foot. A relaxation type method is used. If the column is not only fixed at point D, but is also held fixed at the top of point A, the end moments are $w\,h^2/12$ and the end shears are $w\,h/2$. If point A is released, the shear $w\,h/2$ will act like the force F in the fundamental case and

$$M_D = \frac{w\,h^2}{12} + 0.258\,f\,h = \frac{w\,h^2}{12} + 0.129\,w\,h^2 = 0.212\,w\,h^2 \ldots\ldots (23)$$

The shear at the bottom of the column is

$$V = \frac{w\,h}{2} + \frac{F}{2} = \frac{3}{4}\,w\,h \ldots\ldots (24)$$

In the case of a stepped column, for example, when $I/I_0 = 10$ and $b = h/3$, the first step is to compute the moments at the ends of the column, considered as a beam uniformly loaded (say, by the slope-deflection method), from which

$$M_D = 0.123\,w\,h^2 \ldots\ldots (25a)$$

and

$$M_A = 0.052\,w\,h^2 \ldots\ldots (25b)$$

and the shears at points D and A are

$$V_D = \frac{4}{7}\,w\,h \ldots\ldots (26a)$$

and

$$V_A = \frac{3}{7}\,w\,h \ldots\ldots (26b)$$

The final values at point D are

$$M_D = 0.123\,w\,h^2 + (0.376 \times w\,h^2)\,\frac{3}{7} = 0.284\,w\,h^2 \ldots\ldots (27a)$$

and

$$V_D = \frac{4\,w\,h}{7} + \frac{3\,w\,h}{14} = \frac{11\,w\,h}{14} \ldots\ldots (27b)$$

Similarly, for $I/I_0 = 5$, and $b = h/3$,

$$M_D = 0.277\,w\,h^2 \ldots\ldots (28a)$$

and

$$V_D = 0.77\,w\,h \ldots\ldots (28b)$$

Other loading conditions may be found by the same short cut. For uniform vertical loads on the truss, the point of inflection of the columns will be found to be: For $I/I_0 = 5$, between $0.04\,h$ and $0.06\,h$ below the midheight; for $I/I_0 = 10$, between $0.06\,h$ and $0.02\,h$ above the midpoint; and for a column of uniform section, $h/3$ above point D.

It is assumed in the foregoing analyses that the foot of the column is fixed. In many bents the columns rest on walls or piers, often 20 ft high. These supports are affected by the moments M_D and by the shears, and must be designed accordingly.

There is a question as to what value of I' to use for a Fink truss of a depth equal to perhaps one fifth of the span. The moment of inertia will be greater than that of a parallel chord truss having a depth of about one tenth that of the span; and the foregoing formulas can be used safely, as long as a stiff connection is provided between truss and columns by a brace capable of transferring the moments occurring at the top of the columns.

ARTHUR R. GRAVES,[16] M. ASCE.—The chief contribution of this paper to engineering and technical knowledge lies in Figs. 6, 7, 8, and 9, which may be used in calculating the fixed-end moments for three kinds of loading, and the distribution coefficients and carry-over ratios for any kind of loading. All, of course, are restricted to members with only one abrupt change of section, but their use is not limited to the design of stepped columns. The mill building designer needs such timesaving devices as these because as soon as a project is decided on, the owner, thinking of his anticipated profits, considers every day a loss of one day's profits until the mill is working—the larger the mill, the greater is the urge for speedy construction.

The foundations must be started first and this cannot be done until the column bents are designed. For columns with a constant moment of inertia, the points of contraflexure may be assumed and the horizontal shears distributed over the columns with comparatively little work, yet with satisfactory results. For stepped columns, however, the results from this approximate method will, in most cases, be far from those obtained by more exact methods. An indication of how serious these variations can be is shown by the range in values of the various functions given in Figs. 6, 7, 8, and 9. Another more convincing demonstration may be seen in some of the buildings in which the columns must be plumbed, or in which the crane runway must be lined up every few years, because the actual moments on the base of the columns are much more than those calculated by the approximate method.

In most cases, a more exact analysis of the column bent takes so long that the designer cannot delay the foundations long enough to make it. With the use of these or similar charts (Figs. 6, 7, 8, and 9) the labor and the time of calculation are reduced so that it is practicable to make a closer analysis of the typical bents, which, in turn, afford a better base on which to approximate the irregular bents, if time does not permit a closer analysis of them. It is possible for each designer to make up his own charts, but it is not practicable because of the time and labor required. The writer has a different set of charts, serving the same general purpose, which were developed over a period of more than ten years.

Even with charts such as the author's (Figs. 6, 7, 8, and 9), there is still much work to be done in analyzing column bents, and for most common mill bents the method outlined in this paper may be shortened without too great an inaccuracy in the final results. This method takes into account the deflection of the column between the knee braces and the roof truss. In the most common mill bents this refinement is not as important as it seems at first. The chief effect of this deflection of the column is that it makes the bent more limber and increases the horizontal deflection. If this deflection is assumed not to exist, two more charts may be plotted which will further reduce the amount of work. One chart should locate the point of contraflexure of the bent under translation forces. The other chart should give a stiffness factor to be used in distributing the translation forces among the columns in the bent.

---

[16] Senior Designer, Fabricated Steel Constr., Bethlehem Steel Co., Bethlehem, Pa.

With this alternate method the fixed-end moment at the bottom of the column will be less than that obtained by the original method outlined in the paper. The moment from translation will be greater, however, and, when the fixed-end moment and the translation moment are added together, the resulting moments from the two methods will differ by a small percentage.

The fixed-end moment at the top of the column will be greater with the alternate method and so will the moment from translation for wind load and crane thrust. However, these moments are always opposite in sign and their difference is changed much less than either of the two moments. The fact that the fixed-end moment and the translation moment at the top of the column are opposite in sign makes it possible to vary the calculated moment at this point, due to crane thrust of eccentric load, by varying the number of bents over which the translation effect is assumed to be distributed. With cranes having heavy trolleys the forces involved are considerable. In this connection it is also possible to have the unloaded columns of a bent of just the right stiffness so that the translation moment is equal and opposite in sign to the fixed-end moment at the top of the loaded column. This would result in a calculated moment of zero. To take care of such possibilities it is advisable that no column be designed for less than 50% of the fixed-end moment at the top of the column.

In the case of eccentric loads the signs of the fixed-end moments at both top and bottom of the column will vary with different ratios of the moments of inertia and with different ratios of the length of the upper part of the column to the entire length of the column. For one column the fixed-end moments may have the same sign as the translation moment; for the next column the reverse may be true. This variation in the fixed-end moment is clearly shown in Fig. 9. When adding fixed-end moments from eccentric loads to the translation moments the sign of each moment should be carefully checked.

It should be noted that the author's charts, given in Figs. 6, 7, 8, and 9, were published previously by L. C. Maugh,[2] M. ASCE.

Erik Sollid,[17] Esq.—The work that the author has done in connection with the design of stepped columns is time saving and valuable. Curves similar to the ones presented by the author are in use in the design office of the Bureau of Reclamation (USBR). They were prepared chiefly by L. W. Crandell and H. L. Neve.[18] In addition to curves similar to those shown by Mr. Ling, the USBR memorandum includes a set of curves giving the fixed-end moments for a concentrated load anywhere along the member having both ends fixed, or having the heavier end fixed and the smaller end hinged. It was found that by letting each curve represent a different ratio of

$$m = \sqrt[3]{\frac{I}{I_0}} \qquad (29)$$

---

[17] Engr., Bureau of Reclamation, U. S. Dept. of Interior, Denver, Colo.

[18] "Concrete Building Design Data," by L. W. Crandell, George Evans, Erik Sollid, H. L. Neve, and Samuel Judd under the direction of L. N. McClellan, *Technical Memorandum No. 629*, U. S. Bureau of Reclamation, Denver, Colo., November, 1943.

—instead of the ratio x as used by the author, more orderly curves were obtained—that is, curves that did not have the tendency to intersect or twist around one another as is especially apparent in Figs. 6, 8, and 9.

It is dangerous for a designer to accept any design curves or diagrams, however, without the satisfaction that they are correct. Therefore, the writer wishes to call attention to a simple method for spot checking the diagrams without resorting to the more laborious methods of moment area or column analogy. As seen from Fig. 9, the signs of the fixed-end moments for a moment applied at the change in section varies both with the $\frac{I}{I_0}$-ratio and the value of x, and it is impossible to determine the signs for the fixed-end moments by inspection. In the spot check discussed herein, however, it is a simple matter to determine the direction of the end moments. The method consists of treating the member as a continuous beam with one redundant support.[19] Instead of using the author's sign convention, the writer prefers the following one: If the moment at the end of a member tends to cause clockwise rotation of the adjacent joint into which the member frames, that moment will be called positive (+); conversely, a moment tending to cause counterclockwise rotation is negative (−).

In the following examples a member (as shown in Fig. 24) will be used. This member is similar to the column ab in Fig. 4.[19a]

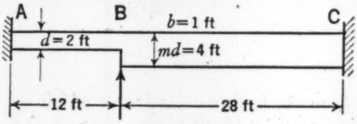

FIG. 24

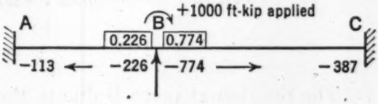

FIG. 25

Tentatively the beam will be supported at point B (Fig. 24), thus defining a continuous beam of two uniform sections. The frame properties of these beams are then as follows: $I_{AB} = \frac{b\,d^3}{12} = \frac{1 \times 2^3}{12} = 0.666$ and $I_{BC} = \frac{1 \times 4^3}{12} = 5.333$.

Case I.—Assuming points A, B, and C fixed, the stiffness ratio equals $K_{AB} = \frac{I}{L} = \frac{0.666}{12} = 0.0555$ and $K_{BC} = \frac{5.333}{28} = 0.19$. The distribution factors around joint B are $r_{BA} = \frac{0.0555}{0.0555 + 0.19} = 0.226$ and $r_{BC} = \frac{0.19}{0.2455} = 0.774$.

Case II.—Assuming point A hinged and points B and C fixed, $K_{BA} = 0.0555 \times 0.75 = 0.0416$ and $K_{BC} = 0.19$, as for Case I. The distribution factors are $r_{BA} = \frac{0.0416}{0.0416 + 0.19} = 0.18$ and $r_{BC} = \frac{0.19}{0.2316} = 0.82$.

Example 1.—Determine the fixed-end moments due to an applied moment at point B (Fig. 24), the change in section.

In Fig. 25 only one distribution around joint B is necessary to find the moments created by an applied load of 1,000 ft-kips at point B. Distribution factors are shown in rectangular boxes and moment carry-overs are indicated by arrows. The reaction on the support at point B will be upward and equal to $-(226 + 113)\frac{1}{12} + (774 + 387)\frac{1}{28} = 13.2$ kips. The true fixed-end moments will now be the moments shown at ends A and C in Fig. 25, plus the moments caused by an upward force of 13.2 kips at the change in section. To find the moments resulting from this force, hold joint B against rotation and give it an upward deflection of $\Delta = 10{,}000\, z$. The quantity 10,000 is chosen arbitrarily and z is the correction factor. The fixed-end moments in spans AB and BC resulting from this deflection are

---

[19] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932.

$$M_{AB} = M_{BA} = \frac{6\,E\,I}{L^2} = \frac{6 \times 0.666}{12^2}\, 10.000\, z\, E = -\,278\, z\, E$$

and

$$M_{BC} = M_{CB} = \frac{6 \times 5.333}{28^2}\, 10.000\, z\, E = +\,408\, z\, E$$

Next, let joint B rotate and distribute the moments as shown in Fig. 26.

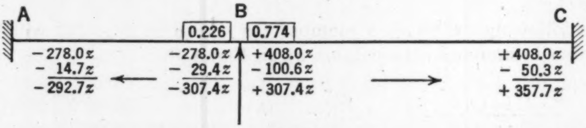

Fig. 26

The reaction at point B due to these moments is downward and equal to 73.8 z. Setting this reaction equal to the reaction of 13.2 kips, caused by the moments in Fig. 25, gives $z = \frac{13.2}{73.8} = 0.179$. The correct fixed-end moments caused by a moment of 1,000 ft-kips, applied as shown in Fig. 25, and without any support at point B, are now

$$M_{AC} = -\,113 - 292.7 \times 0.179 = -\,165.4 \text{ ft-kips}$$

and

$$M_{CA} = -\,387 + 357.7 \times 0.179 = -\,323.0 \text{ ft-kips}$$

For an applied moment of − 120 ft-kips at the change in section, the fixed-end moments are

$$M_{AC} = -\,165.4 \times \frac{-120}{1{,}000} = +\,19.9 \text{ ft-kips}$$

and

$$M_{CA} = -\,323.0 \times \frac{-120}{1{,}000} = +\,38.8 \text{ ft-kips}$$

which agree with the results given by the author in the paragraphs containing Eqs. 8.

Example 2.—Determine the fixed-end moment generated by a concentrated transverse load of 8 kips at the change in section, as shown in Fig. 4. In Fig. 26 the moments have already been obtained for an arbitrary deflection at point B. It is recalled that these moments produced a downward reaction of 73.8 z. The moment resulting from the 8-kip load is then simply $\frac{8}{73.8} = 0.108$ times the moments in Fig. 26, or

$$M_{AC} = -292.8 \times 0.108 = -31.6 \text{ ft-kips}$$

and

$$M_{CA} = +357.7 \times 0.108 = +38.6 \text{ ft-kips}$$

This compares to 31.8 and 38.7, respectively, as given by the author—a very good agreement. Finding carry-over factors and stiffness factors is equally simple. By definition, the carry-over factor is the ratio between the resulting moment at the fixed end of a beam to the moment applied at the other end of the beam. The stiffness factor of a member is equal to the moment required to turn the free end of the member through a unit rotation when the other end is held fixed or free. These are not the general definitions of the stiffness and carry-over factors, but they suffice for the present purpose.

Example 3.—Find the carry-over factor from end A to end C, in Fig. 24. This is done merely by applying a unit moment at end A, considering it as hinged. After distributing around joint B, the moments are as shown in Fig. 27.

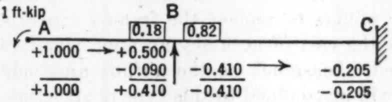

Fig. 27

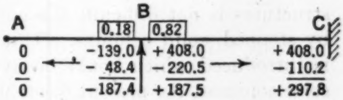

Fig. 28

The reaction at point B is upward and equal to $\frac{1 + 0.41}{12} + \frac{0.41 + 0.205}{28} = 0.14$. In this case, with joint A hinged, the moments generated by an arbitrary upward deflection at point B of $\Delta = 10.000\ z$, after joint B has been allowed to rotate, are as shown in Fig. 28. Moments are in terms of z, the correction factor.

The reaction at point B is downward and equal to $\frac{187.4\ z}{12} + \frac{187.5 + 297.8\ z}{28} = 32.9\ z$. Equating this reaction to the reaction of 0.14, from Fig. 27, gives $z = \frac{0.14}{32.9} = 0.00426$; and the moment at end C is

$$M_{CA} = -0.205 + 297.8 \times 0.00426 = +1.055$$

Since a unit moment was applied at end A, the moment at end C is equal to the carry-over factor. The author gives 1.06—which is also a very good agreement.

The stiffness factor is found in a similar way, but in this case, end A is held rigid while the distribution and the deflection correction are made. The final moment at end A will now be equal to the ratio between the stiffness of the beam of constant section AB, to the stepped beam AC. A more direct way would be to apply the stiffness factor of the constant section AB as a moment at end A. Then after completing the foregoing distribution and deflection correction, the final moment at end A would be the stiffness factor for the stepped beam AC. The correctness of this follows directly from the definition.

It is believed that the foregoing discussion will help a designer in gaining confidence in the design curves, and especially will help in checking as to the direction of the end moments in a beam with a moment applied somewhere in the span—usually a difficult and confusing problem.

A. FLORIS,[20] ESQ.—At great length well-known expressions are derived by well-known methods and applied to the analysis of stepped-column mill bents in this paper. In the mind of a critical reader doubts will arise as to the scope, usefulness, and value of such efforts. Since the introduction of relaxation methods the importance of tables and charts in the analysis of rigid frames and continuous beams with variable moments of inertia has been unduly exaggerated. The integrations involved in the evaluation of various constants can be replaced by summations, and results can be obtained in a comparatively short time. The great advantage of the summation process lies in the fact that it is applicable to all conceivable cases; its use is not restricted to the number or completeness of available tables and diagrams.

Although the application of the moment-distribution method to framed structures is not difficult, the author prefers to replace the framed supports by stepped, solid columns. Thus, at the cost of accuracy an approximation is introduced which could be avoided. Inasmuch as the author uses only solid columns, the present discussion will be confined to this type of structure.

By using one of the general methods of mechanics, all the necessary expressions of the relaxation methods can be derived, quite simply, as follows: Adapting the notation of the paper, let

$$C_2 = \lambda = \frac{1}{L^2}\int_o^L \frac{(L - x)\,x}{I_x}\,dx \ldots\ldots\ldots\ldots\ldots \tag{30a}$$

$$C_1 = \zeta = \frac{1}{L^2}\int_o^L \frac{x^2}{I_x}\,dx \ldots\ldots\ldots\ldots\ldots \tag{30b}$$

and

$$C_3 = \rho = \frac{1}{L^2}\int_o^L \frac{(L - x)^2}{I_x}\,dx \ldots\ldots\ldots\ldots\ldots \tag{30c}$$

Then

$$\phi = C_1\,C_3 - C^2_2 \ldots\ldots\ldots\ldots\ldots \tag{31}$$

For the joint rotations, the stiffness factors are as follows:

At the far end—

$$\Lambda = \frac{C_2}{\phi} \ldots\ldots\ldots\ldots\ldots \tag{32a}$$

---

[20] Los Angeles, Calif.

and at the near end—

$$Z = \frac{C_1}{\phi}; \quad P = \frac{C_3}{\phi} \qquad (32b)$$

For sidesway or bar rotations, the stiffness factors for the far and near ends are, respectively,

$$Y = \frac{C_1 + C_2}{\phi}; \quad \Omega = \frac{C_3 + C_2}{\phi} \qquad (33)$$

Carry-over factors for joint a and joint b (Fig. 29) are C_2/C_1 and C_2/C_3, respectively.

In addition, the fixed-end moments are expressed by

$$M_{f,A} = \frac{1}{\phi L}(F_a C_1 - F_b C_2) \qquad (34a)$$

and

$$M_{f,B} = \frac{1}{\phi L}(F_b C_3 - F_a C_2) \qquad (34b)$$

in which

$$F_b = \int_o^L \frac{M_{ox}\, x}{I_x}\, dx \qquad (35a)$$

and

$$F_a = \int_o^L \frac{M_{ox}\,(L - x)}{I_x}\, dx \qquad (35b)$$

In Eqs. 35, M_{ox} is the bending moment for the given loading of the beam on two supports.

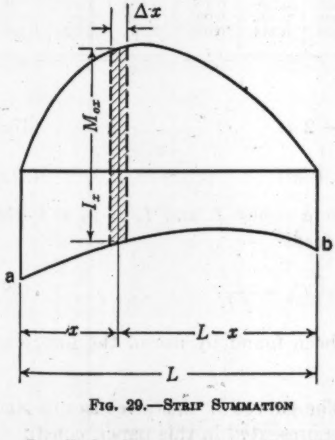

Fig. 29.—Strip Summation

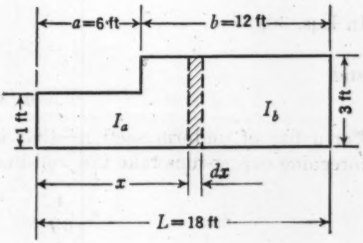

Fig. 30.—Stepped Bar

In all the foregoing equations C_3 will be equal to C_1 if the beams or columns are symmetrical. The bending-moment diagram produced by an external load is shown in Fig. 29. Dividing this area into a convenient number of equal strips Δx, and replacing the integrals in Eqs. 30 and Eqs. 35 by sums, all the necessary quantities can be calculated. The same is true for unloaded beams and columns, in which case $M_{ox} = 0$. Eqs. 30 and Eqs. 35 are applicable to all cases including stepped columns, the simplest of all.

For comparison the constants of a solid column, 1 ft thick and 18 ft long (Fig. 30), are given in Table 6. In case 2 the column was divided into nine equal strips with $\Delta x = 2$ ft, and by means of Fig. 29, the column factors determined. Case 3 gives the basic expressions C_2, C_1, and C_3 taken from Figs. 6 to 9, and the remaining quantities were calculated. The great discrepancy between values for case 1 and those of the author (case 3) raises a fair question as to the reliability of these charts. In order to check the accuracy of the summation method, the integrals of the basic quantities have been evaluated. The results are

$$C_2 = \frac{1}{6\,L^2}\left(\frac{\delta}{I_a} + \frac{L^3 - \delta}{I_b}\right) \quad \text{(36a)}$$

$$C_1 = \frac{1}{3\,L^2}\left(\frac{a^3}{I_a} + \frac{L^3 - a^3}{I_b}\right) \quad \text{(36b)}$$

and

$$C_3 = \frac{1}{3\,L^2}\left(\frac{\gamma}{I_a} + \frac{L^3 - \gamma}{I_b}\right) \quad \text{(36c)}$$

TABLE 6.—COMPARISON OF RELAXATION FACTORS

Case	C_2	C_1	C_3	ϕ	Λ	Z	P	Y	Ω	$\frac{C_2}{C_1}$	$\frac{C_2}{C_3}$
1......	10.30	5.04	51.40	153	0.0674	0.0329	0.336	0.100	0.403	2.05	0.205
2......	10.44	5.17	51.59	158	0.0662	0.0328	0.327	0.099	0.392	2.02	0.203
3......	13.50	6.70	70.00	287	0.0472	0.0234	0.244	0.070	0.291	2.02	0.193

In Eqs. 36,

$$\delta = a^2\,(3\,L - 2\,a) \quad \text{(37a)}$$

and

$$\gamma = a\,(3\,b\,L + a^2) \quad \text{(37b)}$$

For a bar of uniform section—that is, for $a = b = L$ and $I_a = I_b = I$, the foregoing expressions take the well-known form:

$$C_2 = \frac{1}{6\,I}\,; \qquad C_1 = C_3 = \frac{1}{3\,I} \quad \text{(38)}$$

The values for case 1, Table 6, have been found by use of the foregoing expressions.

Charles W. Dohn,[21] **Jun. ASCE.**—The curves of elastic constants and moments for stepped-column mill bents, as presented in this paper, constitute a worthy addition to design knowledge. It is well to note attempts to apply rational methods to problems which, heretofore, were solved by making many broad assumptions. When the final sections chosen are no different from those obtained by prior methods, the more rational analysis serves to justify the many broad assumptions of the prior methods.

Rigid frame bent
Continuous rigid frame crane runway

FIG. 31

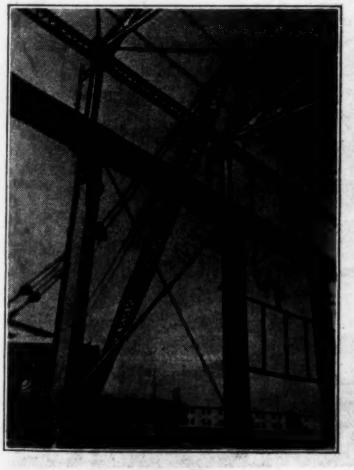

FIG. 32

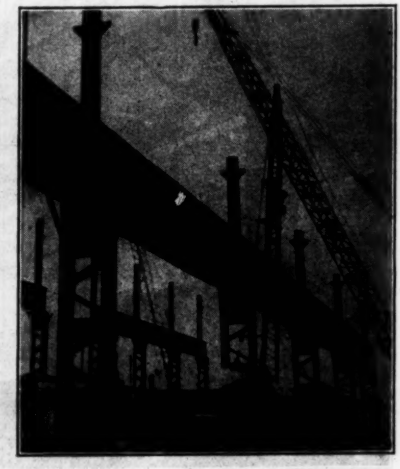

FIG. 33

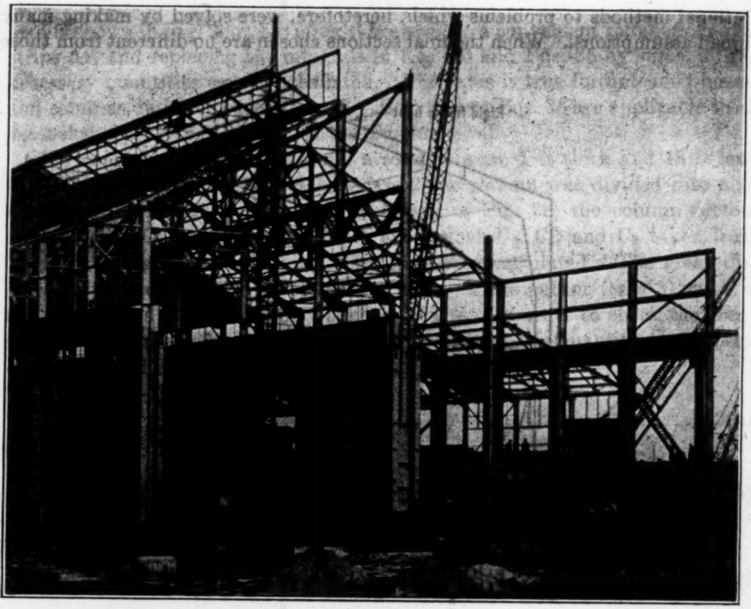

FIG. 34

FIG. 35

The author limits the value of his elastic constants and moments in the designs presented by making assumption *c* (under the heading, "II. General Conditions and Design Assumptions"), which assumes no end rotation of the truss. The statement is made that, unless the truss is subject to considerable deflection, this is a safe assumption. If the span length is rather long, as in the usual wide mill building, under vertical load the truss will exert considerable moment on the small upper stepped-column section, and this plus other loading conditions has been found critical in previous designs with rigid top connections of which the discusser has knowledge. The position of the end diagonal, in the truss shown in Fig. 4, would cause excessive stress in the lower chord of the end panel. If the slope is reversed, thus bringing the end diagonal into the lower chord point at the column, a better stress condition prevails for a rigid joint of this nature. This is especially true for long spans. With further reference to Fig. 4, the author makes the statement:

> "The upper load of 32 kips will also produce some bending, particularly in the upper section; however, this will not be especially severe, since it is near the center line of the lower section."

True, it will not be a severe loading for the lower section; however, it is an extremely severe loading for the upper section when considered in conjunction with moments induced by other loading conditions. The upper step is limited by space requirements in its ability to resist bending. By making the neutral axis of the diagonal and the chord intersect at the neutral axis of the upper column section, the eccentricity of the end reaction may be eliminated, and moment on the upper column section may be reduced.

Example 1 would be more valuable if the complete analysis for all the eccentric loads shown in Fig. 4 were included. The 120-kip eccentric load will cause a translation of the column at the point of application of the couple—hence, the writer is not convinced that the method of superposition applies to Fig. 3(*e*). Inasmuch as bending is combined with axial compression, the deflection changes the action of the axial forces, and the latter produce not only axial compression, but also some additional bending. Small deflections may produce considerable changes in the action of forces.

The space requirements for clearance at the ends of the bridge crane and the difficulty of determining maximum moment conditions for a stepped column as part of a continuous and rigid structure subjected to various independent loads contribute to make the independent crane column economical of design, material, and construction. The diagrammatic sketch (Fig. 31) depicts a mill building with a continuous roof bent connected to a continuous rigid frame crane runway. The connections between the bent and the runway do not transmit vertical or bending forces, but may be utilized to absorb lateral shocks from the crane. Such a design is rigid, positive, economical, and more easily fabricated and erected than the stepped-column mill bent design. In the design of a rigid frame crane runway, such as indicated in Fig. 31, the method presented by R. C. Brumfield,[22] M. ASCE, would be applicable. The arrangement shown in Fig. 31 is, furthermore, unique, as it requires less longitudinal and lateral bracing than a stepped column. Aside from economy of material, this is an advantage at the working level. Argument might be presented that the stepped-column mill bent may also be made rigid with the crane girder. When the stepped column is made rigid with the girder and the roof, the resulting maximum stress conditions are not positively determinable without expenditure of excessive effort, and it is doubtful if such a design can match in economy one which is proportioned for the independent load conditions rather than an unfavorable combination of these dissimilar loading conditions. The independent column is not necessarily much less compact; it can be used economically with wider and variable width bays; and it is more economical of crane girder and bracing material than the stepped-column mill bent when used in rigid frame designs. The independence of the building and the crane runway may increase the value of both. Either the building or the runway can be removed or altered independently to accommodate use, and the building is adaptable to the addition of multiple aisles. It would be debatable which type of column is best in resisting seismic forces. The independent system can be made as stiff or as flexible as requirements dictate; the stepped column is somewhat constrained in dimension and ill proportioned to resist lateral forces as part of a rigid frame.

---

[22] "Moving Loads on Restrained Beams and Frames," by R. C. Brumfield, *Transactions*, ASCE, Vol. 111, 1946, p. 805.

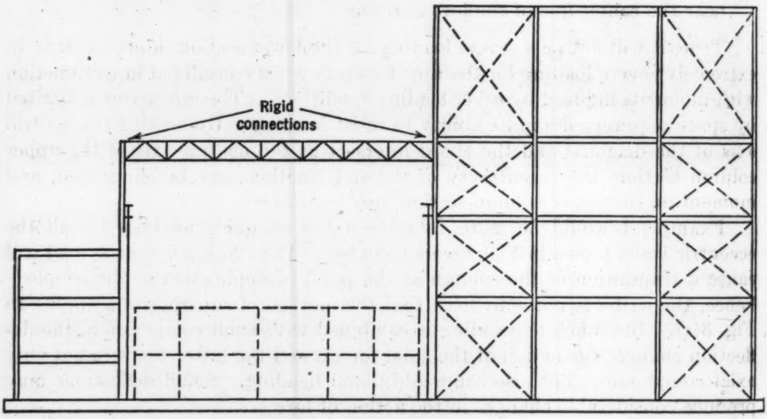

Fig. 36.—Power Station Bent

The mill buildings shown in Figs. 32, 33, 34, and 35 were erected several years ago and represented good practice then. At present, and particularly in the future, continuous frames and rigid connections will vie more for better practice where good foundation conditions are available. The illustrations are presented in the hope of forming a more complete picture of typical engineering problems in selection and analysis of stepped-column designs wherein the author's elastic constants may be applied.

Fig. 32 shows a typical stepped column in a mill building. Note the longitudinal and lateral bracing and the rigid roof connections, not completed at the time the photograph was taken. The girders are not continuous and the bays are not very wide. Brackets are provided for knee braces to transmit longitudinal forces from the crane girder to the column, and thence to the bracing. These knee braces had not been added at the time the photograph was taken. The inside face of the column is a very deep channel section riveted to the lower column section. Brackets and a heavy billet are provided for the crane girder seat.

Fig. 33 illustrates another version of the stepped column wherein two stub columns support two crane runways and a roof column. Note that the bays are wide, and that the crane girders are deep, noncontinuous, and nonrigid. Fig. 34 shows a heavier service, mill building group. Note the maze of bracing and the massiveness of the columns, as well as the deep crane girders, that result with simple spans and relatively nonrigid frames. (The high peak roof truss is not well adapted to use as a rigid frame member.) A stairway has been located so as to utilize part of the "dead" space between the columns. The mill building columns in Figs. 32, 33, and 34 present opportunity in their design for the elastic constants presented by the author.

Fig. 35 illustrates a multiple-aisle mill building with varying bay sizes, and with crane runways at different levels. The independent crane column was used for this difficult framing problem; however, the crane runway spans are neither continuous nor rigid, and the high peaked roof truss is not properly part of a proportioned rigid frame.

Mr. Ling's elastic constants for a stepped column would be useful in the design of a power station bent such as shown in Fig. 36. In this design the roof truss is rigidly connected to the upper crane column in the turbine room. The boiler house is braced for lateral forces. A study of moment connections was made for the boiler house but they were not used because they were not required as much as for, say, an office or apartment building. The bracing in the boiler house thus absorbs the lateral and sway forces from the crane-girder bent over the turbine room.

DANIEL S. LING,[23] M. ASCE.—The various discussions of this paper are greatly appreciated and the writer sincerely hopes that the original paper, clarified and enlarged on by the discussions, will be of practical use to the structural engineer.

Mr. Spaulding's objections are entirely valid. It was realized when the curves were originally developed that actually a gradual, rather than an abrupt, transition occurs at the column step. For most design problems, the error is not believed to be large, but if the designer prefers he can readily use the modified "x L," suggested by Mr. Spaulding.

Referring to the point of application of the side thrust from the crane, again, the writer must agree with Mr. Spaulding. This factor was considered when the curves were prepared but no ready solution was apparent without the complication of another variable, as the point of application of load in relation to the column step would vary with each size of crane girder. It was felt, however, that because of the stiffening effect of the usual crane girder connection the error involved would not be too large. Mr. Gray has suggested that fixed-end moment curves for other points of application would be desirable and Mr. Sollid has stated that such curves are available in a publication of the United States Bureau of Reclamation.

---

[23] Cons. Engr., Detroit, Mich.

Mr. Gray's statement (2) is not clear. Distribution factors around any joint are simply the ratio of $(C\,K)$-values of the various members at the joint (see Table 1); and the use of curves would seem neither possible for the great variety of different conditions, nor of any practical benefit. Curves such as those suggested in statement (3) would, no doubt, have some use but would involve many series because of the variation not only in the point of application, but also in the terms x and I/I_o. The need for curves for carry-over factors is a matter of personal preference. Since the moments from translation derive from $(C_1 + C_2)\,\frac{E\,\Delta K}{L}$, the writer feels that a C_2-curve is preferable to a carry-over factor curve and has, in fact, often been forced to determine C_2-values from the carry-over curves in the series on haunched members published by the Portland Cement Association.

As to the statement that the design is not complete, the writer has noted that a complete design was not shown, but simply the determination of moments from bent action. The completion from that point should be no problem to the experienced designer and it was felt would add no worthwhile addition to the paper.

Mr. Mensch refers to the publications presenting formulas for bent analysis. Often, such bents will fit a case under consideration, but all too frequently the building to be designed does not seem to fit any of the cases and stepped column conditions are not included. Frankly, the writer has always been hesitant to use the sometimes lengthy formula because of great possibility of error due to misinterpretation, involved calculations, and hesitancy to accept a formula of whose accuracy he is not personally certain and which would take much time to check. The latter could, of course, be stated of the curves in Figs. 6 to 9, but a few spot checks are not too difficult.

Mr. Mensch's statement that the writer's moments at the foot of the columns are in error is not explained; certainly, it is at variance with Mr. Sollid's concurrence with the writer. In the examples given in this paper, the writer essentially assumed infinite stiffness of the roof truss. Although this assumption is, admittedly, apt to be considerably in error in many cases, it is readily possible for any assumed K-value of the truss to rotate around a "joint" midway between points a and a′, making use of the curves for determining C-values and fixed-end moments. The writer questions whether the usual roof truss connection to the column is adequate to develop the full stiffness of the truss.

In the time available the writer has not had the opportunity to study fully Mr. Mensch's method of solution. It seems applicable only to symmetrical bents and the writer does feel the greatest merit of his suggested solutions is for use with unsymmetrical bents.

Professor Fiesenheiser suggests a method of temporarily assuming a support at the column step. This suggestion is entirely feasible; and, if no curves for stepped columns were available, would be much easier than construction of the various $\frac{M}{E\,I}$-curves needed for a stepped section. With the use of the curves presented in the paper it would seem that Professor Fiesenheiser's method is somewhat longer, and especially so when bent effect is considered. It does, however, present another useful possibility to the designer when special conditions arise, and could adequately serve to handle the case of the applied loads or moments at points other than the column step. After moments for the applied forces were determined, the effects of bent translation would be found by the method presented in the paper.

Mr. Sollid presents the same general method as that given by Professor Fiesenheiser and suggests it as a spot check for the curves. His statement indicates that *Technical Memorandum No. 629*[18] should be a desirable addition to the reference library.

It is agreed, as Mr. Graves states, that the curves can be used for any type of problem for stepped members other than columns. The writer has knowledge, however, of unpublished curves that are more applicable to stepped beams or slabs. With reference to the moment at the top of the column, the designer should, of course, consider the worst possible combination of loads. Perhaps, Mr. Graves' suggestion of not less than 50% of the fixed-end moment has merit.

Mr. Graves' statement is correct; the curves in Figs. 6 to 9, inclusive, are included in "Statically Indeterminate Structures."[2] Permission had been granted to L. C. Maugh, M. ASCE, to include the curves in his book and because of wartime difficulties and restrictions the book was published prior to the publication of this paper.

If, by "solid" columns, Mr. Floris means a full, rectangular section, he appears to have misinterpreted this paper. The curves are applicable to any section for which the moments of inertia can be determined and the examples in the paper show standard rolled beam sections. The inference regarding integration is not understood. Actually, the writer's curves were prepared by summations from the $\frac{M}{E\,I}$-diagrams, essentially the same process as Mr. Floris' method.

Mr. Floris' C-factors are not the same as the writer's and, therefore, are not comparable. The difference is readily noted in Eq. 38, in which all the C-values include I; whereas, in the slope-deflection equations for uniform section, $C_1 = C_3 = 4$ and $C_2 = 2$. In view of Mr. Floris' statement regarding accuracy, the point should be made that the writer determined, by the conjugate beam method, the slope-deflection coefficient for the case of Fig. 30 in which x (Fig. 1) $= 0.33$ and $\frac{I}{I_o} = \frac{3^3}{1^3} = 27$. The values are: $C_1 = 6.93$, $C_2 = 13.6$, and $C^3 = 68.3$—which, considering the small scale of the curves, are in good agreement with the values determined (case 3, Table 7) by Mr. Floris from the curves.

For a correct comparison of Mr. Floris' factors with those of the writer, the term Λ is the writer's C_2 multiplied by K_o, $Z = C_1 K_o$, $P = C_3 K_o$, $Y = (C_1 + C_2) K_o$, and $\Omega = (C_3 + C_2) K_o$. For the column of Fig. 30, using foot units, $I_o = \frac{1}{12}$, $L = 18$, or $K_o = \frac{1}{12 \times 18} = \frac{1}{216}$. With this multiplying factor, case 3, Table 7, should read $\Lambda = 0.062$, $Z = 0.031$, $P = 0.0324$, $Y = 0.098$, and $\Omega = 0.386$; and, if the values obtained from the $\frac{M}{EI}$-curve were used, the values for case 4 would be: $C_2 = 13.67$, $C_1 = 6.93$, $C_3 = 68.3$, $K_o = \frac{1}{216}$, $\Lambda = 0.0633$, $Z = 0.0321$, $P = 0.316$, $Y = 0.096$, $\Omega = 0.380$, $C_2/C_1 = 1.97$, and $C_2/C_3 = 0.200$. It is thus noted that Mr. Floris' "great discrepancy" does not exist. It would appear that Mr. Floris is simply presenting another, somewhat similar method of obtaining stiffness factors and fixed-end moments, which is as time consuming as the method used by the writer in preparing the curves presented in this paper.

Mr. Dohn's statements regarding design conditions will not be challenged. It is realized that one cannot generalize greatly with respect to design assumptions because what may not be too important in one case, may, indeed, be serious in another. In the main, the writer wished to present his curves for use where applicable.

The argument of stepped columns versus independent columns is, to a great extent, a matter of opinion; but the writer has felt that the objection to stepped columns simply on the basis of difficulty of analysis should not hold. Actually, in many designs using independent columns, the crane columns are so thoroughly connected to the building column with diaphragms or lacing that essentially a stepped column results. The use of knee braces on crane girders is, to the writer, most questionable. Too often such knee braces are used without any consideration being given to the bending produced in the column from the deflection of the crane girder, with consequent overstressing of the column.

The writer wishes to thank all the discussers of the paper and is pleased that several of them feel that the curves presented will be of use to the designer.

SYNOPSIS

Seventeen trusses, thirty-seven joints of structural frames, and three 15-ft struts, all of which had served for some 2½ years as structural parts of the Golden Gate International Exposition buildings at San Francisco, Calif., were removed from these buildings when they were dismantled, stored for some weeks in the open air, and later were tested for failure in a large testing frame constructed especially for this purpose. Also, one hundred and three laboratory specimens, constructed to find the lateral resistance of nails in plywood and the shearing and buckling strength of plywood panels, were tested.

The trusses were of various types, spans, and sizes. Thirteen were entirely of timber. Seven of these had connections framed with split rings or shear plates, and the other six had connections of volts and washers. Four of the seventeen trusses were of the rod and block type, with compression diagonals of wood and with tension members of steel rods. The thirty-seven joints with shear plates, split rings, and bolts were of various types: Seventeen with members connected by steel gusset plates and shear plates, one with plywood gusset plates and bolts, two joints and four splices with split rings, six bolted spliced joints of girders resisting moment and shear, two butt-block end joints of trusses, three joints with steel straps and pins, two bolted joints with steel straps, and four laboratory-built tension splices or compression splices with plywood splice plates and split rings. One spaced column, two T-section columns and struts, eighty-two nail fastenings in plywood, three plywood panels in shear, and eighteen plywood panels subjected to buckling were also tested.

Loads were applied with calibrated hydraulic jacks. Deflections of each truss as a whole, as well as deformations of its component parts, were measured during the progressive loadings. Likewise, deflections and deformations were measured in the various joints, columns, and plywood tests. Numerous photographs illustrate the features of interest in the tests.

Loads and stresses were computed after each test. For example, the strength or weakness of each truss and its parts was investigated theoretically to correlate test phenomena and structural theory.

A. FOREWORD

This report presents: Tests and studies of the load-carrying capacity, strength, deflection, and deformation of members of full-sized wood trusses; similar tests of joints of wood trusses and structural frames, splices of wood girders, and built-up wood columns; tests of the buckling and shearing strength of plywood panels; and tests of the lateral strength of nail fastenings in plywood. All the trusses had supported the roofs or floors of the Golden Gate International Exposition buildings for 2 or more years, and were made available for testing when the buildings were dismantled in 1941. All test specimens were taken intact from these buildings, or were fabricated of material from them. Most of the trusses were framed with modern timber connectors (that is, split rings and shear plates) although some had bolted joints without connectors and others were framed with web members of steel rods and wood struts.

These tests and their analyses are believed to be unique in presenting a comprehensive study of actual wood trusses and structural members, not designed and constructed as test specimens. The structural members had functioned as parts of buildings for 2½ years; they were generally of good material; they had been designed by competent structural engineers; they had been built under ordinary field circumstances and under varying conditions of inspection; and, finally, they were tested as taken from the buildings with such defects as normally exist, without tightening loose bolts and (except in a few cases specifically noted, where trusses were damaged while being taken down) without correcting any deficiencies resulting from service.

The original purpose was to take advantage of an opportunity seldom available; namely—(1) to test entire trusses in place in the buildings, under normal conditions of use as nearly as possible with the various defects of workmanship accompanying commercial practice; (2) to study the relation between laboratory tests of individual members or joints and their combinations as found in framed structures; (3) to determine whether factors had been overlooked in design, construction, inspection, or maintenance on which more information was needed; (4) to note the effect of shrinkage and other factors that develop in service; and (5) to test individual joints with multiple connectors and with several members forming concentric or eccentric connections.

It became necessary, however, to demolish many of the buildings before it was possible to test their trusses in place. As a substitute, although not so desirable, the individual trusses were tested as isolated specimens in a specially constructed testing frame. Some of these trusses were of types in which the influence of tension perpendicular to the grain was an important factor. These tests revealed for the first time the importance of considering this stress combined with horizontal shear or other stress in eccentrically connected joints.

Neither the assumed loads nor the unit stresses for which the trusses were designed are known to the committee. The trusses and the structures all functioned satisfactorily. As a result, it is entirely possible that, in the case of some of the critical conditions found in testing these joints and trusses to ultimate load, the designing engineer may have refrained from utilizing the full strength of a member or joint, fully realizing that eccentricities (for example) produced additional stress which required reduction of stress from direct axial loading.

Phenomena revealed by the tests and subsequent analysis and discussions of these phenomena may be noted as follows:

1. The inadequacy of small individual tests as a premise for determining the behavior and strength of full-sized structures;
2. The importance of considering the effect of combined stresses and the need for further tests and more data on this subject;
3. The importance of adequate supervision or inspection to assure accuracy of fabrication and erection;
4. The tendency of a truss chord to rotate when tension members are connected on one side and compression members on the other, resulting in bending or bowing of web members flatwise;
5. The need of keeping adjacent faces of members in contact by tightening nuts on bolts when it has been necessary to use lumber that has not been seasoned to the moisture content to which it will come during service;
6. The desirability of reducing end checking and splitting;
7. The beneficial effect of cross bolts or stitch bolts, or threaded spikes or dowels, or some kind of adjustable strapping in offsetting the effect of splitting;
8. The importance, where shear plates are used, of avoiding oversized bolt holes, either by error or by reaming to permit passage of bolts through holes bored improperly in the wood;
9. The importance of straight end cuts, without reentrant angles; and
10. The importance of ample end distances in tension members for ring connectors and shear plates.

The main objective of the tests was to determine a factor of safety for the structures tested, for comparison with factors of safety for individual test specimens. This objective was not realized fully, and any comparison of the ratios of ultimate loads as related to assumed safe working loads is misleading unless examined in the light of the material presented in Section C–II under "Safety Factor" and with due attention to individual test comments.

Of the twenty tests made, on sixteen trusses, the results show that: Five failed because of rupture of the wood members at joint details; six failed at bolted joints; and nine failed at connector joints, because of types or combinations of stresses not anticipated.

B. HISTORY

In October, 1940, preliminary work was started on the Timber Test Program at Treasure Island in San Francisco. The program was conceived by John J. Gould, M. ASCE, who had been chief structural engineer of the Exposition, and it was adopted by the San Francisco Section of the Society through the interest and recommendation of the late Frederick H. Fowler (Past-President, ASCE), Harold B. Hammill (M. ASCE), and Walter Dreyer (M. ASCE)—all Past-Presidents of the San Francisco Section. The sponsorship of the University of California (at Berkeley) was obtained through the cooperation of C. T. Wiskocil, M. ASCE, and W. C. Pomeroy, registrar of the university, then acting as administrative officer of the Works Progress Administration (WPA) for the university. The San Francisco Section appointed a Timber Testing Committee with L. H. Nishkian, M. ASCE, as chairman. When he resigned the chairmanship because of press of private work and extended absence from San Francisco, Mr. Hammill succeeded him. The other members of the committee were Mr. Gould and the late Henry D. Dewell, M. ASCE, and Henry J. Degenkolb, Assoc. M. ASCE. Mr. Gould was retained as technical director of the program by the committee, which functioned in cooperation with the various timber industries who furnished the funds required for the work. Mr. Degenkolb was appointed assistant technical director. Byron L. Nishkian, Jun. ASCE, assisted Messrs. Gould and Degenkolb in the first few months of the program. Mr. Gould, in a part-time capacity and Mr. Degenkolb in a full-time capacity, directed all the technical and administrative phases of the program and prepared the preliminary report, which was edited by Mr. Dewell and then reviewed by the entire committee.

Industries that contributed to the program include the West Coast Lumbermen's Association; National Lumber Manufacturers' Association; Douglas Fir Plywood Association; Timber Engineering Company, Inc., of Washington, D.C.; Timber Engineering Company of California; Timber Structures of Portland, Ore.; Summerbell Roof Structures of Los Angeles, Calif.; the Western Pine Manufacturing Company of Spokane, Wash.; Henry Mill and Timber Company of Tacoma, Wash.; and the Northwest Bolt and Nut Company of Seattle, Wash. The following were instrumental in the organization of the project and kept in close touch with all progress: The late Chester J. Hogue, M. ASCE, in charge of technical service, West Coast Lumbermen's Association; A. C. Horner, Assoc. M. ASCE, consulting engineer, Timber Engineering Company of California; and the late J. E. Mackie, Assoc. M. ASCE, then western manager, National Lumber Manufacturers' Association.

The San Francisco Section and the committee owe these three gentlemen particular gratitude, for they more than once were instrumental in securing additional funds when such financial assistance was sorely needed. Finally, Messrs. Mackie and Horner were generous in supplying the services of their office staffs in the preparation of this report. The Division of Timber Mechanics of the Forest Products Laboratory in Madison, Wis., was very helpful in giving consultation, in answering inquiries, and in reviewing this report.

The late John A. Newlin, M. ASCE, formerly chief of the Division of Timber Mechanics of the Forest Products Laboratory, made a special trip to San Francisco for the purpose of witnessing the tests and advising with the committee. Because his death intervened, the report has not had the benefit of his criticism, which would have been of great value because of Mr. Newlin's knowledge of timber mechanics and wide experience in timber testing. Fortunately, notes made by him have been materially helpful.

Preliminary work began in October, 1941, and consisted principally of the selection of specimens, investigation of methods of testing, application for WPA assistance, and general review of the condition of the Exposition buildings for availability of test specimens. Many studies and drawings were made by the technical director and his assistant to determine the most advantageous and economical tests and procedures. Unfortunately, various setbacks beyond the control of the committee hindered progress. Some of the buildings were demolished by the wrecking contractors for the Exposition before any arrangements could be made for securing the required specimens. This circumstance was partly offset by the cooperation of the contractors, who donated or allowed various specimens to be taken in return for payment of labor and equipment costs for the extra trouble involved in setting these specimens aside.

The proposal of the United States Navy to take over all of Treasure Island and its buildings caused several revisions in the list of specimens considered necessary for a satisfactory fulfilment of the program. Later, the Navy did take over the island, necessitating the dismantling of the laboratory built for the test program and removal of its equipment to a new location in San Francisco. Finally, the WPA assistance was secured later than had been anticipated. However, to counteract several of those difficulties, the program was fortunate in having the splendid cooperation of Clarence E. Seage, Assoc. M. ASCE, who was chief engineer of the California Commission for the Exposition and who was instrumental in securing many specimens. Ralph G. Wadsworth, M. ASCE, then deputy WPA administrator for Northern California, was especially helpful in the organization of the project and in expediting the work on the many necessary preliminary details.

On February 17, 1941, the Timber Test Program, known as a WPA project, was opened officially. For several months the major part of the project was the collection of specimens. It had been hoped that these could be assembled simultaneously with the testing. However, the rapidity of the demolition made it necessary to obtain the specimens during this work and to delay the testing. Simultaneously, material was furnished to two senior students of the University of California for a special study in timber supervised by the technical director and his assistant. In May, 1941, tests were made on the Cavalcade cantilever structure; and, in June, a building of 2,800 sq ft was constructed, with a 500,000-lb testing frame, all as described in this report.

During the last few days of June, 1941, the first of the trusses was tested—the San Francisco Building truss; and, shortly thereafter, in turn, the Chinese Building trusses, Alameda Contra-Costa Counties Building trusses, Cavalcade truss, French Building truss, Merry-Go-Round trusses, and two rigid-frame legs from the Brazil Building. At this time, because of the national emergency of World War II, it became necessary to move all timber testing equipment and specimens from Treasure Island to San Francisco. In this emergency, entailing unexpected expenses, a building was loaned to the committee by the City of San Francisco, through the cooperation of the late A. D. Wilder, M. ASCE, then director of public works, and James H. Turner, M. ASCE, then civil engineer of the Public Utilities Commission and later manager and chief engineer of the Hetch Hetchy Water Supply, Power and Utilities Engineering Bureau. There was not enough room in this building, however, for all the specimens and equipment, but through the courtesy of J. F. Marias and T. Twohig, then president and rental manager, respectively, of the State Board of Harbor Commissioners, space was obtained at the Ferry Building for additional storage.

Considerable effort and time were expended in making arrangements for moving, and in settling the new building, after which the remaining tests were conducted. Simultaneously, the office staff began and completed the compilation of the data on which this report is based.

Much credit is due Messrs. Degenkolb and Byron Nishkian for the excellent and full photographic record of the tests, only a part of which appears in this report.

C. GENERAL FEATURES

I. Operations and Computations

Equipment.—The necessity of strict economy affected not only the equipment but also the methods of testing. Although the supply of WPA labor was sufficient, cash reserves were at a minimum. The equipment as planned had to be capable of testing 70-ft trusses, individual joints of other structural frames, plywood panels, and 30-ft columns. In the tests of trusses, the loads had to be applied at various points to simulate actual loading conditions. To meet these varied requirements, a large testing structure, or testing frame of 500,000-lb capacity—one that could be used partly or entirely for all the required operations—was designed by the technical staff and then built with WPA labor, using timbers from the dismantled Exposition buildings, connected with 4-in. split rings and $\frac{3}{4}$-in. bolts.

Hydraulic jacks were used for applying, measuring, and controlling the loads. A pump, flexible hose, two 20-ton jacks, and a 50-ton jack were purchased, along with a large gage for measuring the oil pressure in the jacks. Two 200-ton jacks were loaned to the project by D. J. and T. Sullivan, contractors for moving structures, for testing the heavy specimens. All this equipment was checked and calibrated at the testing laboratory of Abbot A. Hanks, Inc., of San Francisco. Calibration curves were plotted, and studies were made on various factors that might affect their accuracy. Among these factors were the effect of eccentric loading of the plungers, the direction of movement of the plunger, and the effect of using different hose lengths between the pump and the rams.

In loading specimens, care was exercised in centering jacks and loads. As a result, it was felt that the applied loads were measured well within 3% of their true values. A slight source of possible error was that the pressure gage read only to divisions of 25 lb per sq in. for a range of 10,000 lb per sq in. of oil pressure in the jacks. In the truss tests, two or three jacks were used simultaneously with one pump and gage to provide several loading points on a truss, and dividing beams spread the load over several panel points as desired. For this purpose, special Y-connections provided several sources of oil pressure for the jacks.

Twenty gages with Ames dials or Starrett dials, reading directly to 0.001 in., with a range of 0.3 in., were used. In the tests on the trusses, it was desired to read many more deformation points than there were dial gages. A special gage was developed for this purpose consisting of two small metal angles, one fastened to each side of the deformation point. Small ball points were attached on the outside of the outstanding legs of the angles, and the distance between points was then measured with a micrometer. By using the rachet of the micrometer, a uniform pressure was placed on the ball points at each reading so that any deformations due to bending of the angle legs would be constant. These gages had the advantage that, with the micrometers used, they had a range of about 1 in., reading to 0.001 in. By using vernier calipers, this range could be extended to about 5 in., reading to 1/128 in. and to any desired larger range by measuring with a ruler fitted with the heads of two carpenter's squares. The principal disadvantage of this special gage was the time consumed in making the required number of readings. To offset this disadvantage, in several places where an accuracy of 0.01 in. was considered sufficient, simpler gages were made, using a multiplying arm with a large scale. These measuring devices were calibrated with the dial gages and had a range of about 2½ in.

Testing Procedure.—In most of the tests, the actual readings were made by WPA workers, none of whom had previous experience in this field. They were under the direct supervision of the assistant technical director—the only engineer present at all the tests, who followed through all the operations. These assistants were picked with the cooperation of WPA officials, and were then taught to read the various instruments. All required computations were reduced to such simple forms that it was possible to have practically all operations, both in the field and in the office, performed by this staff, despite the fact that its members were only unskilled workers.

Because of the large number of points to be read at each increment of load, the load was applied to a predetermined value, and then held for a sufficient period to read the various gages. Loading was then resumed, and at the next predetermined load point the process was repeated. These reading intervals lasted from a few minutes or less to a half hour or more, depending on the number of gages and other factors. Errors in reading occasionally occurred, because of the inexperience of the workers. When discrepancies were found in the final analysis, the more logical reading was taken or the questionable reading was not used in any computations. In still other cases, the questionable reading has been given in the detailed report with a note of caution indicating the possibility of error.

In timber testing, a variation in results is usually introduced by changing the speed by which a specimen is loaded. Because of the peculiar equipment used in this program, it was not possible to employ a uniform speed; nor were the rates of loading specifically determined. Since a structure is seldom, if ever, loaded at a uniform speed, the value of the test results should not be discounted because of the methods used. In all cases, the times of reading and loading were recorded; and, in this report, the total elapsed time is indicated on the individual test.

Truss Tests.—Trusses were mounted on the frame with their longitudinal planes horizontal—in other words, in a flat position. They were suspended from the roof by hangers composed of two planks, 2 in. by 8 in., nailed to form a T-section. The web of each T-section was nailed to the roof rafters overhead and the flange was nailed to the truss. These roof rafters were then tied down to the frame of the building with plumber's tape, so that the hangers also acted as struts to prevent members of the truss from buckling upward under load. The truss was thus supported at varying spacings, usually from about 4 ft to 8 ft—depending on its weight, dimensions of top chord, locations of gages, and other factors. These hangers offered practically no resistance to the horizontal deflections of the truss specimens under load, for they could be moved easily by hand.

Truss loads were applied in varying increments up to the predetermined point at which the dial gages were removed. Loads were then increased until failure occurred, only the deflection and micrometer gages being read. On several trusses, failure occurred earlier than expected, while the gages were still in place. Reactions were taken on blocks that simulated the actual restraining conditions in the structure from which the truss was removed.

Joint Tests.—The testing frame was designed with the thought of testing full-sized joints of structural frames as economically as possible. In the past, it has sometimes been the custom to test two identical joints at a time, back to back. This method was not considered desirable nor practical in this program; and, in those joints which consisted of three or more members meeting at a common intersection, a procedure was used as shown in Fig. 1. The load was applied through the hydraulic jack, putting compression in one of the members, and was resisted by another member in compression, blocked tightly against the testing frame. In some specimens, a screw jack was installed on this second compression member to help adjust the specimen and to reduce possible secondary stresses. The third member necessary to preserve equilibrium was put in tension by the following procedure. Before testing, large steel plates were fastened to it with bolts or shear plates to provide the necessary tension connection; and, after placing the joint in the testing frame, these plates were connected to two 2-in. steel rods, which were in turn fastened to

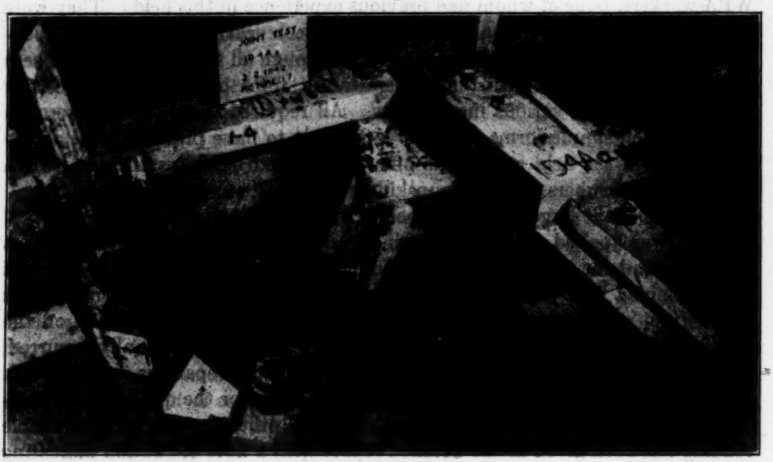

FIG. 1.—TYPICAL FAILURE OF TENSION DIAGONALS OF SHEAR PLATED JOINTS (JOINT J5)

the testing frame. One exception to this procedure was joint J13 in which all the members were put in compression. Gages were installed to measure the various deformations. In almost all the joints tested, additional gages were installed to measure the angular change between members, as a check on any possible secondary stresses that might be induced by the deformation of the joint. In no case were the movements such that these secondary stresses influenced the tests.

Plywood Tests.—The tests of the strength of nails in plywood in resistance to lateral forces, and of plywood in resistance to shear and buckling, were made in the testing frame, as described later in Section D–IV.

Reduction of Data and Calculations.—After the field data were typed and mimeographed, they were reduced, calculations were made as necessary, and stress-strain curves were plotted. Stresses in members of trusses and joints were calculated, making use of forms and with the usual assumptions for the actions of structures under load. In the case of a truss with eccentric joints, stresses were first calculated by assuming pin-ended concentric connections at the panel working points. Then corrections were made, as necessary, to the stress in any members for change of slope and the increased shear in the panel caused by eccentric connection. Stresses in these connections were calculated on an approximate basis only, as a more theoretically correct analysis would have involved unnecessarily laborious computations on structures statically indeterminate to many degrees.

One feature of the mechanics of recording the results of the tests was the use of photography. All specimens were photographed before and during the tests, at failure, and at the disassembly of the specimen to record all possible visual features. These photographs and their accompanying notes form an indispensable record. In the event that other investigators review this work, the field notes should be used with the photographs. For the information of those interested, the data observed, with the curves, field notes, photographs, calculated reductions, etc., were filed at the San Francisco office of the National Lumber Manufacturers' Association, the Engineering Societies Library in New York, N.Y., and the Forest Products Laboratory in Madison, Wis. This report includes only a small percentage of the total data available.

II. Safety Factor

One of the principal results expected from these tests was a ratio between loads causing failure in the specimens tested and the calculated allowable load that the specimen, in its weakest part, might be expected to sustain safely. Such ratios, customarily designated as "factors of safety" are likely to be misleading in a composite structure if compared to factors of safety of isolated test specimens. Quite different results may be expected, for instance, when a joint is tested (1) as an isolated specimen in a testing machine, (2) as a part of a truss tested by itself, or (3) as a part of a roof assembly in a building where the assembly as a whole may provide additional stability. Furthermore, factors of safety used in determining safe working load for nails, bolts, and connectors and for timber are derived from different considerations (ultimate load, proportional limit, deformation, etc.) and hence are not properly comparable.

For these reasons the term "factor of safety" has not been used in this report. Instead a ratio, designated by R, is used in presenting test results. In discussing the tests, factors R are given, which are ratios between the computed member stress at ultimate loads and the usually accepted design capacities (allowable loads), which are further defined in each test or group of tests. These allowable loads, where possible, are based on the recommendations of the Forest Products Laboratory or those of the Timber Engineering Company, Inc. (TECO), in its 1939 manual.[1]

It should be emphasized that, in most tests, failure occurred in a manner neither expected nor previously investigated and the factors R are based on the nearest available criterion usually used by designers. This criterion is clearly defined in each case. For example, in one truss of the North Square Building, the factor R is based on the allowable connector capacities, although failure was clearly due to tension perpendicular to the grain.

III. Nomenclature

Notation.—The following letter symbols, used in this report, and in its discussions, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932) prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = section area; in Table 26, the symbols A to Q are introduced as key letters for typical dimensions indicated in Figs. 84 and 85;

d = depth of a beam;

E = modulus of elasticity in tension and compression;

e = eccentric distances;

F = total stress in a member, imposed by external loads; F_A = total stress in member A, etc.;

K = a factor derived from the curves of Fig. 83(c);

L = length of span or height of a column; height of a panel;

P = an applied load:

- P_b = allowable load on bolts;
- P_c = allowable load on connectors;
- P_l = proportional limit load;
- P_{bl} = proportional limit load on bolts;
- P_{cl} = proportional limit load on connectors;
- P_{wa} = allowable load on wood;

R = ratio between the computed stress at test loads and the usually accepted design capacities (allowable loads):

- R_{ba} = ratio R between maximum test load and allowable load on bolts;
- R_{bl} = ratio R between proportional limit load and allowable load on bolts;
- R_{ca} = ratio R between maximum test load and allowable load on connectors;

---

[1] "Timber Connector Construction," Manual of the Timber Eng. Co., Inc., Washington, D. C., 1939.

R_{cl} = ratio R between proportional limit load and allowable load on connectors;

R_{wa} = ratio R between maximum test load and allowable load on wood;

R_{wl} = ratio R between proportional limit load and allowable load on wood;

R_l = ratio between computed stress at the proportional limit loads and the usually accepted design capacities (allowable loads);

r = least radius of gyration;

s = stress per unit area; s_{wa} = allowable unit stress in wood;

W = total applied load on truss;

w = applied load on truss, in pounds per linear foot;

X = an unknown total force;

Δ = total deformation or displacement; and

θ = angle of twist; also the slope of the grain in relation to the axis of a member.

Explanation of Terms and Abbreviations.—

1. Allowable Stresses in Timber.—The allowable load W on a structural member of either one or more pieces, when determined by the strength of the timber, using the recommended unit working stresses s of the Forest Products Laboratory is termed "wood allowable load," and is abbreviated P_{wa}. The unit working stresses for selected structural Douglas fir (the grade used in practically all cases) are:

Description	Stress, s_{wa} (lb per sq in.)
Bending or tension parallel to the grain....	1,600
Longitudinal Shear Stress:	
In beams..............................	100
In joints..........................	150
Compressive Stress:	
With the grain......................	1,200
Across the grain....................	350

On surfaces inclined at an angle θ with the direction of the grain, the allowable working stress s_{wa} in compression is expressed by the Hankinson formula as given subsequently in Eq. 1.

2. Allowable Stresses on Bolts.—The allowable load on a structural member of either one or more pieces when determined by the safe load on the bolts in a bolted connection, as computed in accordance with the recommendations of the Forest Products Laboratory,[2] is hereinafter termed "bolt allowable load" and is abbreviated P_b.

3. Allowable Loads on Connectors.—The allowable load on a structural member, of either one or more pieces, determined by the recommended standard design loads given by TECO,[1] is hereinafter termed "connector allowable load," and is abbreviated P_c.

---

[2] "Wood Handbook," Forest Products Laboratory, Forest Service, U.S.D.A., Madison, Wis., 1940.

4. Compression Diagonals.—When used in the description of a joint test, the designations "compression diagonal" and "tension diagonal" refer to the nature of stress in the diagonal during the test, and not necessarily to stress function in the structure from which it was taken.

5. Proportional Limit.—The load at the proportional limit, as judged by the load-deformation curves, is termed hereinafter the proportional limit load and is abbreviated P_l.

6. Maximum Stress Ratio.—The ratio of the maximum stress in a member or connection, to a calculated allowable load is hereinafter termed R_{wa}, R_{ba}, and R_{ca}, respectively.

7. Proportional Limit Ratio.—In a manner similar to item 6, the ratios of the proportional limit load to the allowable loads are R_{wl}, R_{bl}, and R_{cl}, respectively.

8. Malleable Iron Washers.—The designation MIW means "malleable iron washer"; for $\frac{7}{8}$-in. bolts, $3\frac{1}{2}$ in. in diameter and $\frac{7}{16}$-in. thick; and, for $\frac{3}{4}$-in. bolts, 3 in. in diameter and $\frac{7}{16}$-in. thick.

9. Identification of Structures.—The Exposition buildings from which the trusses tested were taken, and their abbreviations when applied to trusses, are identified in this report as follows:

Building	Abbreviation
Alameda-Contra Costa Counties Building....	AC
Brazil Building..........................	B
Cavalcade...............................	C
Chinese Building.........................	Ch
French Building..........................	F
Merry-Go-Round...........................	M
North-Square Court.......................	NS
San Francisco Building...................	SF

10. Connectors.—Split rings or shear plates, used for connecting timbers in various ways, are termed "connectors."

11. Member.—A structural element that extends between two panel points of a truss or structural frame and acts primarily in resistance to direct or axial tension or compression is a "member." The term includes those structural elements of test specimens which had so functioned in the structural frames from which they were taken. A member consisting of one piece or one "stick" of solid cross section—as a member composed of one 6-in. by 10-in. section—is variously termed: "One-piece," "one stick," or "single member." Similarly, a member consisting of two separate pieces or two separate "sticks"—as a member composed of two 3-in. by 10-in. pieces—is variously termed: "Two-piece," "two stick," or "double" member.

12. Single Shear.—A member has its end connection, or connections, in single shear when its connectors are in one face of the member only, or when bolts or nails attach the member to a connecting member, splice pad, or gusset plate by only one face.

13. Double Shear.—A member has its end connection, or connections, in double shear when its connectors are in two opposite faces of the member and

are equally divided in number between each face; or when bolts or nails attach the member to a connecting member, splice pads, or gusset plates by two opposite faces.

14. Loose Bolts.—Examination of the bolting of the specimens of this test program led to the conclusion that all bolts had been inserted in slightly oversized holes. Nevertheless, the bolts were found to be tight in their assemblies—that is, they could not be turned by hand. Shrinkage of the wood, from its green condition at the time of framing to its seasoned condition at the time of testing, had caused the sides of each wood member, through which a bolt passed, to draw away from the washers, or from the gusset plate, or plates, to which the member was connected. This, then, is the meaning of such phrases and terms as "the bolts were loose," and "loose bolts."

15. Wood Handbook.—Wood Handbook refers to the "Wood Handbook"[2] prepared by the Forest Products Laboratory of the United States Department of Agriculture.

D. DETAILED REPORT OF TESTS

I. Truss Tests

Alameda-Contra Costa Counties Building (AC) *Trusses.*—For purposes of identification the truss numbers of this building are prefixed by the letters TAC.

These tests were of four trusses from the AC Building, with compression diagonals and tension rods and, except for minor variations in depth of daps and cuts, of identical construction. They were 39 ft 4½ in., center to center of span, about 6 ft deep, and had 6-in. by 8-in. top and bottom chords substantially parallel. Fig. 2 shows the detail. Except for truss TAC–3 the trusses were in good condition. This truss, when tested, was found to have been injured either during erecting or dismantling.

Workmanship appeared to have been good; daps and cuts were well fitted. Bolts at the splices were generally tight in their holes, although spaces between truss members and splice pad indicated that shrinkage of from about ⅛ in. to ¼ in. had occurred. Some of the washers were loose, but the bolts themselves could not be moved by hand. Timbers consisted of Douglas fir of select structural grade, and the trusses were tested with an average moisture content of 12%. The end butt blocks at joints L1 and L7 were in good condition, and no checks were observed in the horizontal plane of theoretical maximum shear—for example, on plane A1-A2, Fig. 3. A sound knot was found in this plane in truss TAC–4.

Testing.—As usual, trusses were tested in a horizontal position, the loads being applied as concentrations at the upper panel point as shown in Fig. 2. Deformations, particularly those of the end joints, were measured by gages. Referring to Fig. 4, a typical installation at one end joint: Gage A measures the horizontal slip between block and chord; the stick between points X and Y is fastened to butt blocks by using blocks at the ends, so that gage B gives a measure of the bending deformations of the block as a beam between points X and Y as well as of the butt blocks; gage C measures movements of the projected end of the diagonal perpendicular to its axis—the movement being measured with respect to the bottom chord at the working point; gage D measures deformations parallel to the diagonal, between points D and Z as the stick between these two points is fastened to the diagonal only, thus projecting movements to gages C and D; gages E, F, and G measure deformations

of the block perpendicular to the chord at the places shown; and gage H measures the "bedding" of the end of the diagonal into the bevel cut of the block. Similar gages were installed on both faces of the joints.

In two trusses, TAC–3 and TAC–4, a smooth steel plate, which had been rubbed on both sides with paraffin, was installed at an end joint to reduce friction between chord and block.

Truss TAC–1.—The first evidence of overstress in truss TAC–1 was observed at joints L7 and U2 at the butt blocks, where the end diagonals were bearing on their beveled cuts. At joint U2, the block showed small splits and about ½-in. embedment of the diagonal. The load in member L_1U_2 at this time was about 45 kips, giving a bearing stress on the butt block of about 2,000 lb per sq in., although this indentation of ½ in. did not cause the load on the truss to decrease. Final failure occurred very suddenly in shearing off the table of the butt block at joint L7, as shown in Fig. 5. The shearing plane was A1-A2, Fig. 3. The load in member U6–L7 was 49 kips, and the calculated shearing stress was 474 lb per sq in., neglecting friction.

FIG. 3.—APPROXIMATE CALCULATED STRESSES AT JOINT L7, TRUSSES TAC-1, TAC-2, TAC-3, AND TAC-4

Truss TAC-2.—Testing on this truss was begun in the afternoon and continued until evening when loads were released, and was resumed the following morning, when failure occurred, as in truss TAC–1, at joint L7 in shearing off the table of the end butt block. Before failure, as shown by the arrow in Fig. 6, a space opened between the inner end of the butt block and the chord, caused by the eccentric pull of the table of the butt block. This phenomenon was typical for all four trusses, although not to the same degree. A detailed analysis of the moments and stresses involved is shown in Fig. 3.

FIG. 4.—TYPICAL INSTALLATION OF GAGES AT AN END JOINT

Failure did not occur immediately upon reaching the maximum load, but about 2 min later.

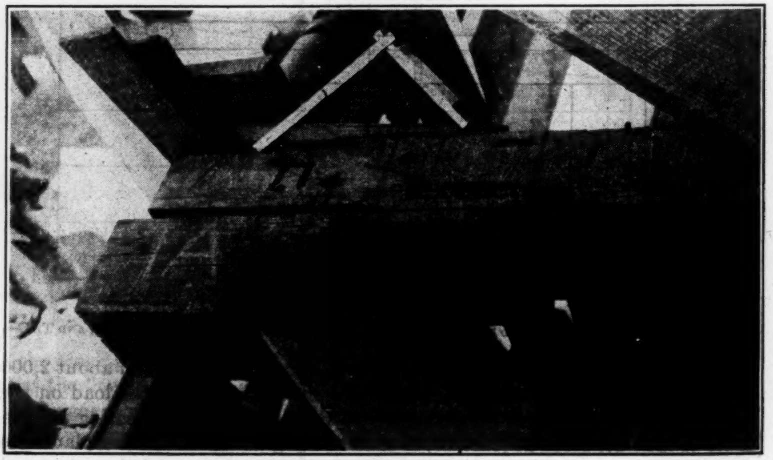

FIG. 5.—FAILURE OF BUTT BLOCK AT AN END JOINT

Truss TAC–3.—As previously noted, a paraffined steel plate was installed at the end joint of panel point L7 in truss TAC–3. Loading was started on a

Saturday; and, at a total load of 49.7 kips on the truss, the lower chord failed in tension between two panel points. The load was released and examination indicated the chord had suffered a previous injury. The chord was repaired by splicing. On the following Monday afternoon testing was resumed, when failure occurred at joint L7 after the maximum load had been applied for about 6 min. The failure was similar to those described for trusses TAC–1 and TAC–2.

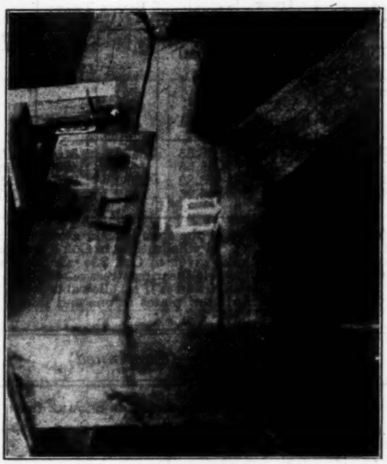

FIG. 6.—BENDING OF BUTT BLOCK PREVIOUS TO FAILURE IN SHEAR

Truss TAC–4.—A paraffined plate was also installed in the end joint of panel point L1 in truss TAC–4. Failure occurred at this joint about 5 min after the maximum load had been applied in a manner similar to that previously described.

Results of Tests, Trusses TAC.—Results of these tests are listed in Table 1. Fig. 2(*b*) includes the deflection curves for the lower chord of one of the trusses, for four different loadings. Fig. 7 shows center deflection of the upper and lower chords of truss TAC–1. Fig. 8 shows the opening of the lower chord splices at L3 and L5; Fig. 9 shows the embedment of the end diagonals in the bevel cuts of blocks at U6; Fig. 10 shows the deformation at gage D; Fig. 11 shows the slip of butt blocks with respect to the chord at gage A. Six curves are presented in Fig. 12, showing deformations at gages on butt blocks of joints L1 and L7 on truss TAC–3, the location of the gages being shown in Fig. 4.

Computations based on a unit shear stress of 150 lb per sq in. in the end butt block indicate that the trusses were designed for an allowable load of about 660 lb per lin ft. Trusses TAC–1 and TAC–2 failed at R_{wo} = 3.15 and 2.95, respectively. The two trusses on which paraffined steel plates were installed failed at R_{wo} = 2.55 and 2.0.

[i] Expressed as fractions of the span between points X and Y, Fig. 4. Deflections in Col. 13 are the highest readings when the load on the truss was as given in Col. 12. [j] Parallel to the grain. [k] Computed maximum tension plus bending stress in the block at the plane A_1–A_2. [l] The difference between these two stresses (117 lb per sq in.) corresponds to a coefficient of friction of 0.315.

Loads at failure of the tables of the butt blocks (at plane A1-A2, Fig. 3) produced calculated shearing stresses of 297 lb per sq in., 382 lb per sq in., 443 lb per sq in., and 474 lb per sq in. The first two values of s_s are for the two trusses in which paraffined steel plates were used, the average shearing stress being 340 lb per sq in. Where plates were not installed, the average ultimate shearing stress was 458 lb per sq in. This increased strength, amounting to 35%, may be explained by the frictional resistance on plane A1-A4 in trusses TAC-1 and TAC-2, relieving the shearing stresses on plane A1-A2.

Failures in the blocks at these relatively low unit stresses were probably due to the abrupt change in section at point A1, resulting in a combination of high bending and shearing stresses occurring simultaneously in the vertical plane at point A1.

Fig. 3 presents an analysis of the stresses in the end butt block of truss TAC–2 at the time of failure. In the analyses it has been assumed that the bolt holding down the block was loose and therefore did not act in tension to reduce the bending moments in the vertical plane at point A1. Actually, the washers under the heads of these bolts were so loose that they did not become tight even in the tests. The bolts could not be moved by hand, however, so that some slight tension may have been present through friction on the surfaces of the bolts. If any such tension did exist, it would have resulted in somewhat reduced bending stresses in the butt block.

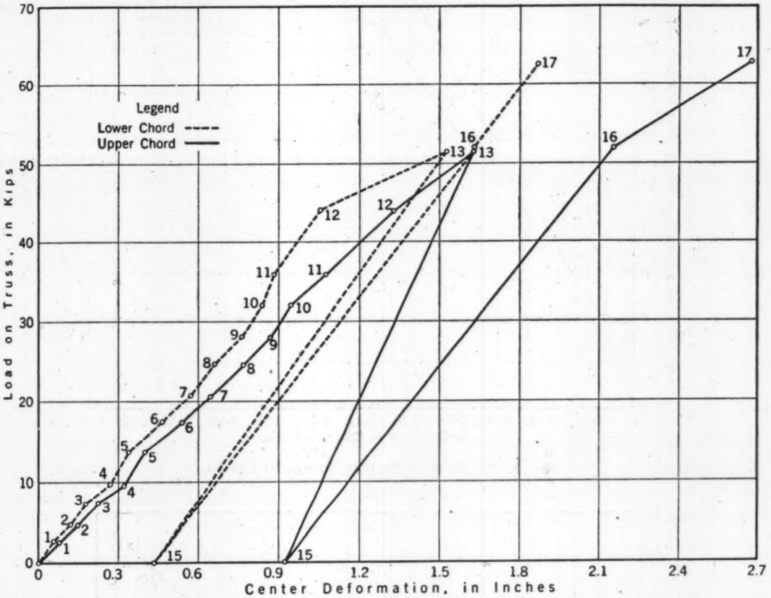

Fig. 7.—Center Deflection, Truss TAC–1

The tests of the two trusses in which the end joints were modified by the introduction of paraffined steel plates seem to indicate that friction plays an important part in the resistance of this type of end joint. However, the tests are not sufficient in number to justify reliance on friction in timber design.

The tests also confirm what good judgment would have dictated—in the end butt blocks, top and bottom cuts should not be made in the same vertical plane. They also seem to show that abrupt changes in cross section of wood members reduce the strength more than is accounted for by present design practice and that, when such abrupt changes cannot be avoided, lower unit working stresses should be used. Further tests on joints in which a combination of shearing stress, direct stress, and bending stress is involved are much needed for clarification.

The effect of shrinkage causing increased stresses in timber joints is illustrated in these tests where the bolts in butt blocks became ineffective in tension, thus introducing bending and causing local flexural stresses.

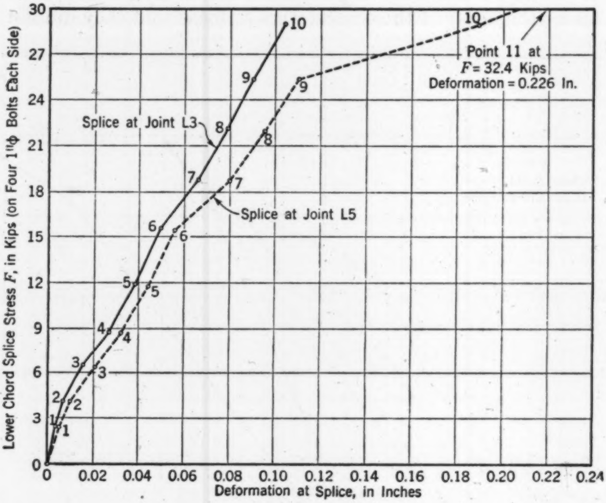

FIG. 8.—OPENING OF SPLICES, JOINTS L3 AND L5

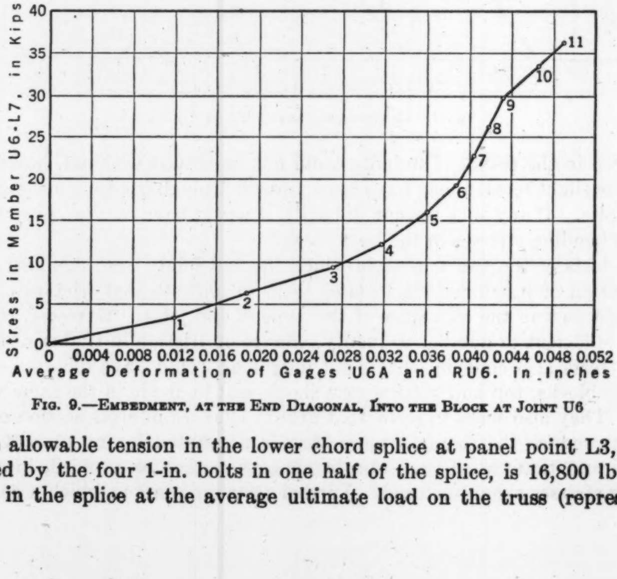

FIG. 9.—EMBEDMENT, AT THE END DIAGONAL, INTO THE BLOCK AT JOINT U6

The allowable tension in the lower chord splice at panel point L3, as determined by the four 1-in. bolts in one half of the splice, is 16,800 lb. The tension in the splice at the average ultimate load on the truss (representing failure of the end butt blocks in shear and not failure of the splice) was 60,000 lb. In the splice bolts, therefore, R_{ba} would have a value of 3.6; and, since the splice evidenced no weakness, the potential value of R_{wa} or R_{ba} would be greater. In trusses TAC–1 and TAC–2, which sustained the maximum ultimate loads (68,500 lb), the value of R_{ba} would be 4.1.

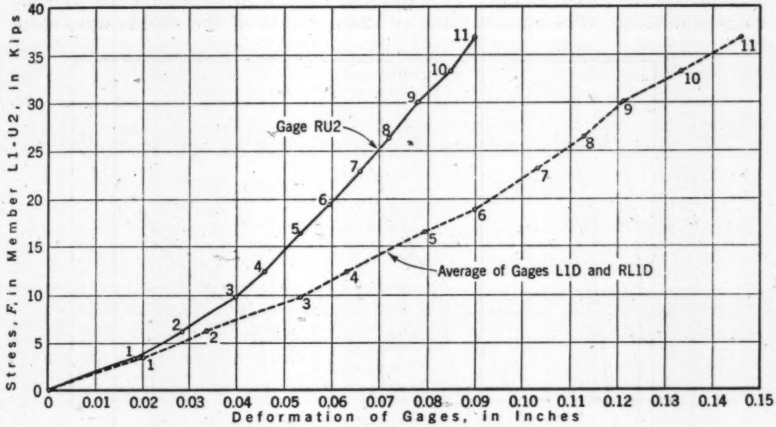

FIG. 10.—TOTAL AXIAL DEFORMATION OF DIAGONAL WITH RESPECT TO THE CHORDS AT PANEL POINTS L1 AND U2

This series of tests furnishes another illustration of the need for tests of full-sized timber trusses and structures since only in such way can combinations of different kinds of stresses show their true effect.

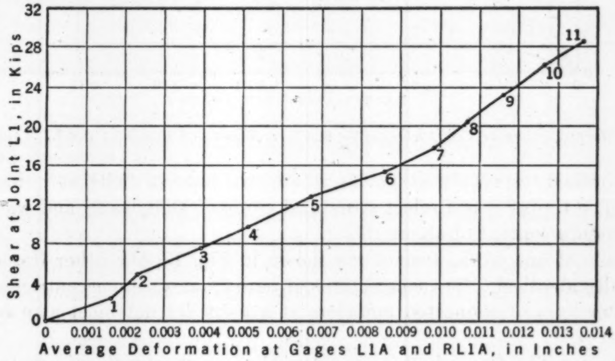

FIG. 11.—SLIP OF BUTT BLOCKS WITH RESPECT TO THE CHORD AT GAGE A

Brazil Building (B) *Trusses.*—Two shallow trusses (perhaps, more accurately, two trussed frames) about 46.5 ft long and averaging 2 ft 10 in. deep were obtained from the Brazil Building and tested. Originally they formed the vertical legs of a rigid-frame bent. Unfortunately, the building had been dismantled carelessly; and, although the two frames, when carefully examined, appeared to be in good condition, the possibility exists that they had been damaged. No evidence of such damage, however, was disclosed by the tests.

The chords of the frames were formed of three 12-in. planks each, with the web members of two 3-in. by 6-in. timbers, connected to the chords by split rings and bolts. The outside 2-in. by 12-in. planks of the chords were quite badly checked, especially at points where two lines of bolts and rings were used. The timber was a select structural grade of Douglas fir and was tested at a moisture content of about 15%.

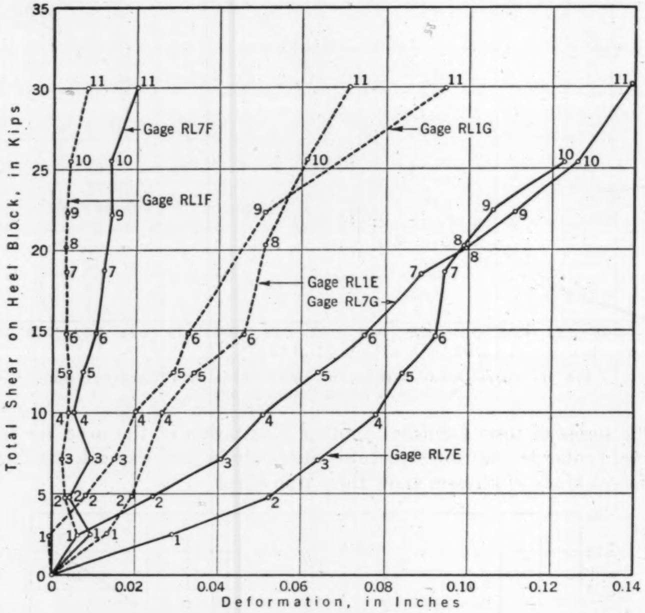

FIG. 12.—DEFORMATIONS AT VARIOUS GAGES ON THE BUTT BLOCKS OF JOINTS L1 AND L7, TRUSS TAC-3

Details of one of the frames are shown in Fig. 13, the other frame being practically identical. The connections of both frames were eccentric—that is, the center lines of connected members at a joint did not meet at a common point.

Testing.—The frame had its loads applied as shown diagrammatically in Fig. 13, in which the points of application of the loads were changed during the test. Deflections and joint deformations were measured as usual; and, in addition, gages were installed on one chord to measure the relative movement of the center plank with respect to the outside plank.

Trouble was experienced in testing both frames because of the large deformations. The loading jacks had a maximum extension of 6 in. so that considerable loading, unloading, and reblocking were necessary to obtain failure of the frames. Thus, testing of frame TB–1 consumed 3 hours, and testing of frame TB–2 required 1 hour and 10 min.

In the test frame TB–1 the first failure occurred at joint U1 and almost simultaneously at joint L10, in tension perpendicular to the grain. About the same time, failure occurred in the lower chord splices. Upon dismantling the truss, it was found that the split rings were missing in one each of the vertical web members of joints L7, L8, and L9, although grooves for the rings had been provided. As failure did not occur in these web members, these conditions apparently did not affect the load capacity of the frame.

In frame TB–2, the tension splices of the lower chord started to open at small loads. When a load of 17.2 kips on the frame had been reached, the center 3-in. by 12-in. plank of the lower chord broke near joint L5 (see Fig. 14). The increase of the load to 23.5 kips sheared the wood in the end distances in the lower chord splices as shown in Fig. 13.

Results of these tests are summarized in Table 2 and deflections for frame TB–1 for five loadings are shown in Fig. 13. Fig. 15 indicates the center deflection for the same frame.

[a] Ratio of span. [b] Load on a splice at failure, computed by the ordinary truss theory. [c] The ratio of R_{ca} for the connection of members U1–L2 and U9–L10. [d] In frame TB–2 the center stick (3 in. by 12 in.) broke in bending at a load, on the frame, of 17.2 kips. The splices failed completely when the load on the frame was increased to 23.5 kips.

Fig. 16 shows the relative movements of the three parts of the lower chord under load. The location of the gages for these points is shown in Fig. 13.

Results of Tests, Trusses TB.—The action of these frames under load is complicated and analysis of test results, therefore, is difficult. Neglecting the bending effects of the chords and using direct stresses as computed by the usual truss theory, the values of R_{ca} calculated for the splices are 2.95 and 2.48. If the bending moments in the two chords, due to deformation of the truss as a whole, are considered, these ratios would be changed.

The importance of stresses due to deflection in shallow trusses, frames, or girders is illustrated in the failure of frame TB–2 in which the through, 3-in. by 12-in. stick of the chord member broke in bending, mainly as the result of

test as well as in other tests of this program, in which the members of a joint were connected eccentrically. The nature of the failures emphasizes the importance of the consideration of secondary stresses in main members, splices, and connections in shallow trusses which may be expected to show relatively large deflections and deformations at working loads.

Cavalcade (C) *Cantilever Truss.*—Opportunity was afforded to test, in place, one of two cantilever trusses of the timber framework that had supported a canvas roof of the Cavalcade (see Fig. 17). The structure had been in service, exposed to the elements, for about 2 years prior to testing, and appeared to be in unusually good condition. The framing lumber was Douglas fir, appraised as "select structural" grade.

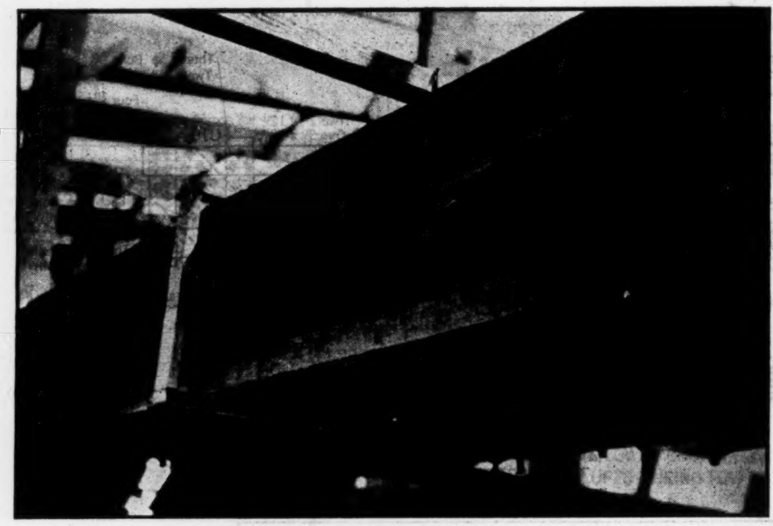

FIG. 14.—FAILURE OF TRUSS TB-2 UNDER A LOAD OF 17.2 KIPS

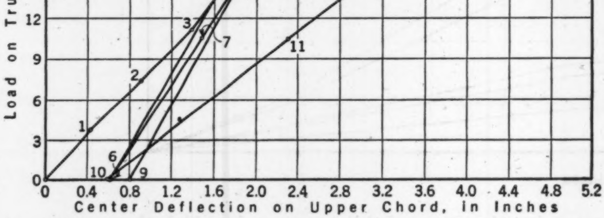

FIG. 15.—DEFLECTION OF THE CENTER OF THE UPPER CHORD, FRAME TB-1

Important joints in the framing were bolted or joined by connectors, the latter involving flush-type shear plates (Fig. 18) with steel gusset plates and split rings. Unless otherwise indicated, all bolts in Fig. 18 were $\frac{3}{4}$ in. in diameter. All bolts, including those at split-ring connectors were provided with 3-in. by 3-in. by $\frac{3}{16}$-in. washers. No bolts were tightened or

frames repaired prior to the application of test load. The gusset plate at joint 6S, Fig. 18, shows the typical minimum dimensions for such plates.

Testing.—Loads were applied by filling water tanks suspended by rope slings. These were fastened about 33 ft from the base of the cantilever. The calibrated tanks were set on temporary jack supports to permit controlled application of load. A preliminary load was applied to one of the pair of cantilever frames, to check the workability and safety of the loading apparatus, by slowly releasing the supporting jacks. Shortly after load transfer occurred, the anchor arm of the crown joint (8S in Fig. 18) failed by the shearing out of shear plate connectors and bolts, as shown in Fig. 19.

(b) DETAIL A

(c) ROOF FRAMING PLAN

Fig. 18.—Details of Cantilever Frame TC-1

The calculated load in the failed member was 64,800 lb although, as shown on later examination of the joint, a lesser load may have caused the progressive failure that occurred. The deflection observed at the end of cantilever at time of failure was about 8 in.

Results of Tests, Trusses TC.–Joint 8S (Fig. 18) in which failure occurred consisted of three 8-in. by 8-in. timber members connected by $\frac{1}{4}$-in. steel plates drilled with $\frac{13}{16}$-in.-diameter holes and three pairs of shear plates, 4 in. in diameter, fitted with $\frac{3}{4}$-in. bolts.

Although the character of the failure was typical—that is, a shearing out of wood and pulling through of bolts causing splitting of the members—failure occurred at less than the anticipated total load. An examination of the joint after test indicated that the center pair of three pairs of shear plates, 4 in. in diameter, had holes $\frac{15}{16}$ in. in diameter. The other two pairs had $\frac{13}{16}$-in.-diameter holes, although all were fitted with $\frac{3}{4}$-in. bolts. The bolt holes in member A (which were bored halfway through the timber from each side) were found to be offset between opposite faces of the timber about $\frac{1}{16}$ in. Excessive loading of connectors and bolts was evident in member A by the $\frac{1}{16}$-in. indentations in the bolts at the contact points between shear plates and steel gusset plates, and by the distortion of bolt holes in connectors and gusset plates, which indicated that the ultimate shearing capacity of each bolt had been approached. These observations indicated that the connectors were loaded progressively, probably not more than two connectors being loaded at one time.

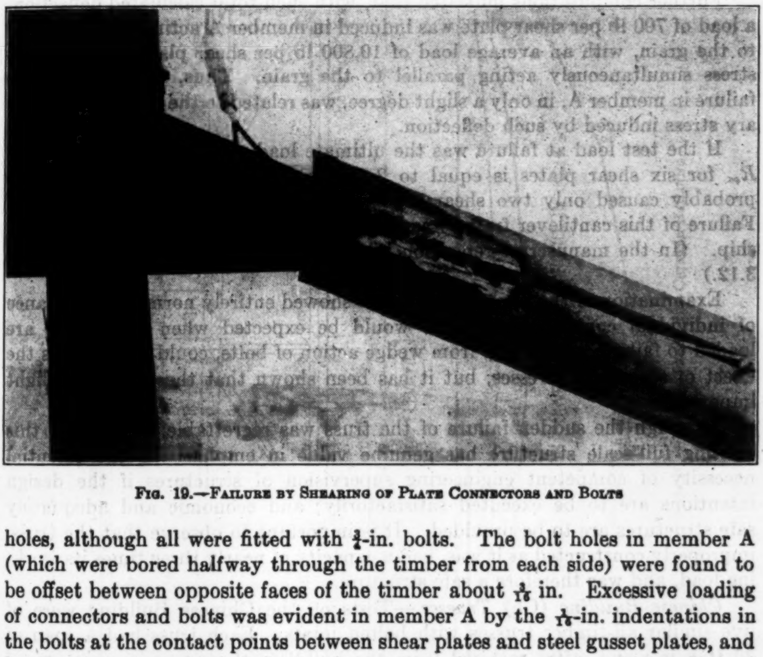

FIG. 19.—FAILURE BY SHEARING OF PLATE CONNECTORS AND BOLTS

Although the fabrication of members B and C (Fig. 18) was found to be essentially correct, the three shear plates on one side of compression member C were found to have $\frac{15}{16}$-in.-diameter holes instead of the required $\frac{13}{16}$-in.-diameter holes for $\frac{3}{4}$-in. bolts. No evidence of distress was found in tension member B or in compression member C.

On the basis of the foregoing estimated failure load, the computed tension in member A was 64,800 lb, or a load of 10,800 lb per shear plate; and an approximate deflection at the end of the cantilever of about 8 in. was observed at time of failure. The possible influence of secondary stresses due to cantilever deflection, using the foregoing load, was investigated. The computed deflections were:

Cause	Deflection (in.)
Elongation of members	3.17
Slip of joint fasteners	3.31
Total	6.48

Further computations indicated that, with such total calculated deflection, a load of 700 lb per shear plate was induced in member A acting perpendicular to the grain, with an average load of 10,800 lb per shear plate due to direct stress simultaneously acting parallel to the grain. Thus, it appeared that failure in member A, in only a slight degree, was related to the action of secondary stress induced by such deflection.

If the test load at failure was the ultimate load of the truss, the value of R_{ca} for six shear plates is equal to 2.81, although the faulty construction probably caused only two shear plates to act effectively at any one time. Failure of this cantilever frame was obviously the result of careless workmanship. (In the manuscript report on joint tests, R_{ca} for joint J11 is given as 3.12.)

Examination of the joint after the test showed entirely normal performance of individual connectors, such as would be expected when connectors are loaded to failure. Splitting, from wedge action of bolts, could be taken as the effect of secondary stresses, but it has been shown that these were of slight importance.

Although the sudden failure of the truss was regrettable, the test of this existing full-scale structure has genuine value in emphasizing the essential necessity of competent engineering supervision of structures if the design intentions are to be executed satisfactorily; and economic and adequately safe structures are to be provided. It is important to observe that the truss, improperly constructed as it was, had a capacity of nearly three times its working load, and was therefore a safe structure.

Chinese Building (Ch) *Trusses.*—Tests on the Chinese Building were of five similar all-timber trusses with bolted joints. Each truss had a span of 36 ft 8 in.; and, after removal from the building, these trusses were stored outside for about 4 months before testing. When tested, their moisture content was about 12%.

Fig. 20 shows a detail of one of the trusses. All truss members were single sticks, of 2-in. dimension stock, No. 1 common Douglas fir. The compression diagonals were framed on one side of the chords and the tension verticals on the opposite side. This detail was later found to be an important factor in the behavior of the trusses under test loads. Single bolts, with cut-steel washers under heads and nuts, were used in all joints except the four end joints. Bolts were found to be reasonably tight at the time of testing; they were not tightened. Although there were a number of knots, none seemingly reduced

the strength of the truss. Members were relatively free of checks except verticals U1–L2 and U5–L6, in which 1⅛-in. bolts had end distances of only 3¾ in.—and checking had started in several instances.

Testing.—The trusses were tested with concentrated loads while supported by hangers from the laboratory roof, as shown subsequently in Table 9. In the building from which the trusses were taken, the roof sheathing had been nailed directly to the top chords, thus giving them lateral support. In the tests short pieces of 2-in. by 8-in. timber were nailed to these chords to form T-sections between hangers, thus providing equivalent lateral support. As usual, deflection readings, as well as deformation measurements, were made at various points.

The peculiar framing of compression diagonals and tension verticals, previously noted, resulted in a twisting of the chords, and a bowing of the web members, under test loads, as shown in Fig. 21*A*. The amounts were measured by gages. It is judged that the method of supporting the chords during testing gave about the same resistance to this twisting and bowing as in the original structure.

Trusses TCh–1 and TCh–3 failed in the lower chord splices, each of which had four ⅝-in. bolts and a few nails. Consequently, the remaining trusses, TCh–2, TCh–4, and TCh–5 were reinforced at this splice, so that failure would occur elsewhere. Truss TCh–2 failed by combined bending and direct stress in the tension vertical U1–L2, as shown in Fig. 21*B*.

Trusses TCh–4 and TCh–5 failed by the shearing out of the wood in the end distances in verticals U1–L2, and by the splitting of the chords. In truss TCh–5, the nut had been omitted from the 1-in. bolt connecting the three members at joint U1. This truss proved to be the strongest of all five, possibly because of the lack of a nut resulted in a reduction of bending moment in member U1–L2, which, with the exception of the lower chord splices, was the weakest factor in all trusses. The omission of the nut threw a larger part of the moment to the end diagonal, and this member, a 2-in. by 10-in. stick, was amply strong.

Results of Tests, Trusses TCh.—The results of the tests are given in Table 3. Fig. 20 shows typical deformation curves for the lower chord for three separate systems of loads on the truss. Fig. 22 shows a typical center deflection curve of the lower chord as plotted against the total truss load. Fig. 23 shows another load deflection curve, for the condition in which one of the trusses was loaded to about 90% of its ultimate capacity (reading No. 11); the load was then released, measurements taken, and the load reapplied. In the test, a permanent set of 1/330 of the span was noted, when the loads were released.

The failure of truss TCh–2 merits explanation. The eccentric connections which twisted the chords subjected the web members to bending moments resisting this twist. In the vertical U1–L2, the calculated stress in the 2-in. by 4-in. vertical, at the bolt where failure occurred, was 1,030 lb per sq in. in tension, and 8,400 lb per sq in. in bending—a total of 9,430 lb per sq in., representing an R_{ws}-value of 5.9 based on 1,600 lb per sq in. of allowable combined stress. The amount of twist in the chords is shown graphically in

Fig. 24. As mentioned previously, this vertical U1–L2 had very short end distances for the size of its connection. In all the trusses, splits occurred in these end distances at loads below the ultimate capacity of the truss; nevertheless, the splits did not directly cause failure of the trusses. If the allowable load in the verticals is taken as the sum of allowable loads on the bolts (2,200

[d] Ends of members U1–L2 and U5–L6, that were not checked, split at stresses, in the members, equal to from $F=2{,}100$ lb to $F=3{,}600$ lb. [e] Nut omitted at U1. [f] Using a value of 90 lb for each assisting 16-penny nail. [g] Did not fail in splice because it was reinforced. [h] At the point where member U1–L2 broke in bending. [i] Based on an allowable load of 1,600 lb per sq in. in bending. [j] Allowable loads on member U1–L2 as governed by bolts, based on their values in the 2-in. by 4-in. stick, parallel to the grain, and without reducing for the short end distance, are 2,200 lb at joint L2 and 1,960 lb at joint U1. To allow for short end distances these values are reduced 50% to 1,100 lb and 980 lb, respectively. Allowable loads on U1–L2 as governed by the bolts, based on their values in the chord, across the grain, are 715 lb at joint L2 and 653 lb at joint U1. [k] In member U1–L2 not in chord.

lb at L2 and 1,960 lb at U1) as given in footnote[j], Table 3, it is seen that these splits occurred early in the progress of the tests. They evidence the effect of short end distances for bolts.

No tests appear to have been made on the complicated action of the bolts as found in these joints; hence, the question arises as to the allowable bolt values for such details. In Table 3, the ratios for the joints L2 and U1 (see Col. 14, Table 3) are based on the perpendicular to the grain value of bolts as given in Col. 9. Table 3 neglects the action of the diagonal on the far side. From this point of view, the ratios would seem ample. On the other hand, the failures in trusses TCh-2, TCh-4, and TCh-5 were in this vertical itself

(U1–L2) where the controlling value would be the parallel to grain value of the bolts, without reducing for short end distance (see footnote[f], Table 3).

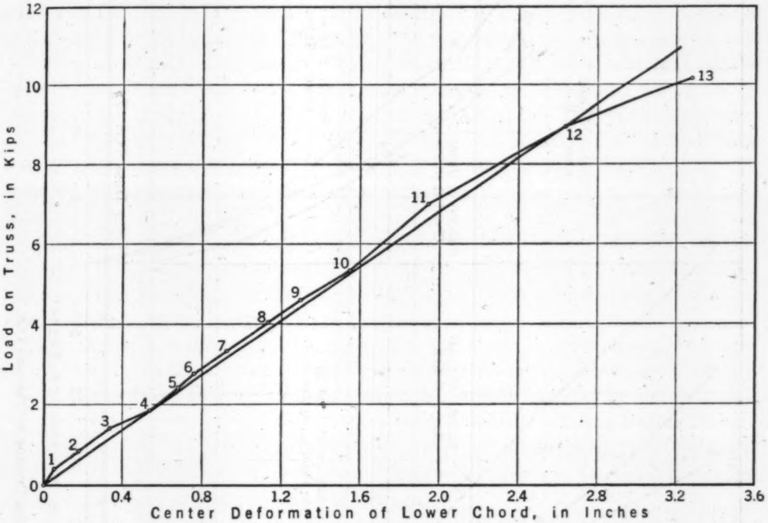

FIG. 22.—LOAD-DEFLECTION CURVE FOR TRUSSES TCH

FIG. 23.—LOAD-DEFLECTION CURVE FOR TRUSS TCH-3

Based on these values (a procedure which seems more nearly correct), the ratios R are lower.

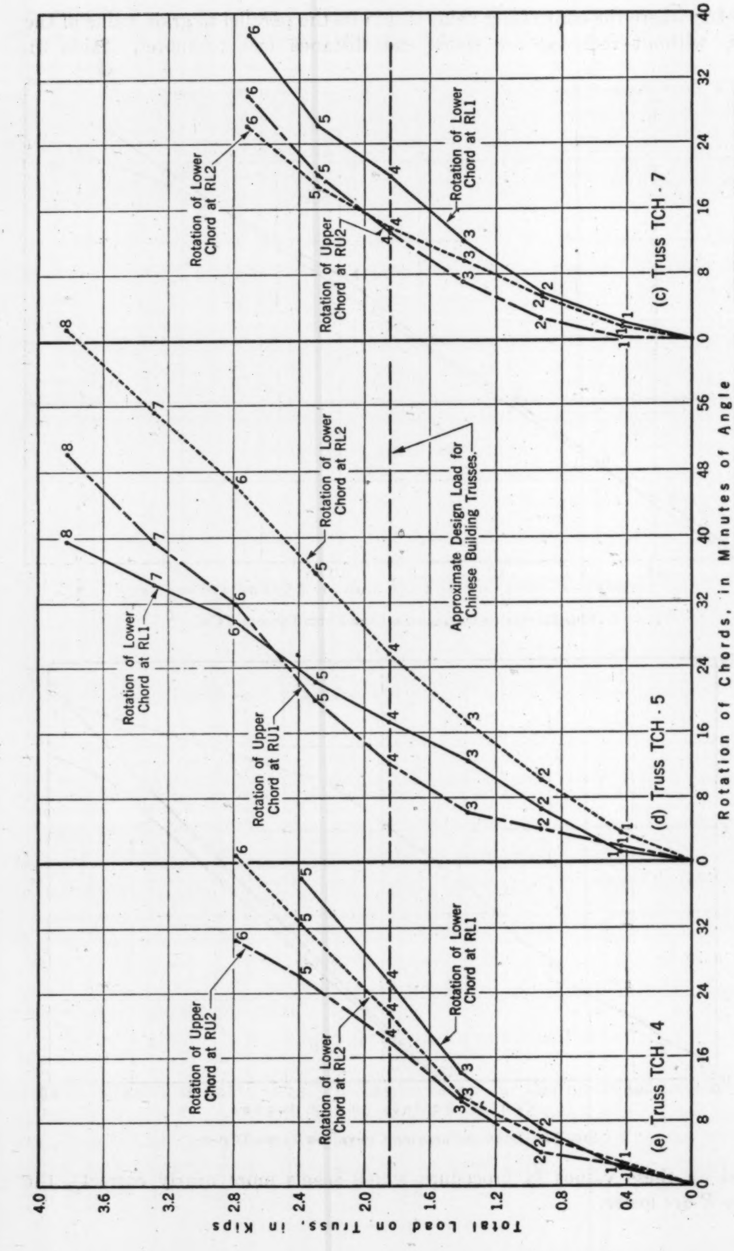

FIG. 24.—MEASURED ROTATION OF THE CHORDS OF TRUSSES TCH

In trusses TCh-4 and TCh-5, the chords developed long splits at failure—probably another result of the twisting of the bolts. These trusses were adequate for the functions they served, although the manner of failure was unexpected and not in accordance with results that might have been expected from usual or conventional investigatory computations. A change in the proportions of members would have affected the distribution and magnitude of stresses. Increasing the thickness of chords, for example, would have increased the bending moments in verticals and diagonals and would also have affected the connections. An analysis of additional stresses in truss members and their connections caused by sizes and arrangement of members would seem to be justified when such factors influence the carrying capacity of the truss.

Apparently, the use of cut washers did not decrease the strength of the trusses. When bolts are subjected to shear only, or when the washers become loose through shrinkage of the wood, the size of the washers appears to have little influence upon the strength of the connection.

The strength values of bolts subjected to twisting, or bolts passing through members subject to twisting should be investigated further; likewise, any tendencies of the bolts to split the members they connect should be determined. This subject is probably related to the strength of bolts passing through loose fillers—a subject on which authoritative data are much needed. The tests indicate the importance of proper end distances; they are important factors in the strength of the connections of a truss.

French Building (F) *Truss.*—This truss, spanning 37 ft, was built of wooden members connected eccentrically at the joints with split rings and bolts as shown in Fig. 25. All web members were diagonals, of two 2⅝-in. by 7½-in. sticks each, and each diagonal was connected at each end to the single stick, 4-in. by 10-in. chords with one pair of split rings with ¾-in. bolts.

While dismantling the building, web members U1–L2 and L5–U5 were damaged, and these members were replaced. Otherwise, no repairs were made. Careful examination of the truss disclosed no other damage than that noted. Wood was of dense select structural grade, Douglas fir, and had a moisture content of 12% at the time of testing.

The truss was tested in the usual manner, loads being applied as shown diagrammatically in Fig. 25, producing approximately equal loads at the panel points. Truss deflections of the chords and joint deformations were measured in the usual manner.

After 1 hour and 13 min of testing, with a total load of 15.00 kips on the truss, the joint at L5 cracked audibly and the load dropped to about 5.0 kips. It was observed that cracks about ¼ in. wide had developed on the wide faces of the chord, these cracks appearing to be similar to the failures of the North Square Court Truss (TNS), described as tension perpendicular to the grain. Loads were then almost completely released, and four ½-in. stitch bolts with large plate washers were installed in the chord at joint L5, and tightened. Similarly, four stitch bolts were installed at joint L2, but these were left untightened so that they would not interfere with further testing. Loads were then reapplied; and, 1 hour and 14 min later, a large split developed at

FIG. 25.—TYPICAL TRUSS, THE FRENCH BUILDING

joint L2 when the truss was loaded with 27.1 kips. This failure, shown in Fig. 26, was apparently also caused from tension perpendicular to the grain. The photograph reveals that the split is widest at the center line of the joint, tapering off to nothing farther from the joint. After this failure the loads were released and the stitch bolts at joint L2 were tightened. Loads were reapplied, when, at a maximum load of 31.2 kips, joint L2 failed again along the original split. In this second failure, because the chord member was held tight together at the joint by stitch bolts, the split grew wider as it went farther from the joint. The widening of these splits was apparently caused by the large bending stresses induced through the eccentric connection which tended to rotate the chord. Immediately after failure, the truss was sustaining a load of 21.7 kips, which was allowed to remain overnight. The following morning this load had dropped to 18.5 kips.

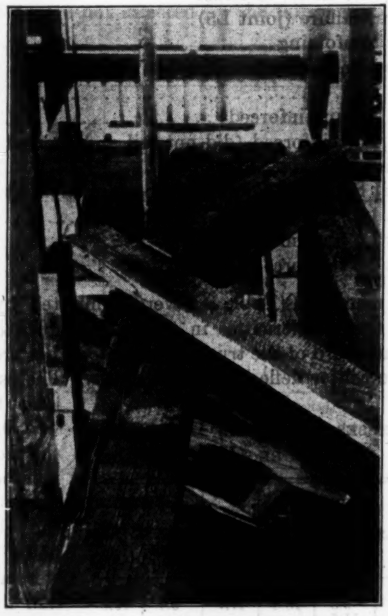

FIG. 26.—FAILURE OF TRUSS TF AT JOINT L2, BEFORE TIGHTENING THE STITCH BOLTS

Results of Tests, Truss TF.—The results of these tests can be summarized as follows:

Item	Description	Quantity
	Deflection of Truss at an Allowable Load of 9.8 Kips (Total Load Based on Dense Select Structural Grade):	
1	In inches	0.60

Item	Description	Quantity
2	Percentage of span	1/720
	Maximum Recorded Deflection (Truss Load, 25.3 Kips):	
3	In inches	1.62
4	Percentage of span	1/270
	Maximum Truss Load, in Kips:	
5	At first failure (joint L5)	15.0
6	After reinforcing	31.2
	Ratio R_{ca} as Limited by the Strength of:	
7	Joint L2	3.2
8	Joint L5 unreinforced	1.5
9	Joint L5 reinforced (did not fail and showed no sign of distress)	3.1
	Average Unit Shear, in Pounds per Square Inch, at Failure in:	
10	Joint L2	450
11	Joint L5 unreinforced	214
12	Joint L5 reinforced (did not fail)	450

Stresses in the members (Table 4) were computed by an approximate method that takes the eccentricities in the joints into account. Deflection curves for the bottom chord of the truss for three loadings are shown in Fig. 25. Fig. 27 indicates the center deflection of the truss. The estimated allowable load W_{ca} on the truss was 9.8 kips, based on the connections of the members that failed.

TABLE 4.—STRESSES FOR AXIAL LOADS IN MEMBERS AT FAILURE (KIPS)

Description	U1–L2	U5–L5		U2–L2	U4–L5	
		Unreinforced	Reinforced[a]		Unreinforced	Reinforced[a]
Stress	36.7	17.1	36.7	28.7	15.0	31.3
Vertical component	18.5	9.0	18.8	17.7	9.4	19.6
Stress, s_{ca}	11.5	11.5	....	....	....	....

[a] The reinforced joints did not fail.

Prior to reinforcing the chords with stitch bolts, the ultimate loads were about one and one-half times the estimated allowable load, giving a ratio R_{ca} of 1.7. After the stitch bolts had been provided, the capacity of the truss was approximately doubled, with $R_{ca} = 3.1$, indicating that the stitch bolts would be of considerable value if they could be kept tight. The nature of the failures of this truss emphasizes again that the stress of tension perpendicular to the grain is likely to be the determining factor in the strength of joints in which the members are eccentrically connected. If such connections are to be used, the probable amount of this stress should be determined so that the limiting capacity of the connections will be known.

Merry-Go-Round Building (M) *Trusses.*—Two all-timber trusses (TM–1 and TM–2) of similar design, spanning 54 ft 1 in. and 51 ft 4½ in., and using the double Warren type of framing, were obtained from the Merry-Go-Round Building and tested to failure. Top and bottom chords were approximately parallel, 6 ft 8 in. apart at the center, and all members were connected concentrically using split rings and ¾-in. bolts. Trusses and columns were connected to form rigid-frame bents for resistance to lateral forces. Details of the trusses are shown in Figs. 28 and 29. In dismantling the building, the trusses were pulled over and fell on the ground, injuring several of their members. Repairs, consisting of the addition of stitch bolts and pads, were made to truss TM-1, as noted in Fig. 28, and to one diagonal and at one reaction point of truss TM-2, as shown in Fig. 29. As a result of the repairing, it is believed that the test results were not affected by the fall of the trusses.

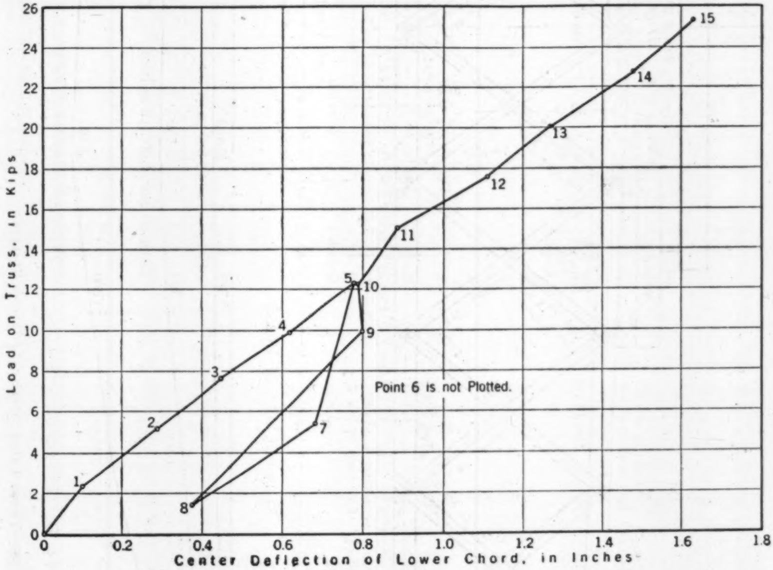

FIG. 27.—CENTER DEFLECTION ON LOWER CHORD, TRUSS TF-3

Timbers were of select structural grade Douglas fir and when tested had a moisture content of about 15%.

Testing.—Loads were applied as shown in Fig. 28. The testing span of TM-1 was 54 ft 1 in., whereas that of truss TM-2, on account of the repairs at the left end, was 51 ft 4½ in. Gages were installed at the top and bottom chords to measure truss deflections, and dial gages were located to measure local joint deformations.

The chords of each half of the trusses were subject to equal and opposite twisting moments. Gages to measure this twisting were installed in locations as shown in Fig. 28.

Truss TM-1 was loaded with 54.2 kips over a period of about 6 hours, when the load was released. Upon reloading to 51.60 kips, failure occurred in the lower chord splice. The splice was then repaired; and, after 21 hours, the truss was reloaded to 72.90 kips, when a check and a bow had developed in the top chord at joint U7. At a load of 81.70 kips a large split appeared in the bottom chord at joint L2 (Fig. 30) and almost simultaneously at joint U2.

FIG. 29.—DETAILS OF LEFT END OF TRUSS TM-2 (REMAINDER OF THIS TRUSS THE SAME AS TM-1, FIG. 28)

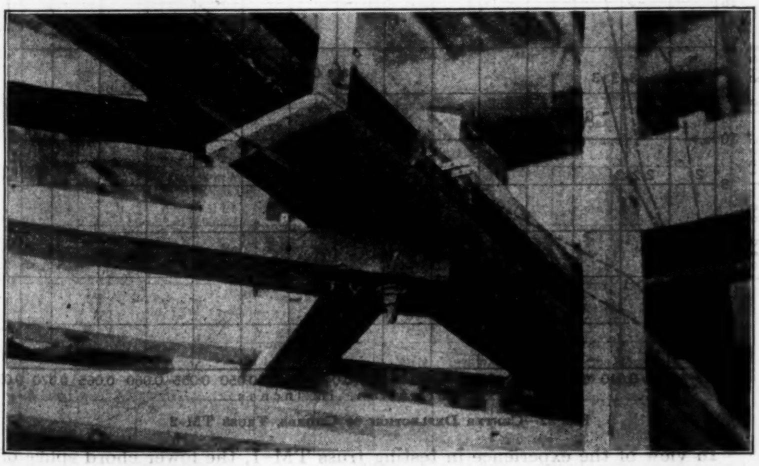

FIG. 30.—FAILURE OF BOTTOM CHORD, TRUSS TM-1, AT JOINT L2

After releasing the load, a total of 83.30 kips was then applied, when these splits became larger and a new failure occurred at joint L2 (see Fig. 31). The diagonal member U5–L4 split and rotated as shown, and failures at other joints then followed in rapid order.

Fig. 31.—Rotating and Splitting of Diagonal Member at the Failure of Truss TM-1

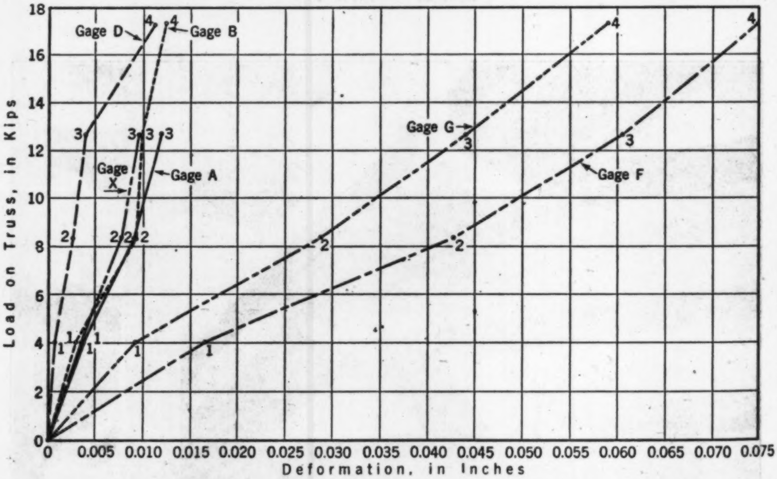

Fig. 32—Center Deflection of Chords, Truss TM-2

In view of the experience in testing truss TM–1, the lower chord splice of truss TM–2 was reinforced before testing. When the load had reached 83.30 kips, a crack about 24 in. long opened on one side of the lower chord of joint

L2, and failure occurred at a maximum load of 88.20 kips. The load then dropped to 80.70 kips—which load was allowed to remain on the truss overnight. On the following morning, the truss still carried 62.10 kips.

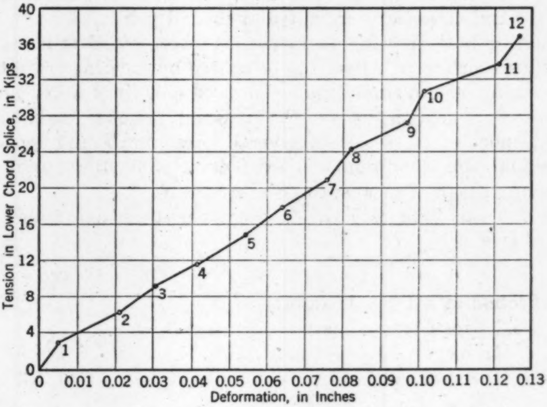

FIG. 33.—DEFORMATION AT THE LOWER CHORD SPLICE, TRUSS TM-1

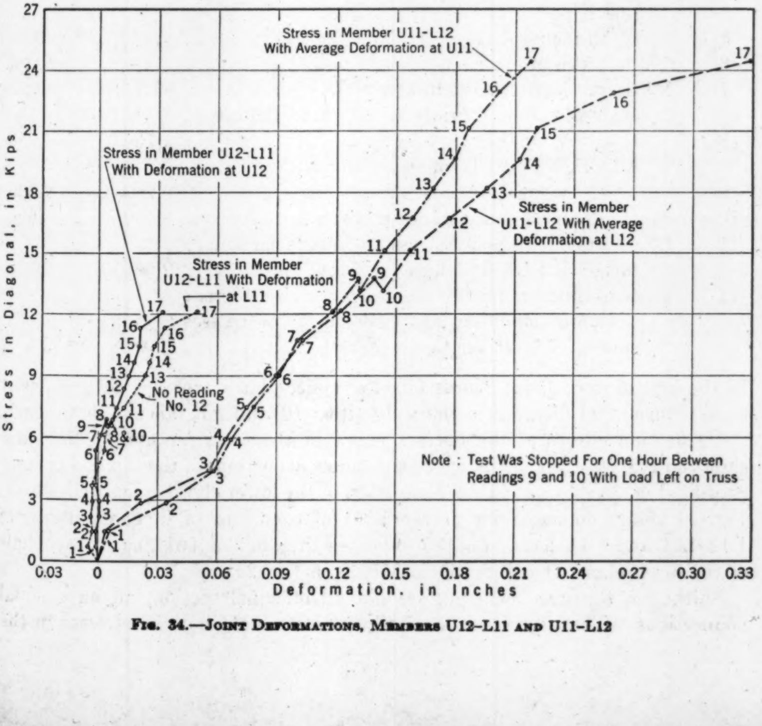

FIG. 34.—JOINT DEFORMATIONS, MEMBERS U12-L11 AND U11-L12

Failures in this truss were quite similar to those in truss TM–1—that is, by a lengthwise splitting of the chords. This truss also showed distress simultaneously at various points before the maximum loads were reached. Like truss TM–1, the top chord bowed and split at joint U7. In addition, shear failures in the end distances were noted at several points.

When testing both trusses, cracking noises were heard at loads of from 30 kips to 40 kips which were believed to be caused by shearing of split-ring cores. Upon disassembly of the trusses, some cores of split rings were found sheared. Most of these were near the ends of the trusses in the chord members. At the lower chord splice of truss TM–1, several cores were found broken off with indications that this condition had existed for some time prior to testing; possibly having occurred in wrecking the structure.

Results of Tests, Trusses TM.—The significant test data to be recorded for these trusses are:

Item	Description	TM–1	TM–2
	Deflection at a Truss Load of:		
	25.3 Kips (Approximate Design Load)—		
1	In inches	1.1	0.99
2	Ratio of span	1/567	1/630
	81.7 Kips—		
3	In inches	3.6	....
4	Ratio of span	1/173	....
	88.2 Kips—		
5	In inches	....	3.0
6	Ratio of span	....	1/187
7	Maximum load in truss in kips	83.3	88.2
	Allowable Load on Critical Members, in Pounds:		
8	Diagonal U5–L4	4,750	4,750
	All Other End Diagonals, Based on—		
9	49° value in chords	9,200	9,200
10	Reduced end distance in webs	8,600	8,600
11	Chord unit compressive stress, in pounds per square inch, joint U7, at failure	2,530	2,320
12	Ratio of ultimate load to the designer's requirement that roof loads be 30 lb per sq ft for trusses spaced 17.75 ft, center to center	3.3	3.5

In the case of item 9, the chords failed at splice plates, whereas designs based on a reduced end distance in the webs (item 10) did not fail in this manner.

Deflection curves of the bottom chord of the truss for five loadings are shown in Fig. 29. Fig. 32 indicates the center deflections of the top and bottom chord. Fig. 33 shows the total elongation of the lower chord splice under load. Fig. 34 shows deformations at the joint of each end of diagonal members U12–L11 and U11–L12. Fig. 35 indicates the angular twisting of each half of the lower chord at points M1 to M5, as in Fig. 29.

Although the web members are not all of equal section, all have equal connections. The trusses are statically indeterminate but the stresses in the web members were calculated on the assumption that each web system took 50% of the shears.

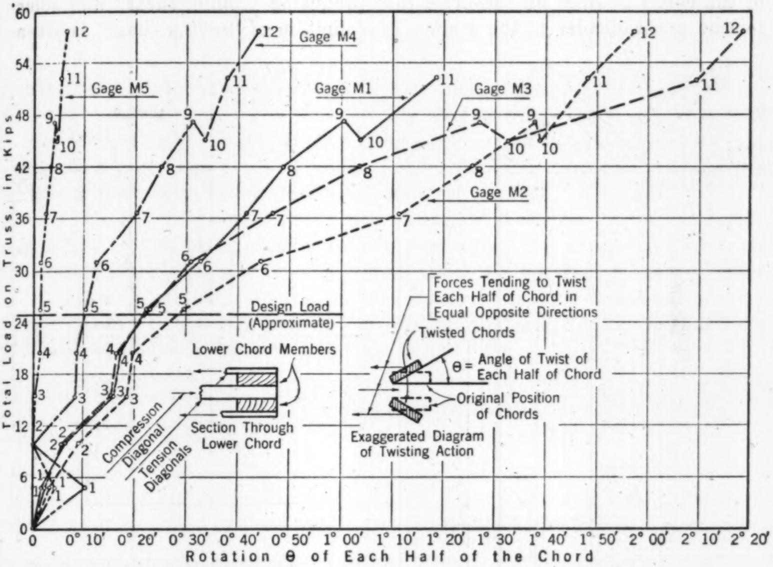

FIG. 35.—ANGULAR TWISTING OF EACH HALF OF THE LOWER CHORD, TRUSS TM-2 (SEE FIG. 29)

In truss TM-1 the first failure occurred in the lower chord splice—possibly the result of damage during wrecking. Therefore, no recommendations or conclusions are presented relative to this failure.

TABLE 5.—RATIOS R_{ca} BASED ON THE WORKING CAPACITY OF TIMBER CONNECTORS

Member	Stress,[a] F (kips)	RATIO R_{ca}	
		Chords[b]	Web[c]
Truss TM-1:			
U1-L2	27.95	3.05	3.25
U2-L1	28.48	3.09	3.30
U3-L4	12.00	2.53	2.53
U5-L4	12.00	2.53	2.53
Truss TM-2:			
I0-L2	31.00	3.38	3.60

[a] Stresses in diagonals at failure of truss. [b] Ratios based on connector values in chords. [c] Ratios based on connector values in the web. The truss did not fail in this manner because the wood in the end distances did not shear out.

The top chord compression splice at joint U7 showed signs of distress because of uneven bearing on the bevel cuts which caused both splitting and bowing of the members. This bow was accentuated because of shrinkage and also because, in the test, the center panel point was unloaded.

The ratios (R_{ca}) given in Table 5 were based on the working capacity of timber connectors P_e although failure of the trusses came about through twisting and consequent splitting of the chords, and was not due to the connectors.

Fig. 36 illustrates one conception of theoretical forces acting on a typical joint. The vertical components of the stresses on diagonal members are

assumed to create bending moments and shears perpendicular to the grain of the chord members. In addition, loads are transferred from rings on one face of the chord to rings on the other face producing "rolling shear" and some tension perpendicular to the grain. (A definition of "rolling shear" is given

(*b*) SECTION A-A

(*c*) ENLARGED VIEW OF ONE 3" x 8" OF CHORDS SHOWING ASSUMED THEORETICAL FORCES

FIG. 36.—THEORETICAL FORCES ACTING ON A TYPICAL JOINT

Note A.—A twisting moment $X e_1$ on each 3-in. by 8-in. stick must be resisted, as shown in the enlarged view.
Note B.—Force F_y, the part of the ring load not carried by the core, induces direct tension across the grain on planes a and b and on all points between.
Note C.—Force F_c produces rolling shear on plane c and planes parallel to it.
Note D.—Force X produces rolling shear on this line—any point between wide faces.
Note E.—On this line a bending moment of $\frac{1}{2}F_c e_2$ induces tension and compression stresses across the grain.
Note F.—This depth of wood, plus that of the opposite ring (or rings), is not working to resist rolling shear, tension across the grain, direct stresses from F_y, nor bending stresses across the grain from the moment $\frac{1}{2}F_c e_2$.
Note G.—Restraining compressive forces F_c induced by the moment $X e_1$ (see Note A).
Note H.—Force F_c resisted by bolt tension to the opposite half of the joint.

subsequently under the heading, "Part II. Joint Tests: Compression or Tension Splice Joints with Plywood Splice Plates and Split Rings." The complexity of the problem makes it pertinent to cite a statement by John A. Scholten, as follows:[3]

> **"Considerable progress has been made in the theoretical stress analysis of connector joints and in correlating the results with basic data on the mechanical properties of the wood and metal. The fact remains, however, that the stress distribution is so complicated, and the assumptions involved are so often invalid, that actual tests must be relied on to provide the necessary design data."**

---

[3] "Timber-Connector Joints: Their Strength and Design," by John A. Scholten, *Technical Bulletin No. 865*, Forest Products Laboratory, Forest Service, U.S.D.A., Madison, Wis., March, 1944, p. 14.

In thin members, such as these chords, grooves of split rings take out a relatively large area of the chord section, thereby reducing resistance of the chords to stresses caused by the forces shown in Fig. 36.

The tests show that the present methods of design analysis usually employed in trusses of this type (using connector values but neglecting the stress effect on the connected members) may not, and probably will not, reveal the critical stress factors. For example, Fig. 36 illustrates the many forces that may be acting in an apparently simple connection. Because of the wide application of these types of joints, further full-sized tests and study should be continued in an endeavor to establish a rational basis of design.

North Square Court (NS) *Truss.*—Perhaps the most important results obtained in this test program were from the test of a truss taken from the North Square Court area. This truss, with all members of wood, about 10.5 ft deep, spanning about 48 ft, had double stick web members connected eccentrically to the 6-in. by 12-in. chords by 4-in. split rings with $\frac{3}{4}$-in. bolts. Details of the truss are shown in Figs. 37 and 38(*b*).

(*a*) JOINT U2 (*b*) JOINT U6 (*c*) JOINT L3

FIG. 37.—TYPICAL JOINTS TNS AND DETAILS OF STITCH BOLTS ADDED DURING TESTS (SEE FIG. 38(*b*))

The workmanship of the truss was excellent, as was evidenced by good fits, indicated by inspection before testing and verified by examination of the disassembled members and their connections after testing. The wood was of structural grade Douglas fir in good condition with the exception of the 6-in. by 12-in. chords. These were of boxed-heart material and had some checks, those in the top chord near joint U6 being about $\frac{1}{4}$ in. wide and extending toward the heart from both faces. For reasons to be explained subsequently, these checks apparently did not affect the test results.

The truss was stored outdoors for about two and one-half months after its removal from the structure and was tested at an average moisture content varying from about 10% to 14%. Because of shrinkage of the timbers, bolts were generally loose from about $\frac{1}{4}$ in. to $\frac{5}{16}$ in.

Testing.—The truss was tested in the typical manner. About one hundred gage points were placed as indicated in Fig. 39 to measure deformations. Loads were applied as shown subsequently in Table 6. Gages LD–1 to LD–11 and UD–1 to UD–13 (see Fig. 39) measured deflections of the truss and indicated bending deformations of the chords caused by eccentric joint connections.

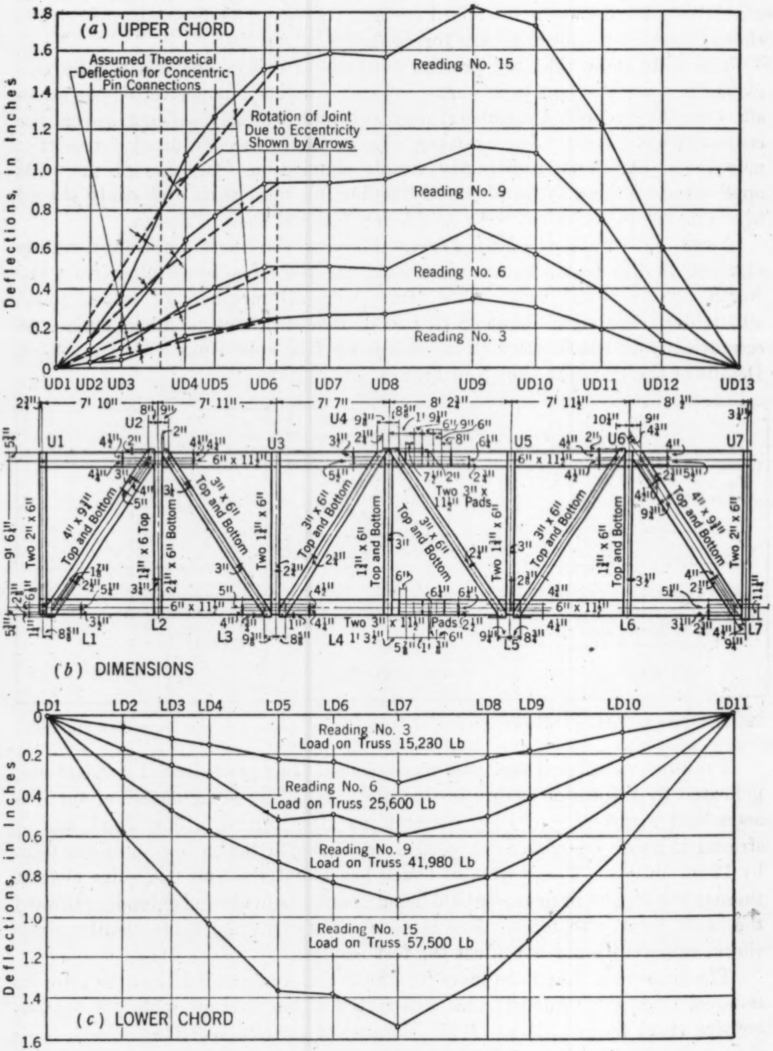

FIG. 38.—LOAD-DEFLECTION CURVES, TRUSS TNS

Angular changes between members as well as slips of connectors were also measured. Additional sets of gages were placed on three of the web members to measure the bending effects caused by direct loads, since these loads were applied at the faces of the members rather than at their centers of gravity.

FIG. 39.—HALF-SECTION, TRUSS TNS, SHOWING LOCATION OF GAGE POINTS

A total load on the truss of 42,000 lb was applied gradually over a period of 8 hours. Loads were then released and testing was resumed about 48 hours later. After reaching a load of 62,600 lb a cracking noise was heard and a split opened in the lower chord at joint L3. This split was ½ in. wide, and was increasing in width as the pressure on the loading jacks decreased. Loads were then released and stitch bolts were installed in the chord at joints L3 and L5 as shown in Fig. 37, although the nuts of the bolts were not tightened until the truss refused to take further load.

When the test was resumed, failure developed again at joint L3 at the same load of 62,600 lb. When it was apparent that the truss would not resist greater loads, the stitch bolts were released and the nuts were tightened. Testing was resumed; and, at a load of 65,020 lb on the truss, joint U2 failed, as shown in Fig. 40 (note the uncovered ring groove on the left-hand diagonal). Further testing after reinforcing the joint with stitch bolts brought about deformation in the top chord, as shown in Fig. 41. After further reinforcing joint U2, the next failure occurred at joint U6 in a similar manner at a load of 67,400 lb. It is important to record that, in spite of existing deep checks at joint U6, splitting followed new lines, although at some points they were only ½ in. apart. Fig. 37(*a*) shows the position of splits in the chords which was typical for all three joint failures. The location of the new splits was seemingly independent of existing checks in all cases.

Results of Tests, Truss TNS.—The results of this test are summarized in Table 6.

[a] After failures shown in table, each individual joint was reinforced to permit further testing and failure at other joints. [b] Not a factor in failure.

The following information concerning deflections was observed:

Item	Description	Quantity
	Deflection at the Allowable Truss Load of 36.5 Kips, Based on an Allowable Stress in Diagonal U2–L3 Corresponding to a Load of 930 Lb per Lin Ft of Truss:	
1	In inches	0.84
2	Ratio of span	1/685
	Maximum Recorded Deflection, at a Truss Load of 57.5 Kips:	
3	In inches	1.56
4	Ratio of span	1/370

Fig. 38 shows the deflections of the bottom and top chords under various loadings. The effect of bending moments in chords, caused by the eccentric connections of the web members, is illustrated by the dotted lines in Fig. 38(*a*). Fig. 42 indicates the center deflections of the bottom chord of the truss at various stages of loading. Fig. 43 gives data on the bowing of the two sticks of diagonal L1–U2, because the loads were applied at their faces instead of at the centers of gravity. This condition occurs quite commonly in timber design, and is generally neglected. As the timbers in such a connection shrink and bolts become loose, the end restraint of the members thus connected becomes less effective with consequent increase in bending stresses. Members composed of two sticks, as were these web members of this truss, would have their load capacity increased at only slight additional expense if their sticks were tied together to form an integral member similar to the "battened" steel column.

Fig. 44 shows the slips of connectors at either end of diagonal member L1–U2. The average slip of a connector (split ring) was about 0.06 in. for a load of 4,000 lb applied at an angle of 50° with the grain of the wood. Fig. 45 shows the deformations at four gage points at joint U2. Using these data, the approximate angular change between the various members may be calculated.

The most important feature of this test was the demonstration that failure in tension perpendicular to the grain in the chord members at the eccentric joints limited ultimate load-carrying capacity. In the history of timber testing, there seems to be no previously published record of this type of failure. It is known that, when designing this truss, shearing and bending stresses created in the chords by the eccentric connections were carefully investigated; yet, in spite of the unusual care exercised in the design and in spite of unusually good workmanship in construction, the truss failed at a R_{wa}-ratio or a R_{ca}-ratio of 1.78—an unexpectedly low value. This weakness would probably not have been developed in tests on small specimens. Again the vital importance of tests on actual trusses is demonstrated.

(a) DIMENSIONS

(b) DEFLECTIONS

FIG. 46.—DEFLECTION OF LOWER CHORD, TRUSS TSF (FOR SECTION DETAILS, SEE FIG. 47)

San Francisco Building (SF) *Truss.*—This test was of an all-timber truss with bolted connections taken from the San Francisco Building. It had a span of 33 ft 4 in. and a depth of 13 ft 10 in., and its chords were substantially parallel. When tested it had a moisture content of about 14%.

The details of this truss are shown in Figs. 46(*a*) and 47. Web members were I-shaped, made of three 2-in. by 6-in. sticks nailed together. The 2-in. by 6-in. webs were butted against the 6-in. by 12-in. chords of the truss, being angle cut in the base of the diagonals, and the flanges were carried over the sides of the chords and bolted through with ⅞-in. round bolts with malleable iron washers. Timbers were of select structural grade Douglas fir, and were in good condition except at joint U1, where the end of one flange of the diagonal U1–L2 had been notched to provide clearance for a roof rafter. This flange had a check which had started at the point of the notch. Shrinkage of the wood had caused all bolts to become loose from about $\frac{1}{16}$ in. to ⅛ in.

Attention is called to the pattern of the bolt arrangement at the end connections of U1–L2 and U4–L3 (see Fig. 46(*a*)). At joint U1, for example, the longitudinal center lines of bolts were staggered by about 1 in. only; and this feature, combined with the notching and checking, proved to be the cause of an early failure of this joint.

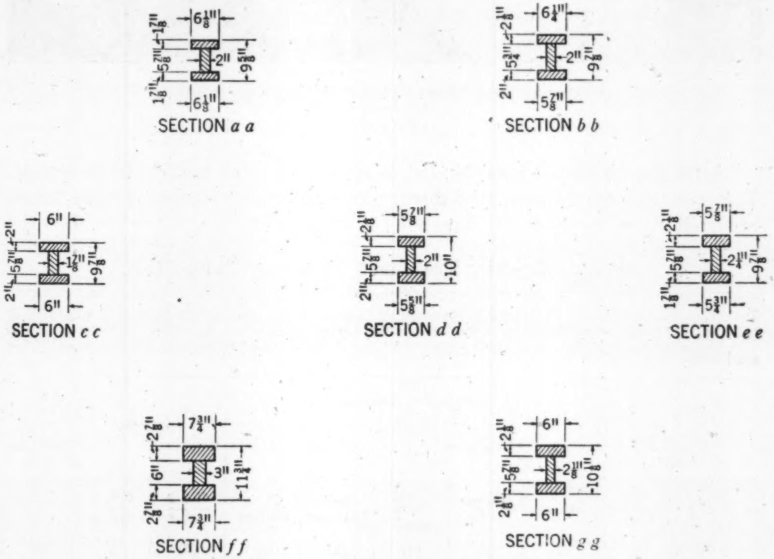

Fig. 47.—Section Dimensions (See Fig. 46(*a*))

Testing.—The truss was installed horizontally in the testing structure, and tested in the usual manner. Testing was started late one afternoon, and loads of 1,840 lb and 1,650 lb were applied to panel points U2 and U3, respectively. Deformations and deflections were measured, loads were released, and the recovery was measured. The next day, the very slight recovery overnight was measured and loads were again applied, The first failure occurred at joint U1 in the notched end of U1–L2, at a total truss load of 18,700 lb. The damaged 2-in. by 6-in. flange of member U1–L2 was removed (see Fig. 48(*a*)). The block had sheared out by the bolt, and its width is the same as the diameter of bolt. Fig. 48(*a*) reveals no evidence of wedge action.

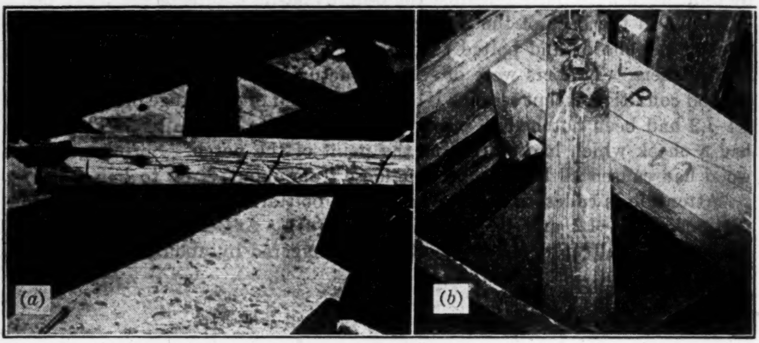

FIG. 48.—FAILURES OF UPPER CHORD JOINTS, TRUSS TSF
(*a*) JOINT U1
(*b*) JOINT U4

After this failure, it was decided to repair the joint and continue testing. This was done on the next (the third) day, and testing continued until failure occurred in one flange of the diagonal L3–U4 at joint U4 at a total load on the

TABLE 7.—SAN FRANCISCO BUILDING TRUSS TSF

Deflection.—At a total allowable load (corresponding to about 375 lb per lin ft of truss, or a total load of 8.2 kips), the deflection at the center of the bottom chord was 0.25 in.—that is, 1/1,600 of the span length. The maximum recorded deflection (with a load of 40 kips on the truss) was 1.70 in.—that is, 1/235 of the span length.

Joint	STRESS IN END DIAGONALS					RATIO R_{bs}		Residual stress (lb)
	At Failure[a]			Allowable (Lb)[b]				
	(Kips)	(Lb per lin ft)	Total load (kips)	End bearings	Cross bearing	$\frac{\text{Col. 2}}{\text{Col. 6}}$	$\frac{\text{Col. 2}}{\text{Col. 5}}$

Total failure[c]	34.8	1,900	41.6	9,000	6,840[d]	5.09	3.87	19,800

[a] Stress *F* in the member (Col. 2) corresponding to applied loads of *w* (Col. 3) or *W* (Col. 4). [b] Based on the bolts of the given joints being subjected to end bearing (Col. 5, at 0° to the grain) or cross bearing (Col. 6) for stress on the end diagonal. In Joint U1 (6-in. by 12-in. chord) the cross grain was at about 57° and in Joint U4 at about 45°. [c] Only the top member of the I-section failed at 31.9 kips. The loading was increased until at 34.8 kips the entire connection failed—top and bottom. [d] Not critical. [e] The load was increased to a maximum of 34,800 lb.

truss of 31,900 lb. Without repairing the joint, the load was increased until, at 34,800 lb, the other flange of the diagonal at joint U4 also failed. Fig. 48(*b*) illustrates these last failures.

Results of Tests, Truss TSF.—All failures of the truss occurred in the wood at the bolted connections. Fig. 46 shows the deflection curves of the lower chord. Fig. 49 shows the center deflection of the lower chord plotted against the total load on the truss, and Fig. 50 shows the axial deformation of the diagonal member U1–L2 with respect to the 6-in. by 12-in. chord at joint U1.

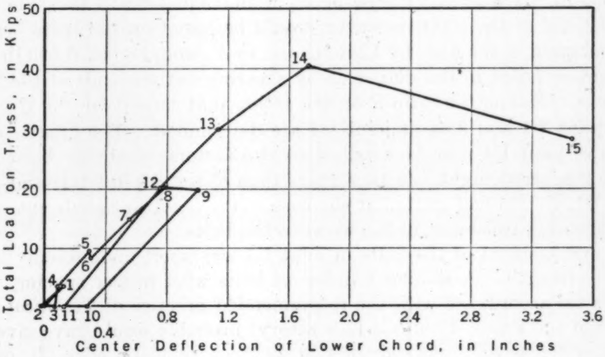

FIG. 49.—CENTER DEFLECTION, LOWER CHORD, TRUSS TSF

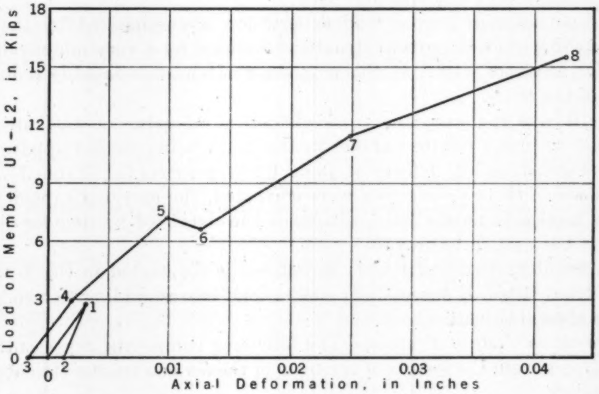

FIG. 50.—DEFORMATION OF U1–L2 WITH RESPECT TO UPPER CHORD TRUSS TSF (CONNECTION CONSISTS OF THREE ¾-IN.-ROUND BOLTS)

The allowable load on this truss is that determined by the safe capacity of the joint detail (U1) that failed—in this case determined by the allowable load on the bolts, P_b. The computed load (8,200 lb) corresponds to about 375 lb per ft of truss. If the failure of the defective notched joint U1 is excluded as subnormal, the truss may be stated to have failed at a load of 31,900 lb, corresponding to about 1,750 lb per lin ft of truss.

It is important to note that the joints did not fail in the manner indicated by calculations of their strength. To illustrate, Table 7 indicates that, in joint U1, the allowable load for the diagonal U1–L2 is the allowable load for the bolts in the end of the diagonal based on bearing parallel to the grain of the two 2-in. by 6-in. diagonals, or P_b would equal 9,648 lb. The critical allowable load of the joint, however, would be based on the bolts bearing at 57° to the grain in the 6-in. by 12-in. chord, or P_b would equal 6,390 lb. Joint U1, however, failed in the diagonals by shearing out the ends of the 2-in. by 6-in. sticks. Basing the ratio R on the action that caused failure, R-values of 1.98 at joint U1 and 3.54 at joint U4 are determined. The greatly superior strength of joint U4 may be ascribed to two factors—first, the bolts at joint U4 were staggered slightly farther apart than those at joint U1; and, second, at joint U1, checks had started at the base of the reentrant angle cut, weakening the shearing resistance of the wood to the bolts.

The arrangement of the bolts in joint U1 was poor, undoubtedly lowering the joint strength. A smaller number of bolts with proper spacing and end distances (in accordance with the recommended practice of *Technical Bulletin No. 332*[4] of the Forest Products Laboratory) probably would have given equal strength, whereas only one pair of 1-in. bolts, with 1½-in. edge distances and 8-in. end distances would have yielded a higher strength than the three bolts with the arrangement and spacings used.

The importance of proper field supervision is emphasized by the unfortunate notching of an important structural member for a very minor purpose—the location of a roof joist. In this case the notch unquestionably reduced the strength of the truss.

Before it was repaired, the truss yielded a R_{ba}-value of 2.94, in bearing at an angle to grain, failure parallel to the grain being caused apparently by design and construction defects at joint U1 (see footnote[b], Table 7). After repairs in which these deficiencies were corrected, the carrying capacity of the truss was increased nearly 75%, although the detail of bolting for joint U4 could have been much improved.

An inherent property of timber structures is illustrated in this test: Even after the truss failed, it successfully held a load corresponding to two or three times the allowable load.

Comments on Tests of Trusses.—The following comments, representing conclusions drawn from the results of the tests of the sixteen trusses (twenty tests), seem justified:

1. Of the twenty tests made, on sixteen trusses, the results show that—five failed because the wood members ruptured at joint details; six failed at bolted joints; and nine failed at connector joints, due to types or combination of stresses not anticipated.

2. The truss with the highest R-value of 7.3 was truss TCh–5 (see Table 8) which had its compression diagonals framed on one side of the chords and its

---

tension diagonals on the other—a type discussed in conclusion 6. Except for the end diagonals, connections of web members to chords were made with single bolts.

TSF.....	2.0[j]	1/1,600	1/235	Bolts sheared at joint U2, emphasizing importance of proper bolt spacing and arrangement.

[a] The results of these tests show a friction value of 0.315 in the butt blocks. [b] In this shallow truss the chord bending effect was ignored in computing the R-values. [c] The bottom chord splice was reinforced. There was considerable distortion under load. [d] R varied between 1.5 and 3.6. [e] Stitch bolts held excellently after first failure, adequately reinforcing joint. [f] Span lengths: TM-1, 54 ft, 1 in.; and TM-2, 51 ft, 4½ in. [g] These values apply after the chord splices had been reinforced. [h] Initial failure at the bottom chord splice which, apparently, had been injured in dismantling. [i] Eccentric joints require check for cross-grain tension. [j] R varied between 2.0 and 5.1.

3. The deflection of trusses was apparently independent of type, the all-timber truss with modern connectors and the truss with butt-block connections for compression members and tension web members of steel having about equal stiffness.

4. The average deflection for parallel-chord trusses with depth-to-span ratios of 1/5 to 1/8 was, for allowable loads, about 1/700 of the span (varying from 1/567 to 1/885).

5. A number of trusses failed at unexpected loads, such failures emphasizing the lack of information on, or knowledge of, the local stresses to be expected in addition to the direct stresses. Even had check computations been made on the design, using conventional methods, some of these weaknesses probably would not have been disclosed, because in many cases customary methods of truss analysis would not have taken into account the stresses that actually caused failure.

6. The necessity of considering tension perpendicular to the grain for correct design of timber joints was one of the outstanding results of these tests. Examples of this need were disclosed in the cases of eccentric connections of truss members, as (*a*) where chord and web members did not intersect at common points, and (*b*) where two web members connecting at a joint or

panel point were framed on the opposite sides of the chords, causing rotation of the chords, bowing of the webs, or both, with resultant splitting of the chord members.

7. The importance of adequate end distances for bolts, proper spacing of bolts, and especially proper arrangement or pattern of the bolts in bolt clusters,[5] was signally illustrated by some of the truss failures.

8. The possibility and effect of combining important stresses should be investigated in some designs. Suitable reductions of allowable stresses should be made if necessary. For example, where shear and flexural stresses occur simultaneously in a timber detail, as in the end butt block of the Alameda-Contra Costa Counties Building trusses (TAC), an assumed working stress in shear of 150 lb per sq in. resulted in a low R_{wa}-value although this unit shear, and even a value of 180 lb per sq in. is allowed in a joint by authoritative recommendations without qualifying limitations for type of detail or presence of other stresses.

9. The high values of R_{ba} were noticeable for bolted connections where the size, spacing, and arrangement of the bolts were carefully selected, although it must be remembered that the design loads recommended for bolts by the Forest Products Laboratory are based on proportional limit loads rather than on ultimate loads.

10. The indentation of the end diagonals of the Alameda-Contra Costa Counties Building trusses (TAC) into the beveled surfaces of their butt blocks indicates the wisdom, in this type of truss, of paying particular attention to the compression areas afforded the ends of diagonal web members, if a balanced design of truss is considered a desideratum.

II. JOINT TESTS

Joints with Steel Gusset Plates and Shear Plates.—This part of the test program consisted of tests on seventeen joints in which from two to four (but generally three) members were connected together with steel gusset plates and flush-type shear plates. Fourteen of the joints were taken from the stage framing of the Cavalcade, two from the cantilever root trusses of the same structure, and one from the Triumphal Arch. All the joints except one (joint J1), were concentrically connected, or substantially so—that is, the center lines of the members met at a common point.

All joints had been carefully handled during removal and in transportation, so that their strength factors would not be altered by such operations. The wood was in good condition except in a few instances recorded in the summarized results of Table 9 and noted in the following descriptions of the individual tests:

Joint J2.—Although there was some slight checking, the pretest condition of the members of this joint was excellent. Failure was characterized by splitting and shearing.

Joints J3–J7.—The pretest condition of these joints was excellent. Failure was characterized by splitting and shearing.

[a] Single stick members at each joint except J15, J16, and J17, which were double sticks. [b] Bolts were all ⅞ in. in diameter except J11 and J12, which were ¾ in. Except joints J15, J16, and J17 each bolt included two 4-in. shear plates. The three joints mentioned were designed with one 4-in. shear plate on each bolt. After disassembling of joint J8 it was discovered that three shear plates had been omitted from one side. [c] Connectors were spaced uniformly 6 in., center to center, except joint J16 which was 6½ in. [d] In joints J10 and J13, the compression member failed. In the other joints failure occurred in a tension member. [e] No "proportional limit load" evident. [f] Held by the side; not sheared. [g] Did not fail. The joint was holding but deforming. [h] 1 hr 9 min on one day and 1 hr 8 min the succeeding day. [i] Tested for 24 min; then permitted to stand at the design load over one week end and tested for 33 min on Monday.

Joint J8.—The members of this joint were grooved for six shear plates. After disassembly it was discovered that the three plates on one side had been omitted. Failure was by tension, characterized by splitting and shearing on one side.

Joint J9.—The pretest condition of this joint is reported as "good."

Joint J10.—The pretest condition was excellent except for a large natural check in the compression member that failed. This member was a boxed-heart stick, and failure was characterized by shearing, splitting, and bearing. The shear plate slid into the large check.

Joint J11.—This joint came from a cantilever which failed at a relatively low load because of careless workmanship. The pretest condition of the member that failed was excellent except that one shear plate had a hole $\frac{15}{16}$ in. in diameter, whereas the remaining shear plates had $\frac{13}{16}$-in. holes. The threads of the bolts were in bearing on the steel gusset plates and the shear plates. Failure was characterized by shearing and splitting, the bolts being almost sheared through and badly bent.

Joint J12.—The pretest condition of the tension member that failed was excellent. As in joint J11, the threads of the bolts were in bearing on the steel gusset plates and shear plates, and the bolts sheared through at the threaded sections.

Joint J13.—Despite some checking, the pretest condition of the compression member that failed was good. Members 1 and 3 of this joint did not fail. The joint came together and the members butted. The wood adjacent to the shear plates had failed and the bolts were badly bent.

Joint J14.—The tension member that failed in this joint had appeared in excellent condition until it was disassembled. Evidently the workmen had grooved the holes and knocked away the wood between the shear plates before assembling the joint. Failure was characterized by splitting and shearing. Bolts were badly bent; and failure occurred by shearing along old lines where split rings had been installed badly and where chips of wood had been removed.

Joints J15 and J16.—The members of this joint were in good condition, with some checking at the ends of tension members.

Joint J17.—The members of this joint were in excellent condition before testing. There were no checks in the tension members, but there were knots and a slope of 1/12 in the grain that caused bending failure in the wood. The tension member failed by tension and bending of wood. The shear plate did not fail.

Except for $\frac{3}{8}$-in. gusset plates of joints J11 and J12, all gusset plates were $\frac{5}{16}$ in. thick; $\frac{3}{4}$-in. bolts were used in joints J11 and J12, otherwise all bolts were $\frac{7}{8}$ in. in diameter. The bolt holes, in both steel plates and wood members, in accordance with recommendation of the Forest Products Laboratory, were $\frac{1}{16}$ in. oversize.

The members that failed in joints J10 and J17 were structurally defective; but, aside from these joints, the timber was select structural grade of Douglas fir. At the time of testing all members had an average moisture content of from 12% to 15%. Shrinkage had caused the wood members to lose their once snug fit with the steel gusset plates, but no remedial measures, such as tightening the nuts of bolts passing through the connectors, were attempted.

In all joints the holes in the wood members and in the shear plates matched those of the steel gusset plates very well. In all the joints removed from the Cavalcade stage framing (joints J1 to J10, inclusive, and J13 and J15 to J17, inclusive), at least one of each pair of gusset plates had been drilled in the field. In joints J11, J12, and J14, the members had been bored from both sides, but good fits had been obtained.

Testing Procedure.—The manner in which the joints were installed in the testing machine is shown in Fig. 1, and Fig. 51 shows, diagrammatically, the make-up of joints and method of loading. In detail, the load was applied in each test by an hydraulic jack which was placed at the end of one member, usually the chord member and termed member No. 1. A new tension connection was built at one end of one diagonal and the third member was blocked up to resist the induced compression. One exception to this procedure is: In joint J13, all three members were placed in compression; all connectors were 4-in. flush-shear plates; all bolts were $\frac{7}{8}$ in. in diameter except as noted in Fig. 51; and all gusset plates were $\frac{5}{16}$ in. thick except as noted.

Gages were installed to measure deformations of the various members with respect to the steel plates—that is, the slip of gusset and shear plates with respect to the wood members. Other gages were installed to indicate the angular rotation between members. The purpose of these last measurements was to obtain a basis from which the secondary stresses induced in a member when its connection deformed under load might be estimated. None of the

bolts in the joints were tightened before testing, and the members of all joints were usually quite loose in their enclosing gusset plates. Because of this condition, all secondary effects and stresses are believed to be negligible and no attempt has been made to evaluate them. Loads were applied in increments of from about 5 kips to 10 kips to approximately the estimated design load; they were then released, the recovery was measured, and the loads were reapplied until failure had occurred in some member or its connection. gages were generally removed before the ultimate loads were reached. After failure the joints were dismantled, while the results of the test, together with any pertinent observations, were noted and photographs taken. Fig. 1 shows a typical failure in the tension diagonal.

Eccentrically Connected Joint J1.—Fig. 52 shows the detail of this joint. It will be noted that the center line of the diagonal is eccentric by 3¾ in. with the centroid of the three pairs of shear plates with its connection to the chord (member No. 1). In Fig. 52, for convenience of reference, the three pairs of connectors are marked C1, C2, and C3, respectively.

The joint was found to be in excellent condition, with member No. 1, which failed with a moisture content of 13%, a specific gravity of 0.53, twelve rings to the inch, 30% summerwood, and a 1.18 slope of grain. Because of previous experience in testing eccentric joints of trusses in which failure resulted from the stress of tension across the grain, blocks were fastened by split rings with bolts to the sides of member No. 2, bearing against the two 4-in. by 8-in. sticks of member No. 1. Also, member No. 1 was blocked laterally to prevent any lateral motion that might have been caused by eccentricity.

(*a*) DETAIL OF JOINT (*b*) LOADS AND STRESSES AT FAILURE

FIG. 52.—ECCENTRICALLY CONNECTED JOINT J1

As indicated in Fig. 52, a tension connection was provided at the end of diagonal member No. 3 and the joint was installed in the testing truss in the usual manner. Loads were applied through the jack at the end of the two 4-in. by 8-in. sticks of member No. 1 in increments of 5 kips released, and then reapplied until failure occurred. Measurements were taken of the widening of the two sticks of member No. 1 due to tension across the grain. At the left-hand connector of this member, the maximum widening of the member was registered, being 0.01 in., whereas, at the right-hand connector, the widening of the member was only 0.001 in.

Failure occurred through splitting of the two pieces of member No. 1 at a total compression in this member of 22 kips and a simultaneous tension in member No. 3 of 33.4 kips. The following excerpts from the laboratory notes are pertinent:

> "At a load of 16 kips in Member #1 a check in one of the two sticks of this member was opening and a new crack started, while at 20.8 kips the other stick also gave, failing in bending. The first stick went gradually

up to 16 kips and then opened up in tension across the grain following an old check that was about ½″ deep. This check kept getting larger until at 20.8 kips the other stick failed in flexure. The first stick failed by bending in the portion that had been split off due to tension across the grain. Both of the sticks also failed by twisting due to the connection of the gusset plates to only one side of each member.

"It was noted that the sticks of Member #3 bent due to the connections of the gusset plates on their sides. This caused the ends of the members to lift off about ⅛″ or more from the gusset plates. Both sticks showed the twisting, or rotational, action of the pull on the inside of members, causing a twist or rotation at failure of an amount sufficient to lift or lower the inside edge of the members about ⅝″ to ¾″."

Results of Tests, Joint J1.—The tension in member No. 3 at failure produced an axial stress of 22.3 kips in member No. 1 (due to the eccentricity of the connection), and a transverse shear of 25.1 kips. The axial stress may be assumed to have been resisted equally by the three pairs of shear plates in the member, or by a shear of 7.4 kips per pair of connectors. Because of the eccentricity of the connection (which was really doubly eccentric, since the chord was of two pieces, each connected by one face only), the total transverse shear was not carried equally by the three pairs of connectors. Computations indicate that the left-hand pair of connectors, C1, took a transverse shear of 16.2 kips; and the center pair of connectors, C2, took a transverse shear of 8.4 kips, whereas the transverse shear in the right-hand pair of connectors, C3, was 0.5 kips. Consequently, the maximum resultant shear was found in connectors C1, equal to 17.8 kips, and at a slope of 66° with the grain of the member. The stress P_c on a pair of shear plates, for nondense structural grade of Douglas fir, at an angle of 66° to the grain, is 8,250 lb. Therefore, R_{ea} was $\frac{17.8}{8.25}$, or only 2.16, instead of a value ranging from 3.5 to 5 as was found in the concentric joints of the series. This illustrates the loss of efficiency occasioned by the eccentric connection.

The test emphasizes the fact that the resistance of a joint of this type is lowered by an eccentric connection: First, because of the increased load and increased transverse shear on one or more connectors (in this case 1.55 times the average) resulting from the eccentricity; and, second, because of the increased intensity of stress in tension perpendicular to the grain.

At failure in the two 4-in. by 8-in. pieces of member No. 1, bending stress of 4.90 kips per sq in. occurred. Based on this bending stress, R_{wa} would be 3.04, this value of R having little meaning because failure was not caused by bending. The twisting, or rotation, of the two sticks has been mentioned in the excerpt from the laboratory's notes. This twisting, or rotation, was caused by the steel gusset plates pulling on the sides of the members rather than through their centers of gravity. This phenomenon may be seen in Fig. 53 where the near face of the 4-in. by 8-in. sticks has spread about ⅝ in. The bending effects caused by plate connections applied on one side of a member is further illustrated in the same photograph where, at the left, the ends of the 3-in. by 10-in. sticks of diagonal member No. 3 are shown separated from the steel gusset plates, which the sticks had caused to bend.

Concentrically Connected Joints.—The details of the concentrically connected joints are illustrated in Fig. 51. Stress ratios, R, are given in Table 9, Cols. 9 and 10.

Joint J2.—Shrinkage of the wood caused the members entering this joint to separate from the gusset plates a distance of $\frac{3}{16}$ in. to $\frac{1}{4}$ in.; and, during this test, this effort resulted in a buckling of gusset plates. At a load of 42.5 kips in member No. 3, the bolts were bending and the gusset plates at member No. 1 were noticed to be buckling at a load, in the member, of 88.5 kips. Failure occurred in member No. 3 by shearing and splitting of the wood at a total stress of 114.4 kips.

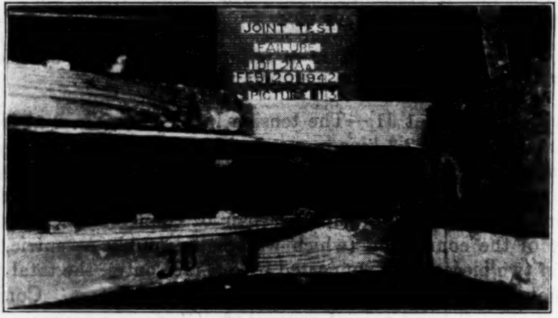

Fig. 53.—Effect of Connecting Steel Plates on Only One Side of Each Member, Joint J1

Member No. 1, with six shear plates at 10-in. spacing, resisted without failure or apparent distress 24.6 kips per shear plate, giving a R_{ca}-value of 4.45. This high value of R may be regarded as substantiating the standard spacing of 9 in. recommended for shear plates, although it is to be noted that the gusset plate on one side of member No. 1 had moved laterally 0.11 in. with respect to the member whereas the relative movement on the other side was 0.40 in.—an average of 0.26 in. The large difference in the relative movements of the two faces is difficult to explain, for there was no evident lateral eccentricity of the joint. The following values based on ultimate loads taken by member No. 3 are of interest:

Ultimate load......................	114.4 kips
Proportional limit load..............	60.0 kips
Ratio R_{ca}.........................	4.56

Joint J3.—At a total axial stress of 53.1 kips in the tension diagonal member No. 4, this member failed by shearing and splitting, a large split occurring through the bolts and shear plates. Failure went through a deep check. Previous to this failure, and at a stress of 46 kips in this member, a large cracking had been heard and the load had fallen off. The end distance in member No. 4 was only 4½ in.

Joint J4.—Although, in this joint, the tension diagonal, member No. 4, failed at a total axial stress of 57.1 kips, with typical shearing and splitting, a new split, about 3½ in. deep, had occurred in the end of the member at a stress of 24.2 kips. This split was located in the center of the member, parallel to the center line of the shear plate.

Joint J5.—Unlike the most of the other joints this joint failed suddenly. Member No. 4, the tension diagonal, failed by typical shearing and splitting at a total stress of 87.7 kips. On dismantling the joint, it was noted that member No. 3, in compression, showed no distress and that it was well fitted. At the time that member No. 4 failed, each shear plate in member No. 3 had resisted 10.2 kips. The end distance was 8½ in. (Figs. 1 and 54(a)).

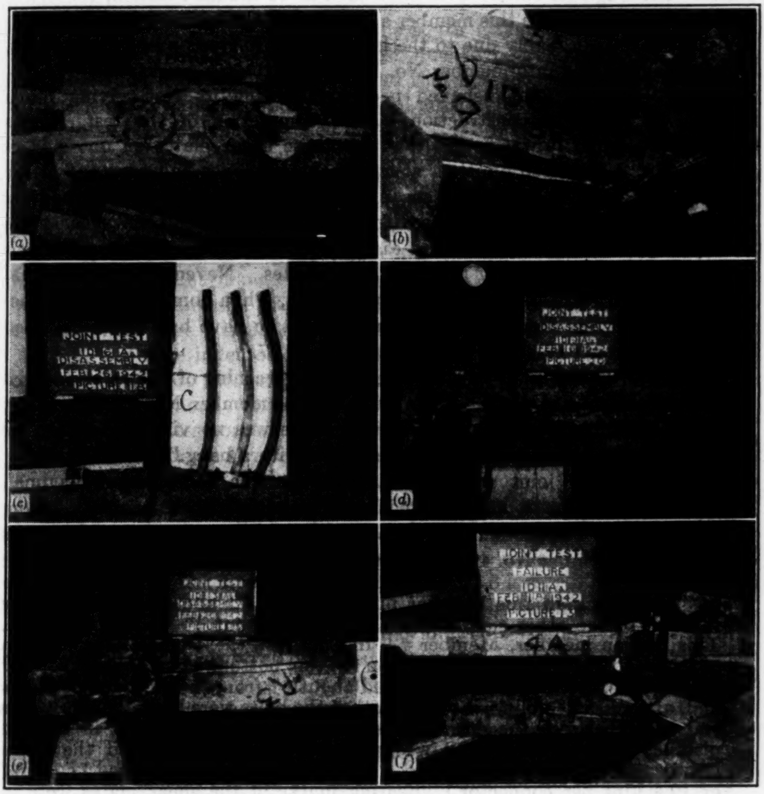

Fig. 54.—The Failure of Concentrically Connected Joints

(a) Joint J5
(b) Joint J8
(c) Joint J8
(d) Joint J10
(e) Joint J11
(f) Joint J17

Joint J6.—The test behavior of this joint was similar to that of joint J5. The end distance was 8½ in.

Joint J7.—Member No. 4, the tension diagonal that failed, did not fit tightly between the gusset plates, because of shrinkage which was estimated to be about $\frac{1}{16}$ in. This member failed, with typical shearing and splitting, at 91.2 kips. Its end distance was 7¾ in.

Chord member No. 1 consisted of two 3⅝ in. by 7⅝ in. sticks, each connected to its gusset plate on one side only, but each stick was fastened with four shear plates. Although its connections were such as to induce rotation, there was no evidence of distress in this member at the maximum load of 44 kips (5.5 kips per shear plate), probably due to the lateral support given by member No. 3, which extended well into member No. 1, between the two sticks.

Joint J8.—This joint behaved peculiarly during its test, giving much evidence of defective construction. After completion of the test, it was taken apart, when it was found that the three shear plates on one side of member No. 3 had been omitted, although their grooves had been cut in the wood. This omission caused the shear plates on the other side of the member to carry almost the entire load. Fig. 54(*b*) shows one of the shear plate grooves without its shear plate, and Fig. 54(*c*) shows the bent bolts with their evidence of excessive bearing from the shear plates. Nevertheless, the actual capacity of the joint, as determined by the test, when compared to the theoretical capacity as designed, assuming the joint to have had all its designed shear plates, would give $R_{ca} = 3.61$, and $R_{ct} = 1.37$.

Joint J9.—This joint gave visual and audible warning of failure at an axial load in member No. 4 of 82.5 kips, the failure of member No. 4 occurring at 87 kips. At this ultimate load, however, there was no visual crack. The laboratory notes record that the failure "came with a bang."

Joint J10.—This joint was defective, in that the compression diagonal, diagonal member No. 2, had a boxed heart, although, when examined before testing, the joint was pronounced to be in excellent condition; however, it was observed that member No. 4 had a large check. The laboratory notes record:

> "The check in this member opened about ½" and split all the way through to the other side, where a new split about ½" wide was opened. This tension member, Member #4, did not fail, there being no indication of any timber distress. No cracks on the top, bottom, or end of the member were visible, but the stick had moved about ⅝" from the steel gusset plates and, after disassembling, it was seen that the bolts were badly bent. Cores and wood between the shear plates had sheared, although not in the end distance area. Member #2 was as expected; the cores and the wood between shear plates had sheared. (This member had withstood 77.7 kips, or 19.4 kips per connector.) Bearing marks of the shear plates were in evidence on all bolts but the shear plates were not damaged (see Fig. 61 [54(*d*)])."

In this joint, the 6-in. by 6-in. member which was in tension, resisted without failure a load of 111.4 kips on two pairs of 4-in. shear plates, spaced at 6 in., with an end distance of 9 in. Thus, each shear plate resisted a load of 28 kips, equal to six and one half times its allowable load.

This member was a single stick, with its connection in double, instead of single, shear; and, although the spacing of connectors was only 6 in., the end distance was 9 in.—the two important factors leading to the high strength. The test of this joint has led to the suggestions, given subsequently under the heading, "Comments on Tests of Joints with Steel Gusset Plates," that: (1) Perhaps the reduced values of allowable connector loads for 6-in. spacings are not justified; and (2) the allowable loads for connectors in single shear should be less than one half of the allowable loads when the connectors are in double shear.

Joint J11.—This joint, taken from the south Cavalcade cantilever truss (which had failed under preliminary test due to poor workmanship), was defective. Upon dismantling it was found that one shear plate had a $\frac{13}{16}$-in. hole for a $\frac{3}{4}$-in. bolt and that both shear and gusset plates bore on the threads of the bolts. Fig. 54(*e*) shows failed member No. 3 after disassembly.

Joint J12.—Fig. 51 illustrates that joint J12 had $\frac{3}{8}$-in. instead of $\frac{5}{16}$-in. gusset plates. The joint was obtained from the north Cavalcade cantilever truss (not the truss that had failed) in which it formed the top detail on the rear end of the anchor arm of the cantilever. To all appearances the joint was in excellent condition, having no important checks or cracks and having undergone but small shrinkage—probably the maximum shrinkage was $\frac{1}{32}$ in.

At a total axial stress of 63.1 kips, member No. 3 failed in its connection. The bolts, which were $\frac{3}{4}$ in. in diameter, sheared off at the nuts, at the root of the thread, and were indented at the ends near the head. The member did not split; neither were there any checks or cracks in the wood of the member. The wood did not shear. After dismantling the joint, it was found that the gusset and shear plates bore on the bolt threads, that a number of shear plates with $\frac{13}{16}$-in. holes had been used with $\frac{3}{4}$-in. bolts, and that these bolts had been bent about $\frac{3}{8}$ in.

Joint J13.—In this joint all members were tested in compression. The joint was in excellent condition with the bolts giving evidence of about $\frac{1}{4}$-in. shrinkage of the wood. The test continued over two days. On the first day, the load on member No. 1 reached a maximum of 15.8 kips. Then, because of mechanical difficulties, the test was stopped. The load automatically dropped to 10.0 kips, and the joint with this load was allowed to stand overnight. On the following day, the load was reapplied, reaching a maximum of 59.2 kips in member No. 1 and 112.1 kips in member No. 3. At a load of 80.4 kips in member No. 2, this member was splitting and (see Fig. 51) the gap between the end of member No. 3 and the side of member No. 1 had closed. With further increase in load, member No. 2 continued to split. The gusset plates were seen to be bowing slightly at the maximum load on the joint (126.4 kips in member No. 2). The shear plates in this member had sheared the wood, and its bolts were badly bent. Because of the bearing of the ends of member No. 2 and member No. 3 against the sides of member No. 1, no direct failure had occurred—that is, the load did not diminish, although it could not be increased (see Table 9).

Joint J14.—As in joint J12, the gusset plates were $\frac{3}{8}$ in. instead of $\frac{5}{16}$ in. The joint was seemingly in excellent condition, the bolts indicating a shrinkage of the wood from $\frac{1}{8}$ in. to $\frac{1}{4}$ in. Although the structure of the Triumphal Arch from which the joint was obtained had been wrecked by falling, the joint gave no visible evidence of having been damaged.

As the load was applied, deformations of the tension diagonal member No. 2 seemed to be quite large; and, at an axial stress of 29.75 kips in member No. 2, the shear plates in this member appeared to have moved about 0.20 in. Distress of the joint was audible. At a stress of 47.8 kips in member No. 2, the split in the member became wider, but the failure of the joint occurred in member No. 3 at a stress of 45.2 kips, by splitting and shearing of the wood by the shear plates.

On disassembling the joint it was found that the wood cores of the shear plates had been broken and sheared off, stains indicating that this damage had occurred prior to the test. Further evidence of prior damage was the fact that the wood between the shear plates on one side of the connection of member No. 3 and part of the wood between the shear plates was missing. The other part was loose and its edges stained, as if the joint had weathered after the wood had sheared off.

Joint J15.—The joint was in good condition except for a check in one stick of member No. 2 and a small check in one stick of member No. 3. Failure occurred in the tensional diagonal (member No. 3) at an axial stress of 52.5 kips by typical shearing of the wood in the end distance and between the shear plates, combined with the usual splitting. This member was not of solid section, but was composed of two sticks, each connected by one side only; hence, $R_{ca} = 2.91$.

Joint J16.—The joint was in excellent condition except for a check in one of the sticks of tension diagonal member No. 4, the check extending from the last shear plate to the end of the timber. The joint was opened $\frac{1}{8}$ in. before testing. Failure occurred suddenly in member No. 4 by the usual shearing and splitting. As in joint J15, note the lower strength of the two stick member, in that $R_{ca} = 2.93$.

Joint J17.—Before testing, the joint appeared to be in excellent condition, shrinkage of the wood being small. Failure occurred in member No. 4 at a stress of 33.1 kips, one of the two sticks of member No. 4 failing in combined bending and tension (see Fig. 54(*f*)). This member was found to have a 1/12 slope of grain, and a knot at the point where the split at failure intersected at the edge of the stick. The gusset plate bent badly as the member could not take the bending moment induced by its eccentric connection.

Comments on Tests of Joints with Steel Gusset Plates.—The foregoing results lead to ten broad conclusions, as follows:

(1) The necessity of careful and continuous inspection during construction, if material, workmanship, and resultant strength commensurate with the design are to be expected, is particularly illustrated by the tests of these joints. For example, joints J8 and J14, before testing, gave the appearance of being entirely normal. Indeed, an extract from the laboratory notes of the test of joint J8 reads—

> "The test of this joint was to have been one of the most important of the Test-Program because of the very excellent condition of the joint and its careful handling prior to the test. However, during the test the behavior of the joint was so peculiar that it was suspected of being deficient internally, and after the test it was taken apart. Then only was it found that the joint had but one-half of its indicated number of shear-plates, those on one side having been completely omitted."

Joint J14 was also found to have been damaged in fabrication; joint J10 had a member with boxed heart with resultant checking; in joints J10, J11, and J12, short bolts had been used, causing gusset and shear plates to bear on the bolt threads; and joint J12 actually failed by shearing of the bolts. Also, in joints J11 and J12 shear plates were used with the wrong size of bolts.

(2) Even with the defects described in item (1), joints J8 and J14 did not fail until they had sustained twice the allowable connector loads P_a for 9-in. spacings and end distances and two and one-half times the allowable loads for 6-in. spacings and end distances.

(3) Effects that can occur due to the presence of boxed heart, knots, or sloping grain are illustrated by joints J10 and J17, in which one or more of these characteristics influenced or contributed to failure.

(4) In a two-piece member each piece is connected on one face only, or with the connectors of each piece in single shear, whereas a one-piece member has connectors in both faces—that is, a double-shear connection. The decreased capacity of the connection of a two-piece member is illustrated by comparison of the average maximum loads at failure of joints J15 and J16 (13.20 kips per shear plate) with the average of joints J2, J5, J6, J7, and J9 (21.6 kips per shear plate). These joints all had end distances well in excess of 6 in. The relative efficiency of the one-piece member with double-shear connection as compared with the two-piece member with single-shear connection raised the question as to whether joints in single shear may properly be considered as having one half of the strength of joints in double shear.

(5) The use of a ¾-in. bolt with a 4-in. shear plate, having a 15/16-in. hole intended for use with a ⅞-in. bolt, would seem to be a comparatively easy oversight on the part of the carpenter. Some method of avoiding this condition should be developed.

(6) In these tests no ⅞-in. bolt used with a 4-in. shear plate failed in shear.

(7) The increased capacity of one-piece tension members in double shear, with end distances of 8 in. or 9 in. over one-piece tension members similarly connected but with end distances of only 6 in. or less, was in the ratio of from 1.4 to 1.0—an increase in capacity of 40%.

(8) The slip of shear plates at the allowable or working load was found to be from about 0.05 in. to 0.06 in., confirming published values.

(9) In view of the comment in items (4) and (7), it will be enlightening to group eight of the joints, J3, J4, J5, J6, J7, J9, J15, and J16 (all having 6-in. center-to-center spacings of connectors, but with varying end distances) into three divisions governed by end distance and type of shear and then to note the average ratio value of R_{ca} of each group. Such a grouping is given in Table 10. The joints with connections in single shear, even though they had

ample end distances (group 1), had low values of R. The joints with connections in double shear, even with substandard end distances (group 2), showed increased R-values; and the joints with connections in double shear and with greater than standard end distances (group 3) had the highest values of R. If the nine tests reported in Table 10 are judged sufficient in number to warrant drawing conclusions it would appear that, in this type of joint—

TABLE 10.—EFFECT OF END DISTANCE AND TYPE OF SHEAR

Group	Joints	End distance (in.)[a]	Average R_{ss}
1[b]........	J15 and J16	10	2.92
2[c]........	J3 and J4	4.5 to 5.5	3.50
3[c]........	J5, J6, J7, and J9	7.75 to 9	4.87

[a] Connector spacing 6 in., center to center. [b] Single shear. [c] Double shear.

a. Shear plates at connections in single shear seem to be considerably less effective than such connections in double shear, at least for relatively thin members (3 in.). This condition may be due to stress caused by eccentricity, shrinkage, or other factors. In some cases, the allowable load on a connector in a double-shear connection should be materially greater than that on a connector in a single-shear connection.

b. The reduction in allowable loads for connectors with a spacing of 6 in. center to center, but with a 9-in. end distance, is too severe.

c. The 7-in. end distance for full allowable load for connectors now recommended as standard, as against the former recommended standard of 6 in., is amply justified. Further increase of end-distance requirements might result in even higher allowable loads.

(10) A comparison of the ratios obtained from the joint tests which failed in the shear plates, joints J2 to J9, J12, J15, and J16, is afforded by the data in Table 11(*a*). Joints J15 and J16 were those in single shear which failed at lower ratios than the others. Without these two joints the comparison would be as shown in Table 11(*b*). The joints were fabricated from unseasoned material and tested after seasoning in service. For this condition the recommended working stresses in the TECO Manual of 1939[1] require a reduction in stress of 20%. Calculated on this basis the test results would give comparisons 25% higher than those shown in Table 11.

TABLE 11.—COMPARISON OF EXPECTED AND R-VALUES FROM TESTS

[a] "Timber Connector Construction," Manual of the Timber Eng. Co., Inc., Washington, D.C., 1939.
[b] Forest Products Laboratory, Madison, Wis.

However, it should be noted that in these tests the load was always parallel to grain, under which condition the effect of fabricating with green timber and testing after seasoning in place is much less severe than when loads are applied at an angle to grain.

Joints with Plywood Gusset Plates, Bolted or Split-Ring Connections.—Joints J18 to J22, inclusive, consisted of one bolted joint connected with a plywood gusset plate and four other joints in which a member was spliced with plywood splice plates fastened with split rings.

The first joint (J18) was removed from the San Francisco Building where it had served as part of the lateral bracing system of the lower chord of the roof trusses. The details of the joint before testing are shown in Fig. 55. The joint consisted of a $2\frac{1}{4}$-in.-thick seventeen-ply Douglas fir plywood gusset plate to which were connected two diagonal members, each a 2-in. by 8-in. stick, with $\frac{3}{4}$-in. bolts in single shear. (This plywood was of "exterior" type, made with phenol formaldehyde resin adhesive.) The other members of the joint (not concerned in the test) were parts of a 4-in. by 10-in. strut and the lower chords of one of the original trusses, consisting of 2-in. by 8-in. and 3-in. by 12-in. members also connected with $\frac{3}{4}$-in. bolts. The joint was in excellent condition and was tested at a moisture content, in the 2-in. by 8-in. diagonal, of about 13.5%.

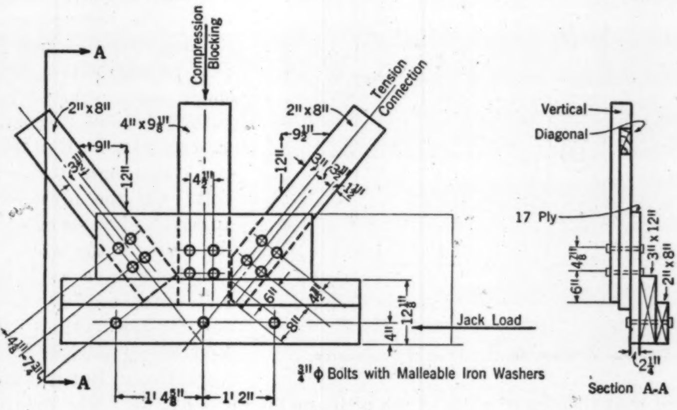

FIG. 55.—DETAILS OF JOINT J18, SAN FRANCISCO BUILDING

The other four joints, J19, J20, J21, and J22, were constructed in the laboratory, of materials from the Exposition buildings. Their details are shown in Fig. 56. Each joint consisted of a center 6-in. by 8-in. block with two splice plates of twenty-nine-ply plywood $3\frac{5}{16}$ in. thick and 8 in. wide, connected to the 6-in. by 8-in. block with eight 4-in. split rings and four $\frac{3}{4}$-in. bolts and with a 9-in. spacing and a 7-in. end distance (see Fig. 56). The grain of the face ply ran parallel to the direction of the load in two of the tests, J19 and J20, and perpendicular in the other two, J21 and J22. The plywood was obtained from the Federal Building where it had been exposed to the weather for about $2\frac{1}{2}$ years.

Bolted Joint (J18) with Plywood Gusset Plates.—Joint J18 failed in the 2-in. by 8-in. tension member by shearing out the end, the end distance being 6 in. The washers were pulled into the face of the plywood causing some splitting of the top plies and creating a corrugated effect. Meanwhile, the bolts had been bent into an S-shaped form.

The total stress in the diagonal at failure was 42 kips. The connection of the diagonal, in which four $\frac{3}{4}$-in.-round bolts were in single shear, had a computed total safe load, based on the 2-in. by 8-in. stick, of 4.7 kips, or 1.16 kips per bolt. On the plywood at an assumed value of 45° to the grain of the wood, the four bolts have a value of 3.11 kips, or 780 lb per bolt. These values yield *R*-values of 8.95 and 13.5, respectively; but it is to be noticed that the slip of bolts at the ultimate load was 0.35 in. The deformation at a working load of 4.7 kips on the four bolts was 0.05 in.

FIG. 56.—DETAILS, JOINTS J19 TO J22, INCLUSIVE

The proportional limit of the bolts is estimated to have been about 8.0 kips, giving a ratio of proportional limit load to allowable, or working load, R_{bl} of 1.7, based on the bolt value of the 2-in. by 8-in. member. The corresponding slip of bolts was 0.10 in. Summarizing these results (in inches):

Based on the 2-in. by 8-in. stick—
$R_{ba} = 8.95$
$R_{bl} = 1.7$
Based on the plywood—
$R_{ba} = 13.5$
Slip of the bolts—
At allowable load $P_b = 0.05$ in.
At proportional limit
load P_l = 0.10 in.

Compression or Tension Splice Joints with Plywood Splice Plates and Split Rings.—Joints J19 to J22, inclusive, with plywood splice plates failed in two types of failure, as illustrated in Figs. 57. Fig. 57(*a*) shows the crushing and buckling of the individual plies of the plywood when subjected to compression loads—the first type. The other type of failure is shown in Fig. 57(*b*) in which the fibers of the plies running perpendicular to the direction of the load are seen to have sheared and "rolled" in the plywood, causing a shear failure at the base of the split rings.

After dismantling the four joints, it was found that all the ring cores in the plywood had failed and that the cores in the rings of the 6-in. by 8-in. center block remained intact. In the ring cores, about 25% of the core area failed in the glue; the remainder failed in the wood. The failures always occurred at a ply located at approximately the bottom of the ring and in a ply whose grain was perpendicular to direction of the load. The cores evidently failed by "rolling shear" action. (The term "rolling shear" has been applied when the shearing force tends to deform the hollow wood cells diagonally in a direction perpendicular to their fibers.)

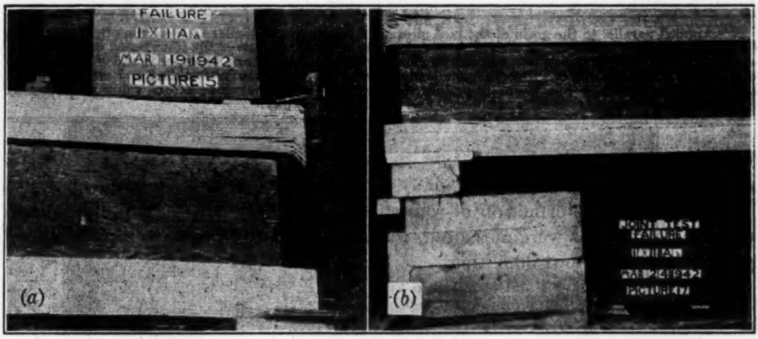

Fig. 57.—Two Types of Failure Joints with Plywood Splice Plates
(a) Crushing of Plywood
(b) Rolling Shear Failure in Lower Plywood Pad

The results of these four tests are summarized in Table 12, which shows maximum loads, manner of failure, and other pertinent data. The working values of split rings in plywood have been taken as the TECO allowable loads for group A woods with direction of load at 60° to the grain. The working capacity of plywood in compression was assumed at 1,735 lb per sq in., and the allowable rolling shear value at 60 lb per sq in.—both of these stresses being those recommended by the Douglas Fir Plywood Association based on tests by the Forest Products Laboratory.

Results of Tests.—The ratio R_{ba} of 8.95, as found in the test of joint J18, is characteristic of bolts; also a value of R_{bt} of 1.7, based on the 2-in. by 8-in. member, seems proper. The tests indicate that the joint had been proportioned correctly. The tests also indicate that an increase in the edge distances in plywood would reduce any effects of rolling shear at a critical plane, and that the plies running parallel to the loads are the effective ones in resistance to compression. It follows that the shearing and crushing strength of the plies needs particular attention in the design of joints of this type. Additional test data in connection with both bolt and connector fastenings when used

TABLE 12.—JOINTS WITH PLYWOOD SPLICE PLATES AND 4-IN. SPLIT-RING CONNECTORS

[a] Applied parallel to the grain of the face plies. [b] Applied perpendicular to the grain of the face plies. [c] Based on group A wood; 60° to the grain. [d] Allowable or working loads of the joint based on plywood in compression at 1,735 lb per sq in. [e] Based on an allowable rolling shear of 60 lb per sq in. [f] After failure the joint was still capable of supporting the loads shown. [g] Failure was by buckling and crushing of the splice plate, as shown in Fig. 57(*a*). [h] Failure was by buckling and crushing of one splice plate and by rolling shear on the other. [i] 29 min one day and 6 min the next day.

with plywood, such as information on plywood splice plates and gusset plates, would be helpful in design, especially when large loads are involved.

The average deformation of joints J19 to J22, at their maximum loads at which deformations were measured, was about 0.24 in., corresponding to a load per split ring of about 30.5 kips.

FIG. 58.—DETAILS OF JOINTS WITH SPLIT-RING CONNECTORS

Joints with Split-Ring Connections.—This series of tests comprised six joints, J23 to J28, inclusive, in which the members were connected by 4-in. split rings and bolts. Two of the joints, J23 and J24, were from an 80-ft roof truss of the Pacific Building. The other four, J25 to J28, inclusive, were compression or tension splices from the stage framing of the Cavalcade of America.

Joints J23 and J24.—One of the truss joints, J23, was taken from an interior panel of the truss, and the other, J24, formed the end joint of the same truss at its supporting column. Fig. 58 shows the details of these two joints. Diagonal member No. 3, Fig. 58(*a*), connects to chord member No. 1 by three pairs of split rings, and vertical member No. 2 was intended to bear on the top side of member No. 1.

The trusses from this building were dropped and damaged during dismantling. The following excerpt from the laboratory notes is pertinent:

> "Joint J-23 was obtained from the Pacific Building where it was an interior joint of one of the 80′ span roof trusses. It was only in fair condition for the two sticks of the chord, Member #1, were badly split. Also, Member #3 had a large check. The truss had been dropped in wrecking the building but the joint had suffered no visible damage. Because of splitting of the chord member, stitch bolts were placed as shown in Fig. 73 [58(*a*)]."

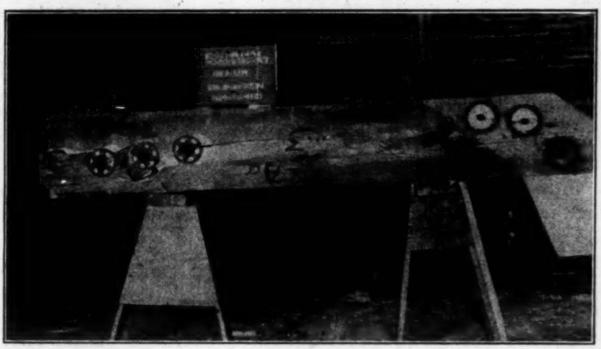

FIG. 59.—FAILURE OF JOINT J24

Although the second of these truss joints, joint J24, was in a somewhat damaged condition prior to the test, the results apparently were not affected. The members of both joints J23 and J24 were of select structural grade Douglas fir, and the two joints were tested at a moisture content of about 15%. No shrinkage was noted that would cause looseness of the bolts; but, in joint J23, there was a space of $\frac{5}{16}$ in. between vertical member No. 2 and chord member No. 1.

Joint J23 failed by splitting of diagonal member No. 3, at a total stress of 44.3 kips, or only 7.4 kips per ring, corresponding to one and one-half times the allowable load. The existing large check had opened into the wide crack. After disassembling the joint, it was noticed that all the ring cores had been sheared off before testing, except one core in member No. 1 and one core in member No. 3. These two particular cores were not even sheared at the completion of the test. The bolts were not bent. The wood in contact with the two end rings appeared to be in good condition, but the inside ring had "slid" into the check.

In the test of joint J24 (see Fig. 58(*b*)), failure did not take place in the original joint but in the tension connection installed for testing purposes at one end of diagonal member No. 3. When the connection had failed, several difficulties prevented its reconstruction, so the test was discontinued. Fig. 59 shows the member after disassembly, and the shearing out of shear plates in the tension connection may be noted. There were several small knots in this particular location. Attention is called to the grooves and cores of the split rings which remained in good condition, although the connectors had been loaded to three times their allowable loads. The maximum load on the member was 87.2 kips.

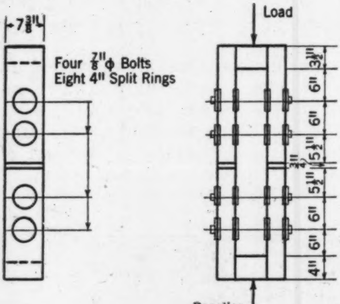

FIG. 60.—TYPICAL DETAILS OF JOINTS J25 TO J28, INCLUSIVE

Joints J25 to J28, Inclusive.—Each splice joint consisted of a 6-in. by $7\frac{1}{2}$-in. center timber, spliced with two $3\frac{1}{2}$-in. by $7\frac{1}{2}$-in. splice pads, and it had a single row of four pairs of 4-in. split rings with $\frac{7}{8}$-in. bolts—a total of eight split rings (see Fig. 60). The joints were in excellent condition. Shrinkage of the wood had resulted in a gap between the center stick and each splice pad of a measured amount of from $\frac{1}{16}$ in. to $\frac{5}{16}$ in.—an average of $\frac{3}{16}$ in. For convenience of testing, in which the joints were placed in compression, a $\frac{3}{4}$-in. to $\frac{7}{8}$-in. gap was provided at the center of the length of splice pads. The movement of splice members was measured. Because of the limitation of slip of joints as determined by the $\frac{3}{4}$-in. to $\frac{7}{8}$-in. gap between the splice pads, the maximum resistance of the split rings was not realized. Table 13 and Table 14 summarize the results, and Fig. 61 shows the stress deformation curves of the four joints.

TABLE 13.—TRUSS JOINTS WITH SPLIT RINGS

Joint	Location	Ultimate load (kips)[a]	P (kips)[b]	R_{ea}	Slip (in.)[c]
J23..........	Intermediate Truss Joint: Tension member..........	44.3	28.9	1.55	....[d]
J24..........	End Reaction Truss Joint: Tension connection........ Joint....................	 87.23 87.23[e]	 23.8 28.9	 3.65 3.00[e]	 .... 0.059

[a] In tension member. [b] Six split rings. [c] Slip of split rings longitudinally in member No. 3 at the design allowable load P. [d] Not evident. [e] In tension member, observed proportional limit was at a tension of 42.3 kips giving an R_{et}-value of $\frac{42.3}{28.9} = 1.46$. This tension member did not fail in the joint, failure occurring in the tension connection provided for testing.

Results of Tests.—Reference to the stress deformation curves of Fig. 61, all plotted to the same scales, and also to Table 14, indicates the erratic test behavior of these joints. The slopes of the first sections of the stress-deformation curves of joints J25, J26, and J27 are very flat as compared with the

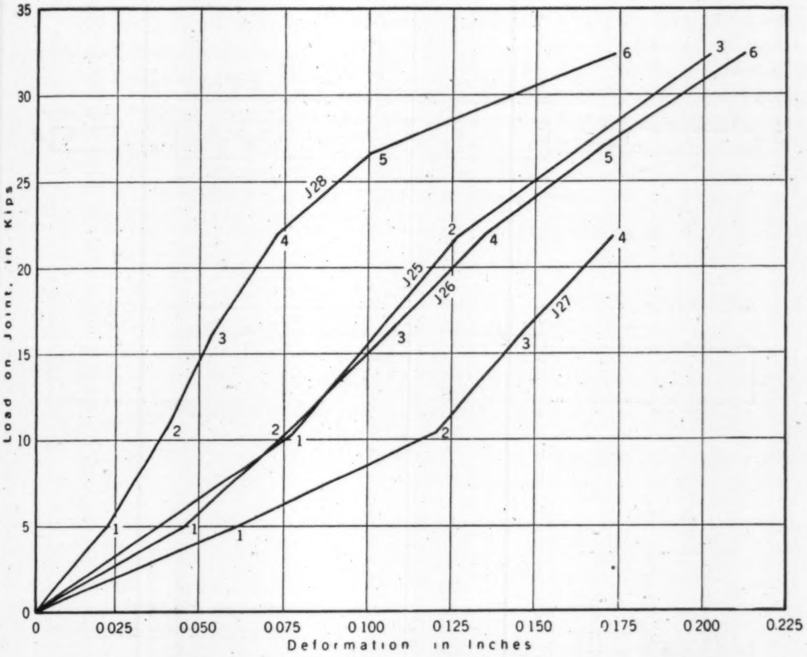

FIG. 61.—LOAD-DEFORMATION CURVE, JOINTS J25 TO J28, INCLUSIVE (SPLICE WITH FOUR, 4-IN. SPLIT RINGS AND TWO ¾-IN. BOLTS ON EACH SIDE)

similar part of the curve of joint J28, indicating that a relatively large initial deformation took place in joints J25, J26, and J27. Up to a load of 10 kips the curves of joints J25 and J26 coincide, having a slope of about 4 on 7, whereas the curve of joint J27 has a relatively very flat slope. Joint J28, which

TABLE 14.—SPLICE JOINTS (J25 TO J28) WITH SPLIT RINGS

Joint	Gap between spliced members (in.)	Maximum Loads on Joint[a]		Proportional limit load[b] (kips)	Allowable load[c] P_e	Ratio[a] R_{ee}	Deformation[d]	Opening caused by shrinkage[e]
		Four rings (kips)	Kips per ring					
J25........	¾	52.5	13.1	22.0	20.2	2.6	0.119	⅛
J26........	¾	51.5	12.9	22.0	20.2	2.55	0.126	1/16
J27........	¾	51.5	12.9	....[f]	20.2	2.55	0.166	1/16
J28........	¾	55.5	13.8	22.0	20.2	2.75	0.067	⅛

[a] The joints did not fail completely, but the test was stopped when the opening between the spliced members was closed. For the maximum load per split ring there was a slip of ¾ in. [b] Values of the proportional limit load are very uncertain because of the large increments of test load. The ratio R_{ee} is equal to the proportional limit load (22.0 kips) divided by P_e, or 1.09. [c] The basic allowable load on four 4-in. split rings is 22.0 kips; but this value was first increased 12% to 24.6 kips because of the ¾-in. bolts, and then decreased to 20.2 kips (or 5.05 kips per split ring) because of the spacing of 6 in., center to center. [d] Deformation, in inches, at a load of 20.2 kips. [e] Total width of the two spaces between the splice pads and the center block, caused by shrinkage. [f] Not measured.

FIG. 62.—MOMENT JOINT, TYPE I (J29, J30, AND J31) (BOLTS ¾ IN.; PLATE WASHERS, $\frac{5}{16}$ × 3 × 3; AND ANGLES, $\frac{5}{16}$ × 4 × 4)

shows a slip of 0.06 in. at the allowable load of its connectors, $P_e = 20.2$ kips, is the only one of the four joints that exhibited normal behavior. These joints were taken apart after testing, and no defective workmanship was evident, so that the lack of consistency in their behavior cannot be explained.

Moment Joints.—The series of bolted joints J29 to J34 consisted of six splices of 6-in. by 16-in. and 8-in. by 16-in. wooden beams which had been part of the framing supporting a canvas roof over the seats of the Cavalcade. All splices had been calculated to resist moment as well as shear, and the framing was designed to support a live load of 5 lb per sq ft plus dead load, with a 50% increase in the usual working stresses. Some of the beams had been continuous, with spans of 40 ft and 42 ft, whereas others had been 21-ft cantilevers extending beyond their supporting girders.

FIG. 63.—MOMENT JOINT, TYPE II (J32, J33, AND J34) (STITCH BOLTS, ⅝ IN.; BOLTS, ¾ IN.; PLATE WASHERS, $\frac{5}{16} \times 3 \times 3$)

The spliced joints were of two types. Type I (joints J29 to J31, inclusive) had its splice pads on the tension and compression faces of the beams, the beam being cut in two to allow its supporting girder to pass through within its depth. It had steel angle clips bolted to its sides and to its supporting girder to resist shear. The splice pads were designed to act in direct tension or compression with their connecting bolts in single shear. Fig. 62 shows the details of this type of joint. The joints of type II, shown in Fig. 63, had their splice pads on the sides of spliced beams, the pads designed to act in bending and shear, with the bolt groups on each end of the pads furnishing resisting moment. In both types the bolts were $\frac{3}{4}$ in. in diameter with 3-in. by 3-in. by $\frac{5}{16}$-in. plate washers under the heads and nuts. These bolts were generally found to have a tight fit in their holes in the wood, but the "play" under the heads and nuts indicated a shrinkage of the wood of from $\frac{1}{8}$ in. to $\frac{1}{4}$ in.

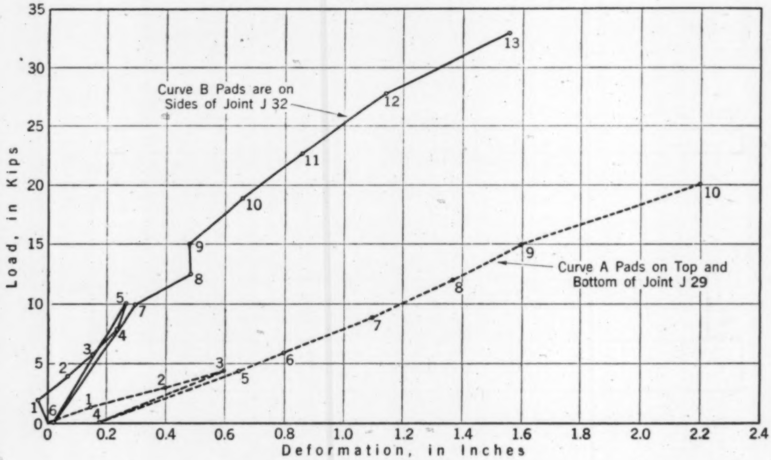

FIG. 64.—CENTER DEFLECTION OF MOMENT JOINTS

The joints had been carefully removed from the structure and were found to be in excellent condition; workmanship and materials appeared to be reasonably good, although some checking had taken place in the 16-in.-wide splice pads. The joints were tested at a moisture content of from 15% to 25%.

Testing Procedure.—After installing the joints in the testing truss, loads and reactions were applied as indicated diagrammatically in Fig. 63. In five of the joints, one concentrated load was applied directly over the splice, and in the sixth joint two equal loads were applied about 3 ft apart, near the center of the splice.

Deflections under the loads were measured on all joints; but, since these measurements were taken on one side of the beams only, some erratic results were obtained, and consequently the actual values of deflections are to be taken with caution from the deflection curves A and B of Fig. 64.

Loads were applied with an hydraulic jack and through blocking to the splice points. When loads that produced bending moments of about 20 ft-kips for type I joints and 30 ft-kips for type II joints had been applied, the loads were released, and deflections and deformations were measured. Joints were then reloaded until failure occurred.

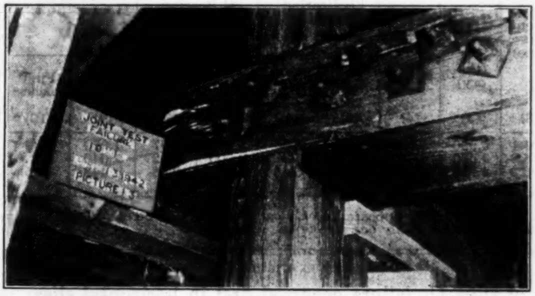

FIG. 65.—FAILURE OF JOINT J31 IN BENDING AND TENSION OPPOSITE THE SPLICE POINT

Results of Tests.—Failure in joints of type I occurred in the tension pads, caused by direct tension and secondary bending stresses. Fig. 65 shows a sharp bend in the pads which created large secondary bending stresses. No attempt was made to calculate these secondary stresses.

TABLE 15.—STRESS RATIOS, TESTS OF TOP AND BOTTOM SPLICE PADS, MOMENT JOINTS, TYPE I, J29 TO J31

[a] Computed shear at the first appearance of shear cracks. [b] To be considered relative only, because the measurements were taken on only one side of the splice.

In joints of type II, failure occurred first in horizontal shear at the pads, as evidenced by offsets at the ends. Usually this first shear failure followed existing checks, but new cracks were also opened connecting to the existing checks—in a manner quite typical of horizontal shear in beams. In a few cases the shearing cracks developed in entirely new and unchecked material. After the splice pads were split into two or more pieces by shearing, each part then broke in bending, or by subsequent splitting.

J34....	6×15½	2¾×15½[a] 2¾×15½[a]	32

[a] Length 14 ft.

The results of the tests are summarized in Tables 15, 16, 17, and 18, from which it may be observed that the joints with side pads (type II) are nearly two and one-half times stiffer than those of type I with top and bottom pads. Fig. 66 shows typical bolt deformation in the joints with top and bottom pads (type I). Comparing the results of Tables 15 and 16 with the bolt slips of Fig. 66, it is noted that considerable deflection of the beam took place with only small bolt slips because of the large ratio of span length to depth of beam—that is, a beam deflection of 0.4 in. corresponds to a bolt slip of 0.075 in.

In joints of type II the determination of amount and direction of shear in each bolt is a complex and indeterminate problem, unlike similar problems in steel construction, because of the difference in the elastic properties of the wood parallel and perpendicular to the grain. It may be conceived that the total moment in the splices is resisted by a combination of two types of bolt action. In the one type, assuming that the bolts act parallel to the grain of the wood only in resistance to the bending moment, each bolt would act in double shear and the pads could probably be split along the center line of the beam with no loss in strength or rigidity. This type of action would produce tension and compression in the pads, but no horizontal shear. Col. 6, Table 17, shows the bolt stresses under such action. In the second type of bolt action, the bolts are assumed to bear perpendicular to the grain of the wood only; and, hence, their pressures would induce large shearing as well as bending stresses in the pads. Bolt stresses for this type of action are shown in Col. 8, Table 17, and the calculated horizontal shear is indicated in Col. 10.

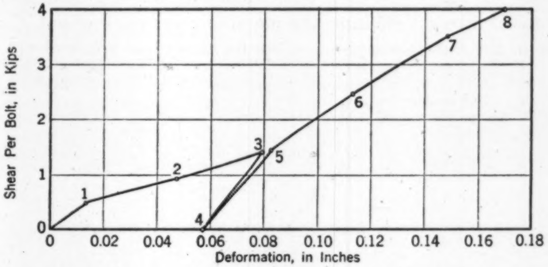

Fig. 66.—Typical Bolt Deformation Curve, Joints of Type I, with Top and Bottom Pads (Bolts, ¾ In. Round in Single Shear)

The total resistance of such a splice must result from a combination of the two types of action. The distribution between the two types of bolt action will depend on the dimension of the joint and the relative elastic properties of the bolts and the wood in the two directions, and is highly indeterminate. Even if only a small proportion of the total bending moment is resisted by bolt action perpendicular to the grain of the wood, high shearing stresses must occur in the pads—as was evidenced in the tests of the joints of type II by the fact that all the first failures were caused by horizontal shear. Further tests and study are needed on splices of this type if a definite and rational method of design is to be determined.

The strength ratios obtained in these tests were adequate—even large. Both types of joints supported approximately the same ultimate loads, but the joints with the side pads were much stiffer. In all these tests, failure occurred in the splice pads, and not in the bolts. Probably the same loads could have been supported by using fewer bolts. In type II joints, it is probable that even larger loads could have been obtained by increasing the thickness of the pads, thus reducing the horizontal unit shearing stresses. In type I joints, secondary bending stresses, usually neglected in design, were the primary causes of failure.

Butt-Block End Joints of Trusses.—Two butt-block end, or heel, joints of identical design (J35 and J36), removed from the 80-ft span roof trusses of the Mission Trails Building, were tested to failure. They formed the connection of the lower chords of the trusses to the building columns. In each joint a heavy butt block supported the end diagonal and was connected to the lower chord with six 4-in. split rings. The members were of select structural Douglas fir, and the joints were tested at a moisture content of 17%. A detail of one of the joints is shown in Fig. 67. Unfortunately for the test results, the butt blocks were of boxed-heart material; and, although aluminum paint had been applied to their ends, considerable checking had occurred.

Joint J35.—In the test of joint J35, when the end diagonal, member No. 1, carried a total of stress of 95 kips, the member was forced about $\frac{3}{16}$ in. into the beveled face of the butt block; and, when its stress had reached 111.5 kips, the indentation had increased to $1\frac{5}{8}$ in. The block itself sheared and split along check planes that followed the rays of the boxed heart. The maximum slip of the split rings was 0.05 in.

FIG. 67.—BUTT-BLOCK END JOINT J35

Joint J36.—In the test of joint J36, to prevent failure by crushing the beveled face of the butt block, a steel plate was installed at the end of diagonal member No. 1. During the test this steel plate was pressed into the block about ½ in., and the block was sheared on a horizontal plane about halfway up the beveled cut. In spite of these failures, the loads did not decrease appreciably, and the maximum load was recorded after the shearing occurred. This condition was undoubtedly caused by the action of the steel plate in reducing the shear on the plane of failure.

When the maximum load on the joint had been reached, it was noted that the reaction bearing of the supporting post (member No. 3), which had replaced the original column for testing purposes, had been pushed into the lower chord member from about 1¼ in. to 1½ in. At this time no further increase in load could be obtained, but the joint continued to hold the full load for about 1 hour, at which time the test was discontinued.

TABLE 19.—BUTT-BLOCK HEEL JOINTS

Allowable, or Working Loads and Stresses:

Longitudinal shear, in pounds per square inch	150
Bearing stress at 45° with the grain, in pounds per square inch	563
Bearing stress at 70° with the grain, in pounds per square inch	380
One split ring, in pounds per split ring	5,500

Joint	MAXIMUM LOAD STRESSES					REACTION BEARING (70° CUT)		RATIO R_{wa} BASED ON		
	Shear			Beveled Face of Block (45° Cut)				Shear in the block	Bearing 45° on the block	Bearing 70° on the chord
	Six split rings[a] (kips)	One split ring[a] (kips)	Unit shear at base of block (lb per sq in.)	Total load (kips)	Stress (lb per sq in.)	Total load (kips)	Stress (lb per sq in.)			
J35...	75.8[b]	12.6	277	111.5	1,640	86.0	574	1.85	2.93[e]	1.51[e, f]
J36...	96.2[b]	16.0	296[c]	139.5[d]	1,453[d]	105.7	729	1.97	2.57[e]	1.91[e]

[a] Neglecting friction effects. [b] Split rings did not fail. [c] The base block sheared at this load but the load did not decrease. [d] Steel plate had been added. [e] These factors are of doubtful value since the working stress in bearing, on inclined planes, should be based on the indentation in the wood. [f] Did not fail.

Results of Tests.—The results of the tests are summarized in Table 19 in which the various maximum and working loads and stresses, corresponding unit stresses, and ratios R are shown. The working stresses of 563 lb per sq in. and 380 lb per sq in. (Table 19) are based on the formula developed by R. L. Hankinson:[6]

$$N = \frac{PQ}{P \sin^2 \theta + Q^2 \cos^2 \theta} \qquad (1)$$

in which P is the allowable unit compressive stress parallel to the grain; Q is the allowable unit compressive stress perpendicular to the grain; N is the allowable unit compressive stress at angle θ to the grain; and θ is the angle to the grain of applied load.

Joint J35 failed by shear in the butt blocks after the diagonal had been impressed about 1⅝ in. into the 45° cut of the block. The split rings were intact whereas the block was completely split.

As in joint J35, the block in joint J36 was split, and failed in shear; but the load did not decrease. The reaction bearing (the post) sank 1¼ in. into the 70° bevel cut of the chord. Despite the steel plate, the 45° bevel dug an impression ½ in. deep.

If the working load for which the end diagonal was designed is taken as the inclined component of the working capacity of the six 4-in. split rings, which fastened the butt block to the chord, such axial and diagonal stress would have been 46.5 kips. The corresponding unit stress on the beveled face of the butt block would have been 580 lb per sq in.; and the corresponding unit shearing stress in the block, 150 lb per sq in. Judged by the failure of the butt block, these working stresses were too high for the quality of butt block used. A bearing stress of 450 lb per sq in. and a shearing stress of 90 lb per sq in. would have been more in order. These values would have given R-values of about 3, based on the ultimate shearing stress and on the butt-block bearing stress at which an indentation of $\frac{3}{16}$ in. was observed. A boxed-heart stick should not have been used for so important a member as the end butt block, for such a stick is liable to serious checking.

---

[6] "Investigation of Crushing Strength of Spruce at Varying Angles of Grain," *Circular No. 259*, U. S. Air Service Information, Washington, D.C., 1921.

Even had the block been of sound material, failure at such comparatively low unit stresses leads one to question whether the generally accepted working stresses for longitudinal shear in joints and bearing on inclined surfaces are not too high. Probably the detail of block could have been modified to provide a lower shearing stress; but, to reduce the bearing stress, a larger end post would have been necessary.

Fig. 68.—Strap and Pin Joints—Joint J37

Strap and Pin Joints.—Tests were made of three joints of similar design (J37, J38, and J39) in each of which a pair of steel pin plates were bolted to each member entering the joint; and each pair of pin plates was then connected to a single pin. One of the joints is shown in Figs. 68 and 69. The pin plates were 6 in. by ⅜ in. Each pair was fastened to each side of each wood member with 1-in.-round bolts, and interconnected with a single 1½-in.-round pin. The joints were in excellent condition; and the wood was of select grade Douglas fir and was tested at a moisture content of about 15%. Joints J37 and J38 had some checks at the bolts in their diagonal tension member—member No. 3. Shrinkage was not apparent in joint J37; but shrinkage in joint J38 was estimated at about ⅜ in., whereas that in joint J39 was estimated at ⅛ in. All bolts were tight in their holes in the wood. The joints were provided with ½-in. stitch bolts as shown in Fig. 68.

The results of the tests are summarized in Table 20. Fig. 70 shows the slip of steel plates with respect to the wood in tension member No. 3, joint J39, which is the member that failed. Fig. 71(*a*) shows the typical splitting of this tension member at the ultimate load, and Fig. 71(*b*) shows the same failure after the steel plates had been removed. From Table 20, it can be noted that the *R*-values of the failed members were 3.03 in joint J37, 3.31 in joint J38, and 5 and 5.9 in joint J39. The values of the proportional limit loads were not determined. Joint J39 took a greatly increased ultimate load as compared to the loads taken by joints J37 and J38.

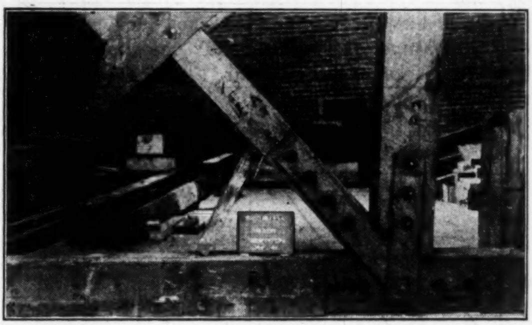

FIG. 69.—STRAP AND PIN JOINT BEFORE TESTING

TABLE 20.—BOLTED STRAP AND PIN JOINTS

Joint	LOADS ON MEMBERS, IN KIPS						Ratio,[a] R_{ba}	DAP OF BOLTS[b] (IN INCHES)		End distance[c] (in.)	Residual load (kips)	Elapsed time[d] (min)

[a] Ratio R_{ba} for member No. 3, which failed. [b] Measured on one side of joint only. [c] End distance on the first bolt at member No. 3. [d] Elapsed time of testing. [e] The tension connection used consisted of six 4-in. shear plates with ¾-in. bolts, 12-in. end distance, and 6-in. spacing. In joint J39, this connection successfully withstood 123.4 kips, the largest maximum load of the three tests. *P* for six shear plates equaled 30.5 kips without reducing for substandard spacing and 23.2 kips if reduced for 6-in. spacing. Thus, $R_{ss} = \frac{123.4}{23.2} = 5.32$.

As stated, there were checks in the tension members of these last two joints which may have lowered the ultimate loads; but it scarcely seems possible that these slight difficulties were responsible for the great difference in load-carrying capacity. After failure, in spite of the splitting shown in the photographs, the joints continued to carry considerable load, as shown in Table 20.

After dismantling, it was found that the bolts nearest the pins were bent the least, whereas the bolts farthest from the pins had larger deformations, possibly due to the action of the stitch bolts. During the tests the members began splitting at the ends; therefore, it is believed that, if the stitch bolts had been placed at the ends of the members, their ultimate loads would have been greater. The excess of the ultimate loads of joints J37 and J38 is unexplainable, except perhaps that it furnishes an example of the old adage that "the exception proves the rule." The increased capacity is apparently not the result of a better quality of wood. Member No. 3 of joint J39 had a boxed heart; it had 25% summerwood as against from 30% to 50% summerwood, respectively, in the

same members of joints J37 and J38; and it had twenty rings to the inch as compared to fourteen and thirty eight, respectively, in joints J37 and J38.

Bolted Joints with Steel Straps.—Tests were made of two joints of identical design taken from the East Cambodian Towers in which the members were interconnected by steel straps and bolts as shown in Fig. 72.

Diagonal member No. 3 consisted of two 3-in. by 14-in. sticks with an 8-in. by 14-in. filler block between. The member was connected to two steel straps, each $\frac{1}{2}$ in. by 12 in., with three $1\frac{1}{8}$-in. bolts. The horizontal member (member No. 1) was a 14-in. by 16-in. stick with four $1\frac{1}{8}$-in. bolts connecting to the same steel straps, the bolts bearing at an angle of $34\frac{1}{2}°$ to the grain of the member.

FIG. 72.—BOLTED JOINT WITH STEEL STRAPS

Vertical member No. 2, an 8-in. by 14-in. stick, bore on a steel plate on the top of member No. 1 and in addition had a steel tension connection to the same member. Joint J40 is detailed in Fig. 72. The wood of both joints was of select structural grade of Douglas fir in good condition. The measured shrinkage amounted to about $\frac{1}{16}$ in. in 14 in. of width. At the time of testing the wood had a moisture content of about 15%.

In the test of joint J40, the tension connection was made to the two 3-in. by 14-in. diagonals using the 8-in. by 14-in. block between them as a filler. In the test of joint J41, the pull was applied directly to the 8-in. by 14-in. stick, so that the two 3-in. by 14-in. sticks acted as loose fills in the transfer of loads to the steel plates. In joint J40, failure took place not in the original joint, but in the new tension connection of member No. 3.

In the test of joint J41, loads were applied until the deformation became so large that the joint merely yielded without further increase in load. Consequently, the test was discontinued because of these large deformations, with the joint still holding its maximum load. The joint was then taken apart and

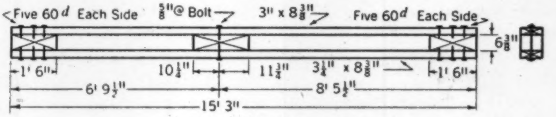
[a] The tension member. [b] Three bolts, loads parallel to the grain. [c] Four bolts, loads at an angle of 34½° to the grain. [d] Not evident. [e] Through two loose filler plates. [f] Includes loose filler plates.

the blocks split open to observe the deformations of the bolts, which amounted to 1½ in. at points of maximum bending. Fig. 73 shows the stress-deformation curves of the joints and Table 21 summarizes the results. The slips of bolts in both joints at their allowable loads were the normal slips (about 0.05 in.), but the influence of the loose fillers in joint J41 is evidenced in the much larger slips of the bolts in this joint at their maximum load.

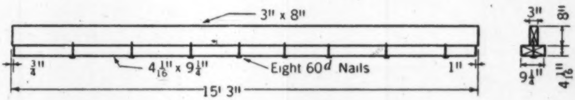
III. Column Tests

Built-Up Columns.—

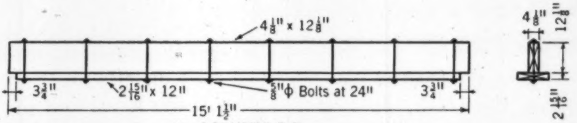
Spaced Column and T-Section Columns.—Because of financial limitations, the somewhat extensive original program of tests of built-up columns and struts had to be curtailed so that only three built-up columns were tested; however, they represented three separate types.



(a) COLUMN C 1



(b) COLUMN C 2



(c) COLUMN C 3

Fig. 74.—Details of Built-Up Timber Columns

Column C1, taken from the Mission Trails Building, was made of two 3-in. by 8-in. sticks spaced 6 in. apart, held together at midheight by a block with a single ⅝-in. bolt and at the ends by end blocks fastened only by nails. Column C2 was from the San Francisco Building, and column C3 was from the Mission Trails Building, where it had formed the top chord of the bracing truss for the main framing of this building. Each of the two columns consisted of two sticks forming T-sections, the two pieces of column C2 held together by nails and those of column C3, by bolts. Details of the three columns are shown in Fig. 74. The columns, about 15 ft long, were of select structural grade of Douglas fir and were tested at a moisture content of about 15%. The shrinkage of column C1 was estimated to be about ⅜ in., and that of column C3 was from about ⅛ in. to ¼ in.

The ends of all columns were carefully squared. In columns C2 and C3 of the T-section, the flanges of the T-section were cut back about 2 in. so that the loads would bear on the vertical web only. All three columns were installed horizontally in the testing machine and the loads applied through steel plates bearing on the ends, as spherical or rolling bearing blocks were not available. Gages were installed to measure deflections caused by buckling, as well as compression deformations. Loads were applied in increments of from 15 kips to 20 kips, about 20 min being consumed for testing each column.

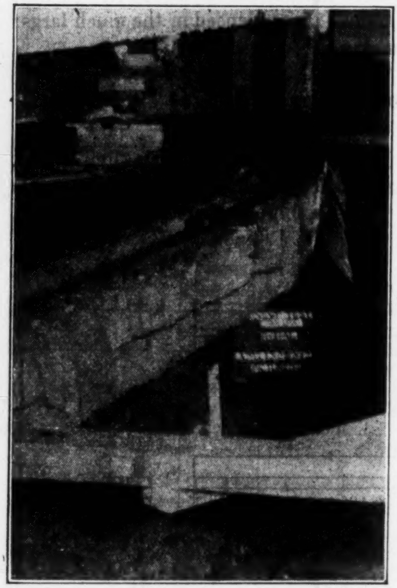


Fig. 75.—Bowing Failure of Column C1

Column C1, the spaced column, started buckling at a load of about 50 kips, but supported a maximum load of 60 kips. Then the resistance to load decreased, and the buckling increased. The manner of failure is illustrated in Fig. 75.

In testing column C2, of the nailed **T**-section, at a load of 70 kips, there was a visual indication of a sine curve with about $\frac{1}{16}$-in. amplitude. At a load of 106.3 kips, the web of the **T**-section suddenly buckled and tore loose from the flange, the nails ripping chunks of wood out of the web section.

Column C3, with a bolted **T**-section, did not fail in buckling. At a load of 182.7 kips, the head of the jack which bore directly on the web of the column crushed the wood. Just before failure, it was noted that the free edge of the web was buckling very slightly.

Results of Tests.—The results of tests are summarized in Table 22. Fig. 76 shows the relationship between the center buckling and the supported load for column C1. The column had a definite proportional limit load of 50 kips. At this load the computed value of E was 1,600,000 lb per sq in. The individual members of this column had an L/d-ratio of 61 corresponding to an L/r of 210 (L = height of column; d = least depth of section; and r = least radius of gyration). The maximum unit stress at failure was 1,146 lb per sq in.

[a] Modulus of elasticity $E = 1{,}600{,}000$ lb per sq in.; allowable $s = 1{,}200$ lb per sq in; and $L/d = 61$. [b] For the entire length of column C1, $L/d = 61$, the maximum between the block and the end being 30.7. [c] For a spaced column, using split-ring connectors. [d] $R_{wa} = 955/295 = 3.3$. [e] Loads were applied only to the web (vertical) of the T-section. [f] Buckling began at failure, web tearing loose from the flange. [g] Unit stress in the web section. [h] This specimen did not fail as a column and did not buckle. It failed by local crushing under the jack, with a bearing pressure of 6,172 lb per sq in.

The nailing of column C2 proved adequate to support the web, and the bolting of column C3 was even more effective. These three tests are too few in number to warrant drawing any definite conclusions. However, the loads that they carried are impressive, particularly when it is considered that: (1) They had seen continuous service for about two and one-half years; (2) they were fastened only with nails and bolts; (3) the shrinkage of the wood had rendered the bolts ineffective in tension; and (4) the bolts were not tightened for the tests. The tests tend to lend confidence in these types of columns, particularly for use as bracing struts, for which they are usually employed.

The characteristics of the wood of these columns as shown in Table 22 are interesting.

IV. PLYWOOD TESTS

This division of the test program comprised the investigation of plywood sheathing when used as a structural element resisting lateral forces, like winds and earthquakes. Plywood-sheathed walls were so utilized in a number of the Exposition buildings.

When the test program was first organized, it had been expected to test large plywood panels from the various buildings, but this procedure was later found to be impracticable. As an alternative, it was decided to investigate three basic requirements in the design of plywood diaphragms. Therefore, test specimens were built from plywood panels that had been exposed to the elements at the Exposition site for a period of about 2 years, and three groups of tests were made as follows:

Group 1.—Strength of nail fastenings under lateral loading.

Group 2.—On the shearing strength of plywood.

Group 3.—On the buckling of the plywood under shear loads with various spacings of studs.

All three groups of tests were run on all three of the following types of plywood:

Type 1.—Three-ply $\frac{3}{8}$-in.-thick Douglas fir plywood unpainted panels that had been used in the interior of buildings and were in fair condition. Glue was a moisture resistant adhesive of the soya bean or casein type.

Type 2.—Three-ply $\frac{7}{16}$-in.-thick Douglas fir plywood specimens removed from exterior walls. They had one coat of paint and were generally in good condition.

Type 3.—Five-ply $\frac{7}{16}$-in.-thick Douglas fir plywood specimens removed from exterior walls. They had one coat of paint and were generally in good condition.

FIG. 77.—DETAILS OF PLYWOOD NAIL SPECIMENS

Glues for types 2 and 3 were phenolic resin adhesives or phenol-formaldehyde synthetic resin adhesives.

The preceding determinations were made in the Tacoma laboratory of the Douglas Fir Plywood Association, from samples submitted by the committee.

Group One; Lateral Strength of Nails in Plywood.—An important criterion of the strength of the average plywood diaphragm is the lateral strength of the nail fastenings to the studs. Before designing the Exposition structures, preliminary tests had been made which indicated that six-penny nails used in plywood $\frac{7}{16}$ in. thick failed first by bending and then by the heads pulling through the plywood. Consequently, when a design called for heavy shears (up to about 1,000 lb per lin ft) to be carried on plywood diaphragms, special roofing nails were specified, with a heavy No. 10 gage shank $1\frac{3}{4}$ in. long, to resist in bending and bearing, and a large head, $\frac{7}{16}$ in. in diameter, to resist pulling through the plywood. For heavy loads, these nails proved to be economical since their number was reduced. These roofing nails, together with more usual types, were tested in this series.

Specimens.—Eighty-two specimens were made up as shown in Fig. 77, including the three types of plywood mentioned previously. Some were to be tested with the loads parallel, and some with the loads perpendicular to the grain of the face plies. Nails were four-penny, six-penny, and eight-penny common wire nails, and two types of special roofing nails—all galvanized. One roofing nail was $1\frac{3}{4}$ in. long, No. 10 gage, with $\frac{7}{16}$-in.-round head, and the other was identical except that its head was $\frac{5}{16}$ in. in diameter. Nails were driven "home." On specimens of type B that had less than twenty-two nails, the top nails shown in Fig. 77(*b*) were omitted. There was no change in the number of bottom nails. The interior block which received the point of the nail was cut from an 8-in. by 10-in. piece that had a moisture content of 14% and a specific gravity of 0.476. All center blocks for the specimens were cut from the same 8-in. by 10-in. piece, so that little variation in results should be expected from this source. Special care was taken in cutting and assembling the specimens to have square cuts and even bearings for distributing the loads equally among the nails. Each specimen had from 14 to 22 nails, so that each test represents the average action of several nails.

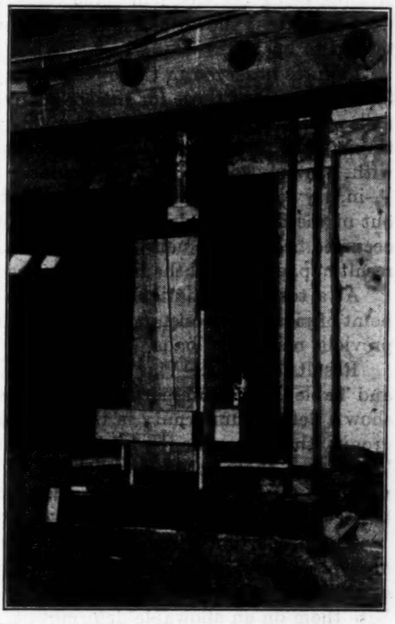

Fig. 78.—View of Plywood Nail Test Specimen in the Testing Frame

Testing.—Specimens were tested in a special part of the large testing frame, using a 20-ton hydraulic jack for applying the load. A view of a specimen in the testing frame is shown in Fig. 78. Two Federal dial gages were used, with the wood mountings as shown in the photograph. These gages were attached to the specimen to measure the deformation between the center block and each piece of plywood.

Because hand pumping was used with the hydraulic apparatus, the speed of testing was indeterminate. Pumping was done at an approximately uniform rate. It required from about 2 min to 2½ min to reach the limit of the dial gages—indicating a deformation of about 0.25 in. Dials were then removed and about 2 min more were required to reach a total deformation of from ½ in. to ⅞ in., at which point the tests were stopped.

Type A specimen (see Fig. 77) was used for all the first tests. Trouble was experienced with some of these specimens, in that the plywood failed in column action, before the nails failed. To remedy this condition, type B specimens were used because of their increased compression area, the number of nails being decreased in some cases. Some specimens with heavier nails were braced, as shown in Fig. 78, to prevent a side movement if the plywood tended to buckle.

Failures observed in these tests were of three types. The majority of the failures—most of those for the six-penny, eight-penny, and the special roofing nails with $\frac{5}{16}$-in. heads—occurred because the nails bent and then the head pulled through the plywood. This also happened in the case of the four-penny nails with ⅜-in. plywood. In the remainder of the four-penny nail tests, on the $\frac{7}{16}$-in. plywood, failure generally occurred because the nail bent and then pulled out of the block to which the plywood was nailed. The third type of failure occurred because the nails bent and then the heads broke and pulled off. This result happened in all the tests of the special roofing nails with the $\frac{7}{16}$-in. heads.

At a total deformation of from ½ in. to ⅞ in., all the nails had passed the point of maximum resistance and were yielding while supporting less than their previous maximum loads.

Results of Tests.—Fig. 79 contains the load-deformation curves of the tests and Table 23 is a summary of the results. The individual tests of each group show a definite uniformity in the great majority of cases. In ten of the fifteen groups, the values for the loads acting at 90° to the grain of the face plies are larger than those acting parallel. This condition is most noticeable for light nails and for the three-ply plywoods. In the case of the five-ply plywood and larger nails, these values are closer together.

The proportional limits of the nail strength values, as given in Table 23, are very approximate since nail tests invariably yield irregular curves. In establishing safe working nail values for practical uses, it appears desirable to base them on an allowable deformation, such as 0.01 in.

Further economies in plywood construction might be realized if nails with heavier shafts and larger heads were to be manufactured. Economies in labor as well as in materials would also result since large nail spacings could be used.

Group Two; Plywood Shear Tests.—The shear resisting ability of the plywood in plywood diaphragms is of importance; yet few data on this subject are available. For this reason panels were made and tested in which the plywood had been nailed to wood studs in a most substantial manner for the purpose of

preventing either failure by buckling of the plywood sheets or failure in the nails.

Specimens.—There were three test specimens of plywood panels—a typical one is shown in Fig. 80. Exterior load-carrying members were made of wide timbers, permitting sufficient roofing nails to be applied at each edge so that the nails themselves would not fail. The panels were also blocked to prevent the plywood from buckling. Fig. 81(*a*) shows the top. At the two corners, where loads were not applied, a gap was left so that the frame itself would not carry any load. Loads were applied directly to the frame on two of the diagonal corners. To prevent bearing of the loads on the plywood itself, edges were clipped on a diagonal thereby providing bearing for plates on the frame only.

The general setup is shown in Fig. 81(*b*). The hydraulic jack is shown at the left, and the reaction into the testing truss at the right is taken through a short heavy beam. Gages were installed as indicated in Fig. 80(*b*). One dial gage A measured the lengthening of the tension diagonal, and another gage B measured the shortening of the entire frame from timber to timber as close to the corners as was practicable. Four gages were installed to measure the nail slip. As these slips were small and correspond to the series of tests on nails, the results are not discussed. Fig. 81(*b*) shows the dial gage setups as seen from the back of the machine. Testing procedures for each panel were as follows:

FIG. 80.—TEST SETUP, PLYWOOD SHEAR TESTS
(*a*) Construction of Specimen
(*b*) Location of Gages

Test No. 1; Three-Ply Panel, ⅜ In. Thick.—This panel was placed in the machine and loaded with a 50-ton hydraulic jack. In the first 21 min of testing, the deformation at gage C, measuring the total frame and panel deformation, was 0.331 in. At this point, with 19,800 lb on the panel, the dial gages were removed and the loading continued until a deformation of about 1 in. was obtained after an interval of about 5 min. At this time the panel failed in shear at a load of 23,000 lb, corresponding to a shear of 2,571 lb per ft, or 575 lb per sq in. At failure, the panel split lengthwise in many fine lines. After failing, the panel still held a load of about 19,800 lb.

Test No. 2; Three-Ply Panel, $\frac{7}{16}$ In. Thick.—This panel was loaded in the same manner as in test No. 1. In the first 20 min of loading, gage C registered a total deformation of 0.241 in. Failure was reached in 6 more min with a total deformation of 0.380 in. at a load of 37,500 lb, corresponding to a shear of 4,068 lb per lin ft, or 775 lb per sq in. At this point, the panel completely "tore" at the third points. Loading was continued until a deformation of 2 in. was noted, the load dropping gradually to about 20,000 lb, which was maintained until the end of the test. After the load was removed, the panel looked as shown in Fig. 82, with offsets of about $\frac{3}{4}$ in.

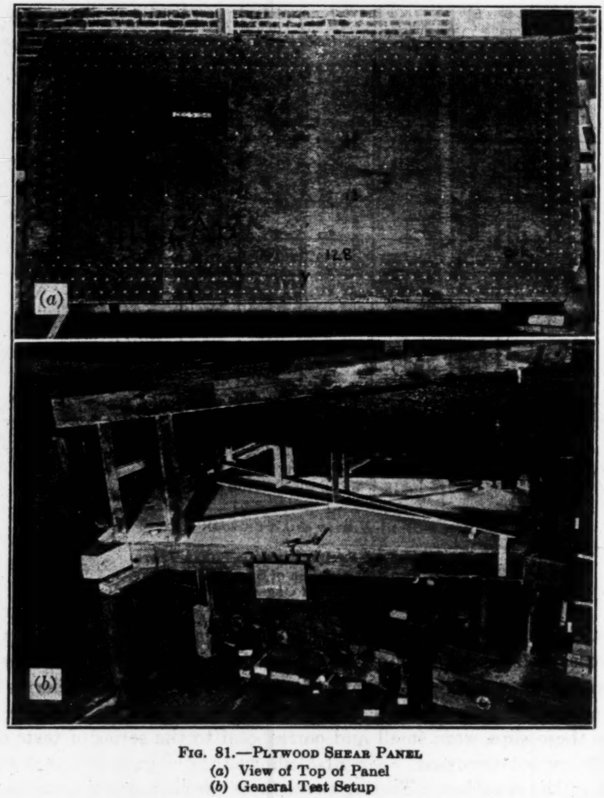

Fig. 81.—Plywood Shear Panel
(a) View of Top of Panel
(b) General Test Setup

Test No. 3; Five-Ply Panel, $\frac{7}{16}$ In. Thick.—The panel was installed in the testing frame and testing was started with a 20-ton jack. Loading was begun and 24 min were required to reach a maximum load of 32,170 lb, with a deformation of 0.239 in. at gage C and a corresponding shear of 3,597 lb per lin ft. Since it was found impossible to increase the foregoing load because of external conditions, it was released, noting a permanent deformation of 0.043 in. at gage C. No detrimental effects were noted. The following day, testing continued with a 50-ton jack which required 20 min to show a total deformation of 0.278 in. at a load at failure of 51,300 lb—corresponding to a shear of 5,736 lb per lin ft or 1,090 lb per sq in. Failure consisted of a single tear down the middle of the panel.

Fig. 82.—Shear Failure of Three-Ply Panel, $\frac{7}{16}$ In. Thick

Results of Tests.—For all three panels, Fig. 83 shows curves relative to the lengthening and shortening of the diagonals under load in terms of a 12-in. gage length and shears per linear foot acting on the plywood. The horizontal displacement of the wall (Δ) caused by plywood deformation can be computed with the aid of these curves and the formula:

$$\Delta = 2.5\, K\, L \qquad (2)$$

in which (see Fig. 83(*b*)) L is the height of the panel; and K is a factor derived from the curves (deformation at design shear). All the times given in Fig. 83(*c*) are for deformation on the compression diagonal. It may be noted that the tension diagonal deformed slightly more than the compression diagonal, which seems to agree with other tests on timber and plywood. Deformations, caused by shear in the plywood, are relatively small, especially compared to nail slips. In most designs they may be neglected.

Table 24 presents a summary of ultimate loads and deformations. According to these tests, five-ply plywood, as compared with three-ply plywood of the same thickness, has about 40% greater ultimate shearing strength. The results of these tests would indicate that the capacity of plywood in shear has

not been fully utilized because of the difficulty of making adequate connections. This deficiency may be remedied by the use of specially manufactured nails, as previously mentioned, by gluing, or by some other equally efficient method. Because of the increase in the use of plywood, these problems appear to be worthy of further study so that its potential strength values can be utilized more economically.

Group Three; Plywood Buckling Tests.—This group of tests included the investigation of plywood panels in which the buckling of the plywood itself

TABLE 24.—SUMMARY OF RESULTS, PLYWOOD SHEAR TESTS, GROUP 2

Plywood	Load on panel (lb)	Shear		Total Deformation,[a] Gage C (in Inches)		
		(Lb per lin ft)	(Lb per sq in.)	1,000 lb	2,000 lb	Ultimate load
Three ply, $\frac{3}{8}$ in. thick	23,000	2,571	575	0.085	0.28	0.469

[a] In only five cases (Nos. 1, 2, 4, 10, and 11) was there any visible tendency to buckle. The nails failed in each case (except as noted by footnotes [b] to [g]). [b] Ultimate nail value (pounds per nail). In specimens Nos. 1, 4, 10, and 11 the nails were not the cause of failure (see footnote [a]). [c] Failure by buckling only. [d] The specimen buckled first and then the nails failed. [e] Ragged edges and ragged spots on top and left sides (see Fig. 84(*c*)). [f] The buckling test was stopped when the load on the specimen would increase no further. [g] Failure was by buckling but the nails were well bent and pulling through. [h] Failure was by nails pulling through the plywood. [i] Test was stopped when the clipped edges touched each other. [j] Nails did not fail completely.

Specimens.—The eighteen panels, measuring 4 ft by 8 ft, were constructed as shown in Table 25 with Figs. 84 and 85. Greater than usual edge distances of the nails were used because all plywood sheets already had a series of nail holes at the edges. In addition, some of the edges were slightly ragged. As in the shear tests, a space was left between framing members to minimize the amount of load that the frame itself would carry. Edges of the plywood were clipped so that no part of the jack or reaction forces would bear directly on the plywood, routing forces thereby through the frame and the nails. The plywood was fastened to the frame with special roofing nails (No. 10 gage 1¾ in. long, with $\frac{5}{16}$-in. heads) spaced 3 in. center to center at the edges and 8 in. center to to center on interior contacts. All nails were driven "home."

FIG. 85.—CORNER DETAILS AND KEY TO TYPICAL DIMENSION IN TABLE 25, FOR ALL BUCKLING TESTS

Testing.—The panels installed in the testing frame were like those used in the shear tests. Loading was applied with a 20-ton hydraulic jack, in a manner similar to that described for the shear tests (Fig. 81(*b*)). Gages were placed at the four edges of the plywood to measure the nail slips. Braces were required to hold the frame in position. Since the web is off center from the chords, the near corner of the panel (Fig. 81(*b*)) tends to move up whereas the corners under the jack and reactions tend to move down. Loads were applied in increments, interrupted long enough to take readings of the dial gages. Panels were tested to failure, or until the deformations were large enough that the edges of the plywood bore on the bearing blocks at the reaction of the jack.

Thirteen of the eighteen panels failed by yielding of the nails (Table 25), most of them pulling through the plywood. In a few cases, the nails pulled out of the studs. In these thirteen tests, several panels failed after holding loads at large deformations for some time. Final failure sometimes occurred from a secondary effect, the block nearest the jack rotating and splitting at large nail deformations. In five specimens, failure is attributed to buckling, as shown by the contours and deflection readings in Table 26.

[a] Deflections are given for the points shown in the accompanying diagrams. [b] Loads on the panel, in pounds, at the time of observation.

Results of Tests.—The data on each test panel together with ultimate loads, manner of failures, etc., are shown in Figs. 84 and 85, and in Tables 25 and 26.

Average test values for all panels at various stud spacings are as follows:

Stud spacing (in.)	Ultimate stress (lb per lin ft)
48	1,889
24	1,875
16	2,025
Average	1,928

From these tests, it appears that a working load of 500 lb per lin ft for plywood ⅜ in. thick is allowable since it would provide a ratio R_{wa} of 3—the lowest ultimate load recorded being 1,509 lb per lin ft. Even in the panel failing at that load, failure occurred in the nails and not in the panel.

The addition of intermediate blocking seems to have had little, if any, effect upon the strength within the limited range of stud spacings and plywood thicknesses investigated.

These tests were not sufficient in number or scope to be conclusive in determining critical buckling proportions even in stud spacings as large as 4 ft.

The ultimate nail values obtained in the buckling tests are comparable with previous nail tests. For example, the average ultimate strength of a special roofing nail with $\frac{5}{16}$-in. head as found in the nail tests of group one was 505 lb per nail; and the average for the buckle tests of group three was 508 lb per nail in those tests in which the nails caused failure.

Conclusions on Plywood Tests.—The following two conclusions on the plywood tests seem justified: (*a*) The value of plywood as a diaphragm to carry large loads, even where panels are as thin as $\frac{3}{8}$ in., appears to be established beyond reasonable doubt; and (*b*) the use of stud spacings larger than the customary 16 in. or 24 in. appears to be possible.

Because of the financial limitations of this program, other contemplated features of plywood panel construction could not be investigated. These further studies are recommended to the consideration of others. Among them are the following:

I. The buckling resistance of plywood beyond the scope of the present paper;
II. The strength of plywood panels in which the edge distances of nails are $\frac{1}{2}$ in. or less, as is the case where 2-in.-wide studs are used;
III. The capacity of nails when plywood panels are nailed to each other rather than to studs or posts; and
IV. The characteristics of large plywood panels, with and without openings, using details of construction as found in current best practice, particularly where bottom sills are bolted to foundations.

DISCUSSION

James H. Carr, Jr.,[7] Assoc. M. ASCE.—Much has been added to the knowledge of timber design and construction by this interesting study, which has already resulted in further studies being made by those who had advance information on the results. The Timber Engineering Company, one of the sponsors of the San Francisco (Calif.) study, for three years has been carrying on a series of tests on full-scale trusses, has completed a series of tests on eccentric joints, and has developed, therefrom, an empirical formula. In addition, it has sponsored research at the Massachusetts Institute of Technology at Cambridge on the distribution of stress around timber connectors.

There are three treatments in the paper with which the writer did not agree at the time of preparation. The first of these is that in many places in the paper the factors relating test load to design load are given when the failure was not directly connected to the design load used. In such cases, the factor given represents only the minimum amount of test load to which the section of the truss was submitted and does not indicate the maximum load it might sustain. The factor therefore is meaningless.

The second is that the comparisons in regard to allowable connector values are based on data published in 1939, although the original designs were not prepared on the basis of these data, but on data published in 1935. It is believed that it would have been more correct to compare either with the 1935 data or with the recommendations published in 1943, which were in effect, and current practice, at the time the report was in preparation, and which continue to be recommended and used in 1947.

The third is that much of the paper centers around a so-called factor of "tension perpendicular to grain," occurring particularly in eccentric joints. The writer disagreed with this theory at the time the report was in process and stated that he felt the tests indicated and closely followed another theory, advanced by Everett Lank, that the shear theory for notched beams more closely fitted the data. The authors, while stressing the "tension perpendicular to grain" theory, offer no design approach. Mr. Lank has subsequently been proved correct by a series of tests[8] substantiating the shear theory, and an empirical formula for design application based on this theory has been developed, as follows:

$$\frac{3}{2}\frac{V}{b\,d_e} = 1.5\,H \qquad (3)$$

in which V is the total vertical shear; b is the width of the section; and d_e is the effective depth of the section, or the distance from the inside edge of the connector (nearest the unloaded edge of the member) to the loaded edge of the member.

Application of these three comments to the data presented brings forth the results given hereafter. In order to simplify the presentation, all values of R_{ca} as developed in the paper for the 1939 data and those based on the 1943 data, published by the National Lumber Manufacturers' Association,[9] are given in Table 27.

---

[7] Secy., Timber Eng. Co., Washington, D. C.

[8] "Tests of Eccentric Split-Ring Joints Yield Rational Design Formula," by R. H. Glass, *Engineering News-Record*, May 29, 1947, pp. 69–70.

The report states the first failure for truss TB–1 is at joints U1 and L10. It is not clear as to just what the initial failure was. However, a comparison on current data gives the result shown in Table 27(*a*).

Applying the shear formula to the French Building truss at failure, the 1943 factor becomes 2.56 (Table 27(*b*)) as against the 1939 factor reported, based on connector values (which did not fail) of 1.7, an appreciable increase.

In the Merry-Go-Round Building trusses the lumber failed and not the connector joint, hence the *R*-values are not true results. However, based on current recommendations the factors of Table 5 become those shown in Table 27(*c*).

As to the discussion of theoretical stress around a connector (under the heading, "Merry-Go-Round Building (M) Trusses"), a paper to be presented at the 1947 Fall Meeting of the Society on tests conducted at the Massachusetts Institute of Technology, under the direction of Prof. Albert Dietz, Assoc. M. ASCE, discusses data developed by use of stress coats and electrical strain gages. Current recommendations include factors developed in these tests; connectors of improved design have also been developed and are now available.

In the North Square Court truss tests the failure was due to eccentric joints and hence the shear formula applies. Factors secured by this method show that for joint L3 the 1943 factor is 2.43. Although they do not reflect the true failure, the factors on the 1943 data would correct the factors in Table 6 to those given in Table 27(*d*).

Also, in Table 8, the changes in factors, where applicable, based on the 1943 data would be as shown in Tables 27(*a*), (*b*), (*c*), and (*d*). The writer disagrees entirely with conclusion 6 (see heading, "Comments on Tests of Trusses") as

[a] Based on shear formula. [b] Connectors did not fail. [c] Not true factors, as grooves sheared and test setup failed. [d] Tests not carried to failure of connector joints.

---

[9] "National Design Specification for Stress-Grade Lumber and Its Fastenings," National Lumber Mfrs. Assn., Washington, D. C., 1944.

it is believed that eccentric joints may be properly and capably handled with the shear formula.

On the basis of the 1943 data, the factors in Table 9 should be corrected as shown in Table 27(*e*). Based on the shear formula application, the 1943 factor for test joint J1 becomes 3.3. However, if connector factors must be considered, the factors are changed as shown in Table 27(*f*). As regards the tests of joints with ring connectors, the factors given in Tables 13 and 14 should be corrected to the 1943 values, as shown in Table 27(*g*).

After eleven years' experience, the writer feels that the comments or conclusions on the tests of joints with steel gusset plates are broader than the data available.

However, in view of the results of this program, it is this writer's opinion that the designer who uses the 1943 recommendations, including the shear formula, is assured of factors which are more than safe when based on these tests inasmuch as the smallest corrected true factor is 2.43, whereas a factor in the neighborhood of 2 would be considered sufficient by experienced timber designers and research men.

Howard J. Hansen,[10] Assoc. M. ASCE.—The descriptions of the equipment used and the methods of testing are quite complete, and will be valuable guides in future tests of full-scale trusses and joints involving eccentricity and loads at an angle to the grain. In most cases, the tests of any one type were too few in number and the variables too involved to provide an exact design procedure for similar types. The writer is, however, much pleased that this extensive test program has been published and is particularly interested to note that the complete report including test data, curves, field notes, photographs, and calculations is filed at several strategic points throughout the United States.

The sudden failure under test loads of the Cavalcade cantilever truss (TC) and the detailed examination of joints in other trusses again emphasizes the need for competent engineering supervision of timber structures if the factor of safety expected in design is to be provided in actual construction. This same fact was brought out during World War II when timber structures were built with little or no competent engineering inspection and investigations of several failures showed that failure was due to improper construction.

The R_{ca}-values calculated for the Brazil Building (TB) trusses did not include the bending effects of the chords. This fact was noted in the report. However, since the stresses due to bending could be rather high, they should have been included in the computations of the R_{ca}-values. The fact that the nature of the failures in the joints of these and other trusses emphasizes the importance of secondary stresses is significant. It is believed that many typical designs of shallow timber trusses have not been checked for secondary stresses in the past. The authors mention the need for additional tests on joints in which a combination of shearing stress, direct stress, and bending stress is involved. This is one of the greatest needs in the field of timber engineering and additional experimental data on combined stresses will aid materially in the development of more efficient and economical design in timber.

---

[10] Prof. of Mechanics and Acting Head, Industrial Eng. Dept., Univ. of Florida, Gainesville, Fla.

Although the data on the lateral strength of nails in plywood are worthwhile and may be used as a guide for further experimental investigations, considerably more data on nailed construction are definitely needed. The tests covered in the report do not include a wide enough range in nail sizes, spacing, and end and edge distances to predict the behavior of nailed joints other than those tested.

TABLE 28.—COMPARISON OF R_{ca}-VALUES FOR JOINTS AS BASED ON 1939 AND 1943 ALLOWABLE LOADS

Joint	R_{ca}		Col. 2 − Col. 3[a]

[a] Excess or deficiency of 1943 values over 1939 values.

As noted in the report, the buckling tests of plywood panels were not exhaustive enough to provide design details. The conclusion that stud spacing may be increased beyond the customary 16 in. or 24 in. seems feasible, but additional tests on Douglas fir structural plywood should be conducted along the lines investigated by the United States Forest Products Laboratory at Madison, Wis., on aircraft plywoods.

TABLE 29.—VALUES OF *R* FOR SHEAR TESTS OF DOUGLAS FIR PLYWOOD

Sheathing	1,090	360	3.03

[a] "G" denotes "Good"; "S" denotes "Side"; and "So" denotes "Sound."

In the joint tests the factor of safety of each joint was calculated on the basis of recommended allowable loads from the TECO manual.[1] A comparison of the R_{ca}-values based on a later TECO manual[11] is given in Table 28.

There are several questions that have arisen from the study of this report and it is believed that the value of the report will be enhanced if the answers to these questions are given. The questions are:

1. What approximate method was used in computing the stresses in the members of an eccentric joint?
2. How was the lower chord splice of truss TM-2 reinforced before testing?
3. Why were blocks added to joint J1 under test loads? Would this give a true picture of the type of failure for this joint?
4. Cannot some explanation for the large difference in movement of the gusset plates in joint J2 be given?

---

[11] "Design Manual for Teco Timber Connector Construction," Manual of the Timber Eng. Co., Inc., Washington, D. C., 1943.

5. Is the statement under the heading, "II. Joint Tests: Comments on Tests of Joints with Steel Gusset Plates: (10)," that "* * * in these tests the load was always parallel to grain" correct?

The values of *R* based on the ultimate shear loads for various thicknesses of Douglas fir plywood, as obtained by the test results given in the report and the allowable stresses for various grades of Douglas fir plywood, are given in Table 29. The report does not mention the grade of plywood used and the values in Table 29 may prove valuable as a comparison of the *R*-values for the different grades.

In conclusion, the report is a valuable contribution to the literature and design data pertaining to timber structures, as well as an indication of the need for more full-scale tests of timber trusses, joints with combined stresses, nail tests, and structural plywood tests of all types. It is true that no two identical timber trusses or joints will behave exactly the same under load; but, as more tests of this nature are conducted, the results can be correlated with those contained in this report.

E. G. STERN,[12] Assoc. M. ASCE.—The report of the committee contains much valuable information for timber designers and fabricators of timber structures. It is of interest to learn what comments designers and fabricators of the tested timber structures may make; whether their assumptions, theories, and computations were verified by the test data, and which theories were contradicted. It is believed that additional valuable information could be obtained from the designers and fabricators if a review of their designs and construction logs could be made available on the basis of the test data obtained.

The fabricators probably can give the answer to this question: Were split rings and shear plates, respectively, omitted purposely in joints L7, L8, and L9 of truss TB-1, and in joint J8 because they were considered unnecessary?

Several of the findings seem to confirm the previously made assumption that, during initial loading and failures of a minor nature, adjustments take place in the local and secondary stresses—often anticipated but not included in detailed computations—which result in reduction and more uniform distribution of such internal stresses and, thus, make the structure safer than it was before adjustments took place. Although such adjustments may increase the load-carrying capacity of the structure, the deformation and total deflection may also be increased beyond those computed. Rolling shear of the core within split rings may often be accounted for as a result of such adjustments.

It is hoped that the appropriate industry will sponsor performance of some of the recommended, additional tests in order to secure the needed information. It cannot be expected that engineers or architects will employ timber structures as long as some of the basic design data are lacking and not available to them. Industry may be reminded that several United States technical institutions and universities are willing to assist industry in obtaining such vital data by assigning specific problems to graduate students interested in timber structures or by assigning their experienced staff to industry-sponsored projects.

---

[12] Associate Prof. and Head, Wood Constr., Virginia Polytechnic Inst., Blacksburg, Va.

Melvin W. Jackson,[13] **Jun. ASCE.**—The San Francisco Timber Test Program Committee calls attention to the necessity of considering tension perpendicular to grain for the correct design of timber joints, but it does not suggest how this may be taken into consideration. The problem raised is apparently an unsolved one. In testing approximately 250 ring-connectored timber joints of the type shown in Fig. 86, the writer obtained some information pertinent to this case.[14] The test specimens were intended to simulate conditions in a truss joint of the type shown in Fig. 36. The investigation was partly an outgrowth of a previously published report of this type of failure.[15]

In the test specimens (Fig. 86) member Nos. 1, 3, and 5 were end-matched 2 in. by 8 in. by 18½ in. long, and the cross members, A and B, were similarly end-matched, but varied in dimensions. The lower bolt was provided to prevent excessive spread of member Nos. 1 and 5 under load. Standard procedure was followed in the laboratory in installing 4-in. split-ring connectors in the faces between each member. The test specimens, to which the data given hereafter apply, were of Douglas fir, structural grade (allowable working stress = 1,200 lb per sq in.). Two general types of failures occurred in members A and B; that is, either cores sheared, or the horizontal members split longitudinally. The tests were stopped at the first indication of failure to determine the type of initial failure. It was necessary to take the joint apart to determine whether a core had sheared.

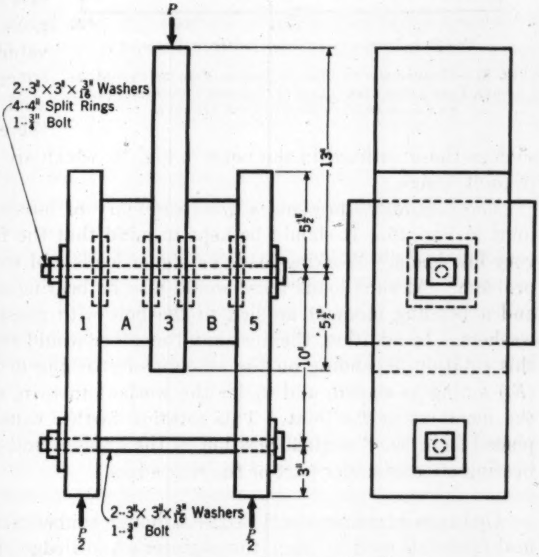

Fig. 86.—Assembly of Test Joint

Tension perpendicular to grain tests following the recommended procedure of the American Society for Testing Materials were made from members A and B, and these values and the load at initial failure in the five-member specimens were compared. Where the horizontal members were 2 in. thick (nominal dimensions) and 20 in. or more long, and where the initial failure occurred by splitting, the correlation shown in Fig. 87 was obtained. Fig. 87 indicates that there is some correlation between the strength of a timber in tension perpendicular to grain, and the load which will cause it to split in a joint of the type tested. It is apparent, however, that the problem in this case cannot be solved simply by dividing the total stress in tension across the member by an allowable working stress in tension perpendicular to grain, because doubling the strength of the material in tension perpendicular to grain does not double the load required to produce initial failure. Possible explanations of this fact may be that the law of stress distribution within the member is not known or that the member and the control tests for establishing the tension perpendicular to grain values are subject to stress concentrations not evaluated. On the other hand, there may be other factors, such as those outlined in the notes in Fig. 36, which are not usually considered in joint design.

---

[13] Champaign, Ill.

[14] "An Experimental Investigation of Some Properties of Five-Member Ring-Connectored Timber Joints," by Melvin W. Jackson, thesis presented to the Univ. of Illinois at Urbana, in 1945, in partial fulfilment of the requirements for the degree of Master of Science in Civil Engineering.

[15] "Preventing Failure of Timber Joints," by Charles Mackintosh, *Civil Engineering*, December, 1943, p. 573.

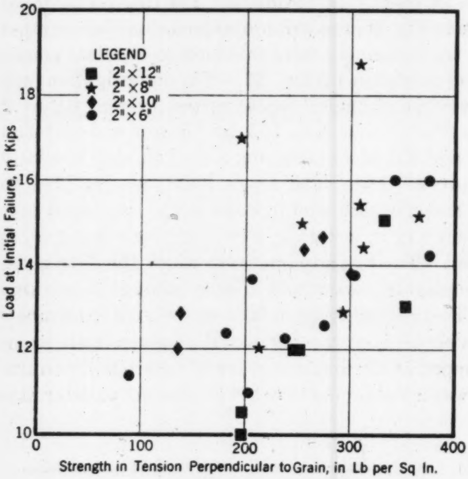

Fig. 87.—Comparison of Load at Initial Failure in 5-Member Test Joint with Tests of Tension Perpendicular to Grain in 20-in. and Longer Members

The committee presents a good summary of forces acting on the typical joint in Fig. 36. It should be kept in mind that the forces shown are under very low loads. Working loads or higher loads add to the complexity of the problem. At such loads there would also be bearing stresses under the bolt, and a bending moment applied to the bolt with resisting stresses under the washers. In addition, the horizontal member would rotate, the magnitude of this rotation depending on the amount of crushing of fibers under the forces (F_s) acting as shown, and under the washers in turn, depending on the fit of the members in the joint. This rotation further causes the rings to be displaced from their original position in the grooves and adds additional lateral bearing stresses under part of the ring edges.

Charles Mackintosh,[16] Esq.—Although timber is one of the oldest structural materials used by man, the engineer's knowledge of its proper use in large frame structures is appallingly meager. This paper makes a signal contribution to the understanding of the actions of timber joints. It makes unmistakably clear the fact that the strength of the bolt, and split-ring (or other) connection in a given joint is dependent not upon the tables of values of such connecting devices, but rather upon the nature of the connection itself and the timber in the connection.

---

[16] Cons. Engr., Mackintosh and Mackintosh, Los Angeles, Calif.

The tables of safe loads for bolts, split rings, and other connections are, in general, based upon the expected safe load when the failure is at the maximum value obtained from the most advantageous position of the connector. These tables do not generally anticipate the failure of the timbers in the connection. It is stated in the "Foreword," that nearly one half of the failures occurred "* * * because of types or combination of stresses not anticipated"—which is a most revealing evaluation of the present quality of engineering design.

The importance of secondary stress due to bending in the shallow trusses of the Brazil Building is well emphasized. This writer has found that similar importance should be attached to any condition where concentrated long-time loads occur on the chords between panel points of normally proportioned trusses. A heavily loaded beam supported between panel points on the lower chord of a timber truss may cause such a deflection over a long period of time that enough additional stress is caused by eccentricity to produce failure.

In discussing the failure of the cantilever frame in the Cavalcade Building, the paper emphasizes that oversized bolt holes may have contributed to the failure of the joint by causing some successive loading. If the effect of the oversized hole is so great when shear plate connectors are used, should not the manufacturer's recommended value be questioned? These values are based upon ultimate loads having greater movement than the tolerance caused by enlarged bolt holes. It is clear that final failure will occur if the loads which caused an initial movement of ⅛-in. are maintained for a sufficient length of time. Such failure is attributed by some timber research men to "creep" or "progressive failure."[17] In the data published relative to split rings, "* * * the loads listed as maximum are the highest loads obtained within or at a slip in the joint of 0.60 inch, beyond which the tests were continued."[18] Is not 0.60 in. much too great a slip to give any worthwhile data for the design of connector joints subject to long continued load?

In discussing the heel failures of the trusses in the Alameda-Contra Costa Counties Building, the paper states (under the heading, "Detailed Report of Tests,") that: "Failures in the blocks at these relatively low unit [shearing] stresses were probably due to the abrupt change in sections * * *." Reentrant grooves in timber for various connectors cause abrupt changes in section and greatly influence the relative safe values of long-time and short-time loads. Unfortunately, few data are available on any type of connector stressed by long-time loads. Such tests have been initiated in both Australia and the United States, but are of such recent origin that final reports are not available. Oversized holes have long been prohibited by skilled timber truss manufacturers because of the large deflection in trusses with oversized holes, rather than because of the reduced value of the connection.

The necessity of considering tension perpendicular to grain and proper end distance and spacing has been well presented by the committee, and these comments point to more complete analysis than most engineers have been accustomed to making. This analysis must be supplemented by additional series of tests such as those sponsored by most universities.[14] The fullest use of timber cannot be made until such test data are available. A practical solution may lie in a type of connector which obtains more uniform attachment to the to the wood and does not require large end and edge distances.

[18] "Timber-Connector Joints: Their Strength and Design," by John A. Scholten, *Technical Bulletin No. 865*, Forest Products Laboratory, Forest Service, U. S. D. A., Madison. Wis., March, 1944, p. 39.

Because of timber truss failures in Los Angeles, Calif., and particularly the failure of a splice in a truss using shear plates, the Superintendent of Building and Safety of the City of Los Angeles requested recommendations from the Structural Engineers' Association of Southern California. The subsequent report of this association and its Committee on Timber Research puts into usable form some of the conclusions to which the paper points.

The report recommends wider use of grade marking, straight grain tension members, the rejection of previously recommended methods [19] for computing spaced column values, greater attention to the moisture contents of lumber, calculation of tension across grain stresses and stresses due to eccentricity, and a reduction of connector values below those recommended by the manufacturers.

The authors of this paper are to be commended for the material aid that they have given to the development of a better understanding of structural design in wood.

SIDNEY NOVICK,[20] JUN. ASCE.—It is of interest to compare the results of the plywood shear buckling tests (under the heading, "IV Plywood Tests; Group 3") with the values at which failure in buckling might have been predicted on the basis of previously published information concerning shear buckling of rectangular plywood plates. The method and results of this comparison are described below.

All calculations require basic assumptions regarding the specific plywood constructions. From the descriptions in the text, it was inferred that plywood type 1 was of the sanded face ply variety, and that types 2 and 3 were unsanded; the thicknesses of the individual plies could then be found from data issued by the Douglas Fir Plywood Association.[21] Assuming the modulus of elasticity along the grain for a single ply to be 1,600,000 lb per sq in. and that across the grain to be 0.045 times the value along the grain,[22] all necessary plywood stiffness properties may be found.

A convenient method for calculating the theoretical buckling stress of a simply supported rectangular plywood plate under shear has been presented elsewhere.[23] Later empirical investigation[24] (with plates acting as webs of box beams) indicated that the theoretical stresses require correction within a given range of plate dimensions. From the empirical data the writer has derived a curve[25] from which the required correction factors can be obtained. Specific values necessary to derive factors needed for the ultimate buckling stress calculation were also obtained from other published data.[26] Values given in Table 24 were used as the maximum plywood shear stresses in these calculations.

[22] "Design of Plywood I-Beams," by Howard J. Hansen, *Transactions*, ASCE, Vol. 112, 1947, p. 955.

[23] "Buckling of Flat Plywood Plates in Compression, Shear or Combined Compression and Shear," *Bulletin No. 1316* and Supplements, Forest Products Laboratory, Forest Service, U.S.D.A., Madison, Wis., 1942–1945.

[24] "Design of Plywood Webs in Box Beams," *Bulletin No. 1318* and Supplements, Forest Products Laboratory, Forest Service, U.S.D.A., Madison, Wis., 1943–1944, Fig. 16.

The comparison of results of the foregoing calculations with the actual shear stresses at failure, the latter derived from Table 25, is given in Table 30. This tabulation shows that the scatter in the percentage variation values is large for the specimens that failed by buckling. That this behavior is typical is evident from a consideration of the Forest Products Laboratory (FPL) results:[23] For the range of plate dimensions in Table 30(*a*), the FPL data show a variation between 50% and 150% greater than the values on the empirical buckling curve (the latter, of course, taken along the lower limits of the range of values). It appears that the average fixity of plywood plates when glued or nailed sufficiently to insure shear buckling is well above the simply supported condition, but that the variations in the extent of fixity lead to large variations, not only between the actual stresses and those predicted, but also in the extent of the disagreement, so that the actual values are not in constant relation to the theoretical.

TABLE 30.—COMPARISON OF PREDICTED SHEAR BUCKLING STRESS AND ACTUAL SHEAR FAILURE STRESS IN PLYWOOD

Specimen No. (1)	STRESS (LB PER SQ IN.)		Variation of actual from predicted stress (%) (4)
	Predicted shear buckling (2)	Actual shear failure (3)	
(*a*) FAILURE DUE TO BUCKLING			
1	135	370	+174
2	170	330	+ 94
4	265	395	+ 49
10	220	475	+116
11	340	375	+ 11
Average	...	...	+ 89
(*b*) FAILURE DUE TO NAILS			
3	240	320	+ 33
5	405	440	+ 9
6	580	395	− 32
7	370	395	+ 7
8	580	340	− 41
9	850	440	− 48
12	395	410	+ 4
13	295	335	+ 11
14	445	340	− 24
15	615	300	− 51
16	370	500	+ 35
17	605	350	− 42
18	865	420	− 51
Average	...	...	− 15

From the results for the specimens in Table 30(*a*), the specimens in Table 30(*b*) might have been expected to fail in shear buckling at values proportionately above the predicted buckling stresses. It is evident that the actual failure of the nails at much lower values forestalled development of the requisite buckling stresses. Thus, the results for the specimens in Table 30(*b*) are in qualitative agreement with the behavior expected on the basis of the previously published information.

Results of the shear buckling tests reported in the paper, therefore, tend to confirm previously published data and the general method for design calculation derived therefrom. The general method, in turn, is applicable within the entire practicable range of design variables, the latter including the spacing of studs and intermediate blocking, and the thickness of plywood sheathing.

[25] *Transactions*, ASCE, Vol. 112, 1947, p. 968, Fig. 5.

[26] "Design of Wood Aircraft Structures," *Bulletin No. 18*, Army-Navy-Commerce Committee on Aircraft Requirements, U. S. Govt. Printing Office, Washington, D. C., 1942.

It should be particularly noted that by this method the value of the intermediate blocking can be found in explicit quantitative terms, making it necessary to alter the implied conclusion in the text that the value of such blocking is open to question.

FRANK J. HANRAHAN,[27] M. ASCE.—Those closely associated with this enormous, complicated test program are to be congratulated, both for their unceasing efforts in the face of great obstacles and for the important contribution made to the knowledge of timber engineering. These investigations, together with extensive research by the United States Forest Products Laboratory (Madison, Wis.), the Timber Engineering Company (Washington, D. C.), and others have resulted in substantial changes and technical improvements in engineering design recommendations. Such modifications are reflected in a design specification[9] which has been widely adopted as a design standard by government agencies and many other organizations. Among the items which were more accurately evaluated and are incorporated in this specification are the effect of end distances, spacings, edge distances, thickness of member, angle of load to grain, moisture condition of lumber at time of fabrication and in service, and loads for multiple fastenings—all in relation to the basic design capacity of connectors.

Among other things, the analysis of these 1941 tests, and the report on them, focused attention on the need for further study of eccentrically loaded joints and the cross-grain stresses resulting from such eccentric loading. In spite of studies conducted subsequent to analysis of these tests, no satisfactory criteria for designing eccentric joints and taking care of the resulting stresses had been developed prior to the issuance of the "National Design Specification for Stress-Grade Lumber and Its Fastenings" in 1944. There appeared to be little correlation between values obtained from standard tension perpendicular to grain tests and values obtained from tests of eccentric joints which presumably were loaded in cross-grain tension. Consequently, the aforementioned specification recommended avoidance of eccentric joints.

Subsequently extensive research studies developed an empirical approach which when applied to a wide range of tests showed a proper relationship between allowable design loads and test loads at failure. This recommendation, which currently is officially incorporated as an amendment in the national design specification and which assumes the mathematical form of the horizontal shear formula but with allowable shear stresses 50% greater than otherwise permitted, may be stated as follows:

> "In computing the horizontal shear in eccentric joints the depth of the member shall be assumed as reduced by the distance between the unloaded edge of the member and the nearest edge of the connector. Where bolts

---

[27] Chf. Engr., National Lumber Mfrs. Assn., Washington, D. C.

> alone are used, the depth shall be reduced by the distance between the unloaded edge and the center of the bolt. Shearing stress for joint details may be taken as 50% greater than the horizontal shear values otherwise permitted."

In addition, the stresses induced by axial loading, if any, and bending moment should be calculated and taken care of in the design in the customary manner.

The effect of these technical advances through the incorporation of the additional technical findings of recent years in current recommendations[28] is indicated by the values in Table 27.

When the structures tested were designed for the 1939 Golden Gate International Exposition, in San Francisco, Calif., the designer did not have access to design recommendations later than those of 1935, which were considerably less refined than those of 1939. Design stresses for lumber and design loads for fastenings higher than those commonly used in 1935 were used in the Exposition buildings. John J. Gould,[29] M. ASCE, chief structural engineer for the Exposition, has stated:

> "Split rings gave satisfactory service despite working stresses 30 to 50 per cent more than usual. * * *
>
> "The wholly satisfactory performance of exposition structures, designed with 50 to 100 per cent increases of the usual timber unit stresses, suggests that where competent engineers make the design and supervise construction and maintenance, building codes should be revised to provide for increased unit stresses—perhaps 30 to 50 per cent more than now permitted."

It should be noted that the ratios given in the report and in discussion approach true safety factors for those instances where failure occurred. The so-called factor of safety as commonly used is not a true factor of safety for any material in the sense that the load required to produce failure of the completed structure is the design load times the factor. This so-called factor of safety contains allowances for variability of material, inaccuracies of design and fabrication, and other factors. When the structure is tested to failure, many of these items are incorporated physically in the structure itself, instead of as allowances in the so-called factor of safety. Consequently, the true factor of safety as determined by test of the structure logically should be lower than the factor of safety as commonly stated.

It is interesting to note from Table 27 that, for those joints in which failure is approached under test load, the lowest ratio of test load to design load is approximately 3 when based on current design recommendations[28] and is approximately 1¾ when based on those for 1939. Hence, these particular data indicate that present design recommendations actually result in structures approximately 70% stronger than those based on 1939 recommendations, in spite of the fact that the current basic allowable design values for lumber and fastenings are 20% higher than in the 1939 recommendations.

[28] "National Design Specification for Stress-Grade Lumber and Its Fastenings (1944) Including 1947 Amendments," National Lumber Mfrs. Assn., Washington, D. C., 1947.

[29] "Experience in Maintenance of Large Timber Structures," by John J. Gould, *Engineering News-Record*, August 15, 1940, pp. 72–74.

Although the writer does not intend to imply that such a percentage increase in strength can be expected generally, the data do indicate that improvements in design recommendations do offset increases in allowable design stresses in so far as total strength of structure is concerned. The data also illustrate the greater technical accuracy and reliability of the design recommendations incorporated in the aforementioned design specification[28] and the increased safety of structures conforming to this current specification.

Walter J. Ryan,[30] M. ASCE.—The Timber Test Committee of the Society's San Francisco Section deserves the thanks of the profession for publishing this report of its project, hindered as it was by many obstacles that threatened to make its completion impossible. We are fortunate to have this record, which marks a big step in the progress of timber construction from an art to a science.

Builders of the ninteenth century carried forward the knowledge of timber construction that had been accumulated since the beginning of its development. They were artisans, and the structures they built were erected by men trained and interested in their work. Following the introduction of newer materials of construction, engineering methods became an essential part of the development. Now that timber engineering is becoming a science instead of an art, it is suffering from a lack of these artisans of former generations and from the lack of understanding of a common material. The very name "lumber," so frequently used in the United States, is an indication of the lack of respect for a familiar product. This report illustrates clearly how intricate a material wood really is, and the designer of timber structures should keep the ten notations, made in the "Foreword," always in mind. These findings[31] support the "ten commandments" of a west coast association.

Most of the grief in design and construction in timber is caused by a lack of uniformity of strength within the piece due to "grain," changes through "seasoning," and variation within and between "grades." These tests will supplement laboratory studies and leave no excuse for the designer to notch a timber or neglect an analysis of the various stresses acting on a member. Lumber grading rules are nearly as perfect a guide as human interpretation makes possible. However, some pieces may be unsuited for the specific application. The framer must have the knowledge and the authority to cull such items and to select material suitable for the particular purpose. The report illustrates instances where this was not done. The principal difficulty came from shrinkage and checking. This problem is inherent with the use of green timber and seems to be without a solution. The answer is in the use of seasoned material.

Air seasoning of large timbers is not practical. Drying in a kiln is difficult and expensive. Modern practice can secure the most satisfactory results by treatment in a retort. This can be accomplished with or without the addition of preservative. Such trusses as those used in the Treasure Island Buildings will be built of seasoned or treated material in the future.

---

[30] Weyerhaeuser Timber Co., Tacoma, Wash.

[31] "Ten Essential Standards for Fabricated Timber Structures," West Coast Lumbermen's Assn., Portland, Ore., 1946.

The design of the first heavy trusses built in the United States with split rings was based on the tables published by the manufacturer, Carl Tuchscherer,[32] of Breslau, Germany, supported by a limited series of tests made at the University of British Columbia (Canada) in Vancouver. Later tests proved that the values assigned, especially to the large 9-in. and 11-in. rings, were excessive, but that the bridges served adequately for railroad loading until the timber was destroyed by decay. The bolts in these trusses were kept tight.

In the San Francisco tests, the committee saw fit to test the joints in their condition in the structure. This condition reflected the result of shrinkage and little or no maintenance. There was lack of uniformity and, in the case of loose bolts, there was the loss of the frictional resistance which is an important element in the strength of a timber joint. Perhaps these results will help to emphasize the importance of continuous inspection and maintenance. A more valuable result will be attained, however, when adequate tests are made with perfect examples and engineers, builders, and owners are taught to treat the design and the structures with the care they deserve.

WALTER M. PRATT,[33] Assoc. M. ASCE.—In the "Foreword" of this paper reference is made to "The need of keeping adjacent faces of members in contact * * *." The moisture content of the wood is apt to vary even after long periods of service in a structure; there may possibly be no moisture equilibrium condition. Use of moisture control might avoid many problems in wood construction. In contrast to various treatments of woods to resist moisture, so-called "fog-outlets" are available from some of the automatic sprinkler companies. These units are designed to control the humidity in a building automatically.

The Committee refers favorably to the use of plywood. Bonding strength of the glue used does not seem to be mentioned, but it might reasonably be as good as the wood in longitudinal shear, or from 100 lb per sq in. to 150 lb per sq in. The wider use of glue at surfaces of contact might be helpful, just as is the use of phenolic resin glues in laminated wood truss work, particularly with recent developments of the high-frequency electric current method of application. Casein glues might be practicable for use without special heat facilities for temperatures as low as 40° F. Surfaces of contact referred to would include splice plates, heel pads, and assemblies of web members in contact with chords.

In Fig. 28 the bottom chord joint pad has a contact of 7½ in. by 18 in., or 135 sq in. Using a unit stress of 100 lb per sq in. on this area, the total transmitted load is 13,500 lb. Because of a possible lack of uniformity in sizing the wood, a reduction factor could be applied, but it seems likely that the stress in the split rings shown could be materially reduced, at the same time keeping the adjacent surfaces in contact. Without adhesives, the friction between wood surfaces in contact can be a factor in carrying loads, but it is often lost through wood shrinkage, and its amount is doubtful.

---

[32] "Der Holzbau," by Theodor Gesteschi, Springer, Berlin, 1926.

[33] Mgr., Pratt Roof Truss Co., Detroit, Mich.

The background of these tests is such that all the truss work shown is of "ordinary" construction and not "slow burning." A slow burning truss can be defined roughly as one in which no single member has an area of less than 56 sq in. Use of the authors' data on plywood for gussets suggests possibilities for future truss designs where greater resistance to fire is desired through slow burning construction.

Several joints tested involved the use of "split rings," and in several cases the wood cores sheared. The results indicate the value of tests on full-size trusses, compared with laboratory tests often made. The tension across grain phase is very properly emphasized. A hollow ring dowel, and any round dowel, must necessarily produce a splitting action. There is no constant angle to the grain in a round dowel. The force in the dowel may be at an angle to the grain, but the bearing of the ring dowel on the wood is never at a single angle—rather it is at many angles.

Referring to Fig. 36, it is also possible that the core within a ring may receive load before the exterior bearing of the ring, producing an extra "punching shear." The wood core may or may not take up one half the ring load. It is customary, but not necessarily correct, to assume that each half of the ring takes one half of the load. With a ring 4 in. in inside diameter having a center bolt $\frac{3}{4}$ in. in diameter, the core shear area is 12.12 (say, 12) sq in. At 150 lb per sq in. its load transmitting value would be 1,800 lb. Let the value for this ring be 6,400 lb at 0° to the wood grain and let the value at 90° be 4,500 lb. If the core is working independently, and is limited in capacity by horizontal shear, the opposing halves of the ring must carry 4,600 lb and 2,700 lb, respectively. Dividing by the projected area of $4 \times 1 \times \frac{1}{2}$ or 2 sq in., the resultant unit stresses would be 2,300 lb per sq in. and 1,350 lb per sq in., respectively—even if the bearing were truly at 0° and 90°, respectively. The allowable stresses for these rings, given in "III. Nomenclature: Explanation of Terms and Abbreviations," paragraph 3, can be compared with the design stresses described under the same heading (paragraph 1).

If a hollow square dowel or a hollow rectangular dowel were available, the core could be analyzed on the basis of the allowable stresses mentioned in the "Nomenclature." Thus, a hollow square dowel, 4 in. by 4 in. by 1 in., at 90° to the grain would develop a resistance of $2 \times 4 \times \frac{1}{2} \times 350 = 1{,}400$ lb, compared with the 4,500 lb previously stated for the 4-in. split ring.

The round dowel is used partly because a convenient turning tool is available; a hollow square dowel could be tooled with a routing machine. As the authors state, workmanship is a very important factor. There is also the possibility that round wood cores shrink to something approaching an ellipse. From an economic standpoint, structural use from the core is desirable, but the dowel design should have balance, and the same factor of safety could well be used for ring cores as is demanded for the remainder of the structure.

To approach the phase of tension across the grain from a different viewpoint, a round dowel can be compared with a square one. If a hollow square dowel, 4 in by 4 in. by 1 in., has a value of only 1,400 lb at right angles to the grain, and if a 4-in. standard split ring has a value of 4,500 lb under similar conditions, it can be assumed that a ring-type dowel never acts at any one angle to the grain. Consider the wedging and splitting action of such a 4-in. square dowel set at 45° to the grain. It would have a theoretical bearing area of $2 \times 4 \times \frac{1}{2} \times 1.41 = 5.6$ sq in. At an allowable stress of 540 lb per sq in. (determined by the Hankinson formula), this area will transmit a stress of 3,050 lb, which compares with 5,500 lb—the value of a 4-in. split ring at a 45° bearing angle. It seems likely then that tension across the grain is inherent in the ring-type dowel, and that forces that tend to separate the fibers of the wood are set up.

Regarding reentrant cuts in wood—some may be eliminated. If a joint assembly needs a cluster of ring dowels, the web members could at times be balanced around resultant force lines as shown in Fig. 88, using only one row of dowels, as is shown in the bottom chord.

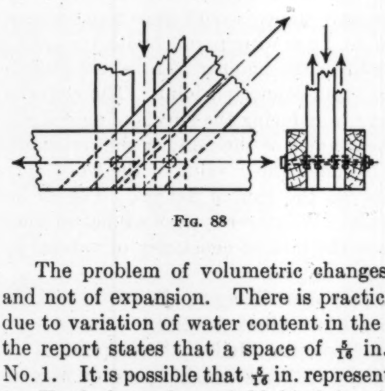

FIG. 88

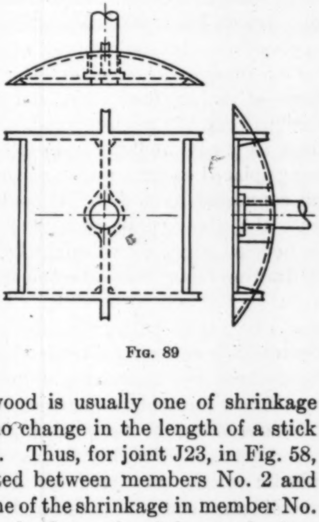

FIG. 89

The problem of volumetric changes in wood is usually one of shrinkage and not of expansion. There is practically no change in the length of a stick due to variation of water content in the wood. Thus, for joint J23, in Fig. 58, the report states that a space of $\frac{5}{16}$ in. existed between members No. 2 and No. 1. It is possible that $\frac{5}{16}$ in. represents some of the shrinkage in member No. 1. Vertical members of this kind, bearing on the flat grain of the wood, often show such a separation, and the authors rightly recommend that such details be avoided. The use of free body diagrams will often assist the designer to avoid such bearings. Thus, if the vertical members in Fig. 88 were fastened on the outside of the chord, the angle to the grain on chord would be 90°. Placed as shown, the diagonal is the only member working at an angle to the grain.

However, there is the possibility in a joint assembly that different members shrink at different rates and at different angles. Splice pads may have different water contents than the member joined and they may shrink at a different rate than the member, thereby causing possible secondary stresses, particularly if more than one row of bolts or connectors is used. Each member may shrink in both width and thickness, the shrinkage usually being about one third less radial to the annual growth rings than tangential to them. Depending on how the lumber is cut from the log, shrinkage may be unbalanced and cause warping and twisting. Lumber is certainly an intriguing material for the designer. It would seem best, as often as possible, to keep wood connectors on the center lines of joined pieces, and to avoid clusters of off-set connectors.

The report stresses the need for new thought and improvements on timber connectors. It indicates the desirability of a type of connector that can be analyzed readily and also the desirability of reducing flat grain bearings, of providing for wood shrinkage, and of preventing the overstepping tolerances by manual labor. In order to avoid the complications in stress analysis of ring dowels, the use of plane surface contacts instead of rounded contacts would greatly simplify analysis. The report definitely uses, in making comparisons, "connector allowable load." Such loads were apparently developed from tests by others. Undoubtedly, in a great deal of construction, hollow ring dowels have been used with satisfactory results, but their continued wide application, even at reduced values, would still leave many engineers hoping for an improved connector after considering all the factors—safety, rational basis of design, feasibility, and economy. Perhaps one of the writer's own designs (Fig. 89) might furnish some constructive thought along these lines, at least as a new angle of approach. The unit shown would have two arcuate wings placed at right angles to the grain, and one wing parallel with the grain, all connected by a web. It could be used in the manner of a "shear plate," with the whole connection computed as a pin-connected joint. The concave or beveled edges shown might be effective in reducing the effects of shirnkage. A limiting factor might be the single shear value of the bolt, or the resistance value of the bolt to bending. The longitudinal shear value of the wood core could be regulated by the distance between the pair of flanges. The single center fin is entirely subtended by the bolt. Whatever type of connector may be devised, the underlying difficulties are the lack of constancy of volume in wood, and its nonhomogeneous character.

Concerning the workmanship—some play must likely be allowed in making wood fittings. Possibly the use of cementitious fillers (similar in character to plastic wood), powdered metal with an asphaltic binder, thermoplastics, or metal shims could be considered. Tolerances in workmanship possibly may be overcome by means other than providing flexibility in a dowel.

COMMITTEE OF THE SAN FRANCISCO (CALIF.) SECTION, ASCE, ON TIMBER TEST PROGRAM: HAROLD B. HAMMILL,[34] M. ASCE, CHAIRMAN, JOHN J. GOULD,[35] HENRY D. DEWELL,[36] AND LEON H. NISHKIAN,[37] MEMBERS, ASCE, AND HENRY J. DEGENKOLB,[38] ASSOC. M. ASCE.—Although the number of discussions of the report of tests of timber structures from the Golden Gate International Exposition at San Francisco, Calif., has not been great, the committee feels gratified with those presented. The committee realizes that the proper study of a report of this character requires great effort before an engineer is prepared to present a discussion.

[37] Mr. Nishkian died on June 2, 1947.

[38] Structural Engr., San Francisco, Calif.

Since the completion of testing for this report, many more data on plywood have been published by the United States Forest Products Laboratory in Madison, Wis., and the Douglas Fir Plywood Association. It is gratifying to find that the tests are in general agreement with later, more comprehensive tests and data as reported by Mr. Novick. Regarding stud spacings and the need for intermediate blocking as questioned by Professor Hansen and Mr. Novick, the committee's conclusions referred to the use of plywood in stud walls for resistance to lateral forces and not to glued plywood web girders. Obviously, these conclusions would be open to question when applied to glued plywood webs, which are usually stressed more highly in shear.

In reference to the questions of fabrication raised by Professor Stern, the split rings and shear plates omitted in certain joints and trusses were omitted by error and not by design. Grooves had been made in the timbers in all cases and carelessness on the part of the erection crews was responsible for the omissions.

The thought contained in Mr. Mackintosh's question—"If the effect of the oversized hole is so great where shear plate connectors are used, should not the manufacturer's recommended value be questioned?"—has no connection with the failure of the cantilever frame in the Cavalcade Building. The report states that this frame was very carelessly fabricated and the relation of bolt size to bolt hole was not in accordance with manufacturer's recommended values. In fact, the report shows that, in tests of other specimens, when manufacturer's values were used with proper workmanship, excellent *R*-values were obtained.

Regarding various questions raised by Professor Hansen, the committee comments as follows:

1. In computing the stresses in a truss with large eccentricities, preliminary stresses were calculated assuming concentric joints. Then diagonal member stresses were corrected for the change in slope and the additional leverage caused by the eccentricities, assuming the points of inflection to be at the midpoints. The forces were then checked for balance and further corrections were applied as necessary.

2. The lower chord of truss TM-2 was reinforced with four 3 by 8 pads, boxing the section, twenty ½-in.-round bolts, and eight ⅜-in.-round stitch bolts.

3. In joint J1, it seemed obvious to the investigators, from previous types of tests, that failure would come at a very low load and that the test would not yield any new information. Therefore, the blocking at the sides of the vertical member was added to investigate a new condition. It is felt that this reinforcement greatly increased the capacity of the joint but manifestly did not give a true picture of the failure of the joint as originally constructed.

4. Regarding the testing of joint J2, an inaccurate statement (see heading, "II. Joint Tests: Concentrically Connected Joints—Joint J2") was made. At the next to the last reading for the first series of tests the top plate had moved 0.132 in., and the bottom plate had moved 0.137 in. When retested the next day, the plates moved approximately the same amount—up to the last reading. Then the top plate moved a total of 0.11 in., and the bottom plate took a sudden jump to 0.40 in. On disassembly it was found that the shear plate on the bottom side had cracked and broken, thus explaining the large deformation.

5. For joints J2 to J17, inclusive, it is correct to state that "* * * in these tests the load was always parallel to grain."

Mr. Carr disagrees with several statements upon which the committee comments as follows:

The *R*-Values Used in the Report.—In many cases where an *R*-value is given for a member that did not fail, data were furnished to show that the element in question successfully held at least the loads shown. Where *R*-values were so given, the fact was clearly stated. In other cases, for example, truss TNS (see Table 6), all factors were given, as there is unquestionably a doubt as to which was the critical one. In such cases, the highest factor was recorded and used in the tables and discussions. In any case, the comment that the "* * * factor given represents only the minimum amount of test load * * *" is not justified by the facts.

The Use of 1939 Connector Values.—In reference to Mr. Carr's comment on the use of 1935 or 1943 connector values versus 1939 connector values, the committee may be subject to some criticism for using the 1939 values instead of the 1935 values, but certainly not for failing to use the 1943 values. This subject was discussed at great length and the committee decided the report would be more valuable if based on currently used connector values. The committee still considers the decision sound although it was known that new connector values were to be published in 1943. With the tests based on a definite table of connector values, any interested designer can determine, from the information given in the report, the factors found by use of any different table of connector values. Great difficulties were encountered in the preparation of this report and the major part of the computations was completed before publication of the 1943 connector values. The committee believes that the report could never have been published if new computations had been required for results based on the 1943 table of connector values.

It should be mentioned that the major difference in *R*-values between 1943 and 1939 (see Table 27) is found in the 20% stress reduction for members fabricated green and used after seasoning. A more realistic comparison of the basic revisions is given by Professor Hansen in Table 28, which the committee, in general, checks. Although, in Table 28, the effects of moisture conditions when fabricated were neglected, it should be noted that few, if any, improvements of original inconsistencies were made. In fact, when adding all the pluses and minuses, the improvement is +0.41 for seventeen joints, or an average of +0.02 per joint. Furthermore, this improvement is indiscriminate and does not increase low factors nor decrease high ones. Any other improvement is due to the blanket 20% seasoning factor.

If other parts of the test results were compared with the latest design specifications,[9] all tests on bolts would show a 150% increase in R-values to account for the presently recommended 67% reduction for fabrication when green, as illustrated in Table 31.

Both Messrs. Carr and Hanrahan have mentioned the new "National Design Specification"[9] and advocate its use, although Table 31 lists large R-values. The use of a specification requiring such large R-values does not result in sound economic designs. With the exception of joint UI of truss TSF (design and fabrication mistakes are detailed in the report), these bolted joints gave some of the highest R-values of the whole test program. Nevertheless, in accordance with new design standards, the factors for these bolted joints fabricated green and tested dry are increased 150%, whereas similar connector joints are increased 25%, although some connector joints loaded at certain angles to the grain proved to be deficient. Certainly, with such a large variation in R-values, further revision should be investigated in the new "National Design Specification" for bolts, and similar revisions should be considered for connectors with parallel to grain loading.

Tension Across Grain.—Mr. Carr received the preliminary report in progressive stages and therefore knows that considerable space was given to discussing the tension across grain features of certain failures and that a design method was tentatively advanced. This method was supported by certain tests,[39] which were made by the University of California at Berkeley on specimens furnished by the Timber Test Committee. The final edition of the report had to be drastically shortened and as a result the "tension across grain" method was deleted. The following is quoted from Mr. Carr's discussion:

---

[39] "Tests and Analysis of Crossgrain Tension in Eccentric Wooden Truss Joints," by O. H. Degenkolb and J. J. Holstein, a thesis presented to the University of California at Berkeley, Calif., in 1942, in partial fulfilment of the requirements for the degree of Bachelor of Science.

> "The authors, while stressing the 'tension perpendicular to grain' theory, offer no design approach. Mr. Lank has subsequently been proved correct by a series of tests[8] substantiating the shear theory, and an empirical formula for design application based on this theory has been developed * * *."

Everett Lank's formula has been developed from tests of fifty-four small-size, dry, selected laboratory specimens with results varying more than 100%. From experience on the timber test program the committee is convinced of the soundness of the conclusion (see heading, "A. Foreword"), which calls attention to "1. The inadequacy of small individual tests as a premise for determining the behavior and strength of full-sized structures." The committee believes that conclusions from such small-size tests should not be considered in preparing specifications for universal use until the results of such tests have been checked by testing full-sized specimens.

With regard to factors of safety, it is realized by the committee that, in testing complete structures or trusses, smaller factors are acceptable than for individual joints. The committee does not disagree with a factor of 2 as noted in the last paragraph of Mr. Carr's discussion, provided all factors of design are considered, including long-time loading.

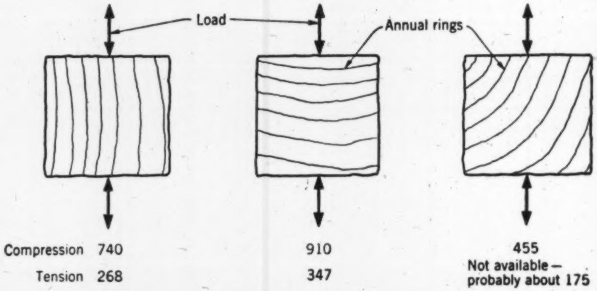

FIG. 90.—ULTIMATE STRENGTHS, IN POUNDS PER SQUARE INCH, OF DOUGLAS FIR AT 12% MOISTURE CONTENT LOADED PERPENDICULAR TO THE GRAIN AND AT VARIOUS ANGLES TO THE DIRECTION OF ANNUAL RINGS

The committee is very much interested in the results found by Messrs. Jackson and Mackintosh on their joint tests. Fig. 87 confirms the committee's opinion that the stresses in a typical timber joint using split rings are definitely connected with the tension perpendicular to the grain strength of wood. Particular notice has been paid to the variation of the tension strength from 90 lb per sq in. to 380 lb per sq in., as this confirms the committee's observations. It is believed that the worst condition for tension across the grain is not usually reported (see Fig. 90). For example, the "Wood Handbook"[2] gives average values of 740 lb per sq in., 910 lb per sq in., and 455 lb per sq in. for the compressive strength perpendicular to grain of wood when load is applied parallel, perpendicular, and at 45°, respectively, to the annual rings. The Forest Products Laboratory in unpublished data also gives 268 lb per sq in. and 347 lb per sq in. as the average tensile strengths when load is applied parallel and perpendicular to the annual rings, but neither knowledge of tests nor test data are available for conditions at 45°. However, by analogy to the compression tests, the 45° condition would possibly be the minimum, with an average value of about 175 lb per sq in. Considering variability and other factors, this could help explain many erratic results. In the University of California[39] tests, it was inferred that this tension strength at 45° might be related to the number of annual rings per inch; the closer the annual rings, the higher the tension strength. In the joint shown in Fig. 86, it is felt that it would have been better if the horizontal members A and B had been longer, since the University of California tests confirm the theoretical distribution of tension stress as extending each side of the point of application of the force about two and one-half times the depth of the member. Thus, for example, for a 2 by 6 member the minimum length is 5 × 6 in., or about 30 in., and for a 2 by 12 member, it is about 5 ft. The effective length of tension surface, from both tests and analyses, seems to be about 3.1 times the depth of member.

The Douglas Fir Plywood Association reports that three of the four subjects recommended by the committee for further consideration have already been considered. The general case of plywood buckling, together with specific applications, has been solved both theoretically and experimentally by the Forest Products Laboratory.[26] The Treasure Island tests confirm the formulas of the Forest Products Laboratory.

The lateral bearing strength of nails having reduced edge distances in plywood is discussed, and test data are presented in Section 6 of "Technical Data on Plywood."[40]

Some information on the behavior of large plywood sheathed walls, both with and without openings, under wracking loads is contained in an article by Alan D. Freas,[41] Assoc. M. ASCE. Further test data on the shear strengths of specific prefabricated plywood panels may be found in various reports of the National Bureau of Standards.

In Table 29, Professor Hansen gives values of R on the ultimate shear loads of Douglas Fir Plywood shear tests. It is unlikely that the grades tested were higher than sound two sides, according to officials of the Douglas Fir Plywood Association who examined these panels for the committee. The allowable stresses used are evidently based on stresses recommended for loads at 45° to the grain, which are twice those recommended for parallel and perpendicular directions. N. S. Perkins and D. Countryman of the Douglas Fir Plywood Association, in a communication to the committee, state that in their opinion these R-values should be based upon the parallel condition, which would give double the values. The tests were made with plywood in "pure" shear. Neglecting edge conditions, shear is equal in all directions. The committee presents this information without comment.

INVESTIGATION OF DRAINAGE RATES AFFECTING STABILITY OF EARTH DAMS

By F. H. Kellogg,[1] M. ASCE

With Discussion by Messrs. Harry R. Cedergren, Ross M. Riegel, T. W. Lambe, W. L. Shannon, and F. H. Kellogg

Synopsis

The investigation described in this paper was undertaken for the purpose of studying the effects of increased rates of reservoir drawdown on the stability of an earth dam. Field observations of the rates of drainage of several dams were compared with rates computed from a method of analysis similar to procedures used in the theory of heat. Computed and observed rates agreed fairly well. To obtain a wider range of comparison, laboratory observations were made of models and sand samples under a variety of conditions. Both analytical and observed results indicated that the possibility of mass slides resulting from reservoir drawdown has been somewhat exaggerated, but that "sloughing" due to a process of flotation or "piping" induced by drawdown may deserve more attention than it has received. Limitations for the method of analysis are suggested.

Introduction

Anyone who has watched a spring during the dry part of the summer must have been impressed with the efficiency of nature's system of rationing, which continuously distributes water stored in some long-forgotten wet season at rates that instantly adjust themselves to the supply on hand. Engineers in many fields have endeavored to learn the mechanics of this system and to apply it to problems of water supply, land reclamation, and stabilization of foundations and subgrades, as well as to petroleum production and agriculture. They have been successful as long as water is constantly supplied to the ground from an external source. When underground pore spaces constitute the only source of outflowing water, engineers must either use empirical rules, with their numerous qualifications and local exceptions, or rely on flights into the realm of theory

that often require a certain amount of "nature faking" to facilitate mathematical treatment.

It was necessary to choose between these alternatives in searching for a solution to a specific problem, relative to the effect of rate of reservoir drawdown on the stability of an old earth dam. Both were tried. The best results were obtained from an analytical method similar to that used in problems involving heat and consolidation. A description of that method, together with supporting data from field and laboratory observations and a discussion of the application of the results to estimates of slope stability, constitutes the principal part of the subject matter presented in this paper. Some suggestions as to the limitations of the methods used are offered in the hope that other engineers can supply a wider variety of data indicating the applicability of such analyses to drainage problems in general.

The term "steady state" is used to describe a condition of constant rate of seepage and a distribution of heads that does not vary with time. Seepage through a dam when the reservoir is held at constant level, so that all water escaping is replaced from the pool, is an example of this condition. The term "unsteady state" is used to represent a condition of variable rate of seepage and head distribution changing with time. Seepage from a dam during a drawdown, when all escaping water is not replaced, is an example of unsteady state flow. The scope of discussion is limited to those conditions under which Darcy's law is valid. No direct consideration is given to the related subject of consolidation.

INVESTIGATION

Specific Problem Involved.—The particular problem that led to the investigations was one of judging the maximum safe rate of drawdown of the reservoir impounded by the Blue Ridge Dam, a semihydraulic fill dam built about 1930, in northwest Georgia. Since 1939, Blue Ridge Dam has been operated as a part of a regional system of power plants.

An operating rule, inherited from the original owner, limited the rate of drawdown of the reservoir to 1 ft per day or 5 ft per week, to prevent "sloughing" of the dam. In 1943, during a period of unprecedented demand for power, this rule caused a bottleneck in the operation of the entire reservoir system. The question arose as to whether the rate of drawdown could safely be increased, and if so, how much.

The problem was attacked by trying to determine the rate of decrease of the hydrostatic pressures exerted by the water in the pores of the embankment, during a given drawdown, so that (*a*) stability against mass sliding could be estimated by "slip circle" analyses,[2] and (*b*) stability against flotation or "piping" could be estimated by analysis of the stresses at the upstream face.[3]

Published Data.—An analysis of seepage in the unsteady state similar to that used in problems of unsteady state heat flow has been applied to ground waters involving very low hydraulic gradients. The method and its fallacies were discussed by Morris Muskat,[4] in 1937. Charles V. Theis[5] has used a thermodynamic analogy in computing the rates of drawdown of a pumped well. His computed data show a remarkably close agreement with observations under certain conditions. Mr. Muskat[6] has presented an analysis of steady state flow in which time enters as a boundary condition. This theory specifically applies to the rate of advancement of an oil-water interface. Karl Terzaghi,[7] M. ASCE, discusses the time rate of drainage of an ideal sand through its base. J. H. A. Brahtz[8] considers unsteady state drainage of an earth dam which involves three factors that must be determined in the laboratory—namely, permeability, percentage of air voids, and modulus of compressibility. Lacking the required facilities, the last of these factors could not be determined during this investigation, so no checks on this method could be made.

[3] "Uplift and Seepage Under Dams on Sand," by L. F. Harza, *ibid.*, Vol. 100, 1935, pp. 1354–1358.

The various empirical rules generally applied to drainage involve grain size and plasticity. Their application would lead to the conclusion that clays cannot be treated by drainage. This conclusion is contrary to field experience, since many cuts in flocculent clays have been stabilized by drainage.

Since references to such literature as was available gave no procedure readily applicable to the problem at hand, it was decided to study observations of the rate of change of pore-water pressures in various earth dams in the hope of obtaining some empirical rule or of developing an analytical treatment with the aid of factual information not immediately available.

Notation.—The letter symbols in the paper are defined where they first appear, in the text or by illustration, and are assembled for convenience of reference in Appendix I.

Method of Investigation.—For the first stage of the investigation, the pore-water pressures were observed within several earth dams that had been in operation for two years or more. The initial observations were made while the elevations of the impounded reservoirs were held constant at high levels for prolonged periods. Thus, for each observation point, a pressure could eventually be read which would not change with time, indicating a steady state. Later, as the reservoir elevations were lowered, the rates of change of pore-water pressure at each point were compared with the rates of drawdown.

Obviously, any change in hydrostatic pressure indicated by sounding an open well involves a flow of water either into or out of the well. Unless this flow occurs in an infinitely short time, a sounding made during periods of changing water levels will merely represent the apex of a cone of depression or the top of a water cone. The height of such a cone will become progressively greater as the change continues.

Therefore, in this investigation, the same type of measuring devices were used that are employed in reading pore-water pressures in silts and clays.[9] Special pressure cells, reading to 0.1 in. of hydrostatic head, were developed for use in studying model embankments. The purpose of these cells was to disturb the natural flow of pore water during drainage as little as possible by the pressure measurement.

Since pore pressures in an earth dam sometimes rise as the reservoir falls (for example, curve C, Fig. 1(*b*)), they have been converted to values that will be more sensitive indicators of response to reservoir fluctuations. These values are expressed in terms of "potential head." Potential head at a given point is defined as the sum of the pressure head at that point, u_w/γ, plus the additional head between that point and the drain, $z_p - z_d$, or

$$h = z_p - z_d + \frac{u_w}{\gamma} \qquad \text{.....................(1)}$$

in which h is potential head, at a given pore pressure cell; z_p is the elevation of that cell; z_d is the elevation of the drain or outlet; u_w is the pore pressure reading; and γ is the unit weight of water. Fig. 2(*a*) illustrates this conception. The dotted curves in Fig. 2(*a*) represent contours of potential head at zero time (initial steady state), and the curves marked by arrows represent lines of flow.

In Fig. 2(*b*), hydrographs have been plotted showing the variation in potential heads at various points within a sand model embankment during a drawdown of the pool impounded by that embankment. The potential heads (ordinates) were computed, from readings of pore pressure cells, by Eq. 1. Where observed values of head for zero time differed from those taken from the theoretical flow net of Fig. 2(*a*), the former were used in Fig. 2(*b*). The topmost curve of Fig. 2(*b*), marked "Pool," shows the time rate of drawdown of the pool. Comparing the hydrographs of the cells with the hydrograph of the reservoir, a functional relationship between the rate of change of reservoir level and the rate of change of potential head at each cell location is noted at once, whereas such a relationship is less readily apparent if only the rate of change of pore pressure is studied. (Compare Fig. 2(*b*) with Fig. 2(*c*).) Fig. 2(*b*) shows clearly how the rate of change of potential head during an unsteady state increases as the downstream toe or drain of the dam is approached.

A most important approximation revealed by such hydrographs was that, over most of the dam at least, all cells with a given potential head during periods of constant pool level would show the same hydrographs during periods of changing reservoir level, regardless of the locations of the cells. The hydrographs of cells 0 and 5, or of cells 2, 3, and 4 in Fig. 2(*b*), illustrate this. Such an observation does not hold in regions which, at the time of observation, are well above the level of the pool at that same time.

These properties of the hydrographs of pore pressure cells strongly invite the development of an empirical rule. In fact, one was formulated which expressed, quite closely, the rates of drainage for two particular dams. However, it indicated that rate of drainage is independent of permeability. Since these two dams involved extremely slow rates of drawdown, the effects of permeability

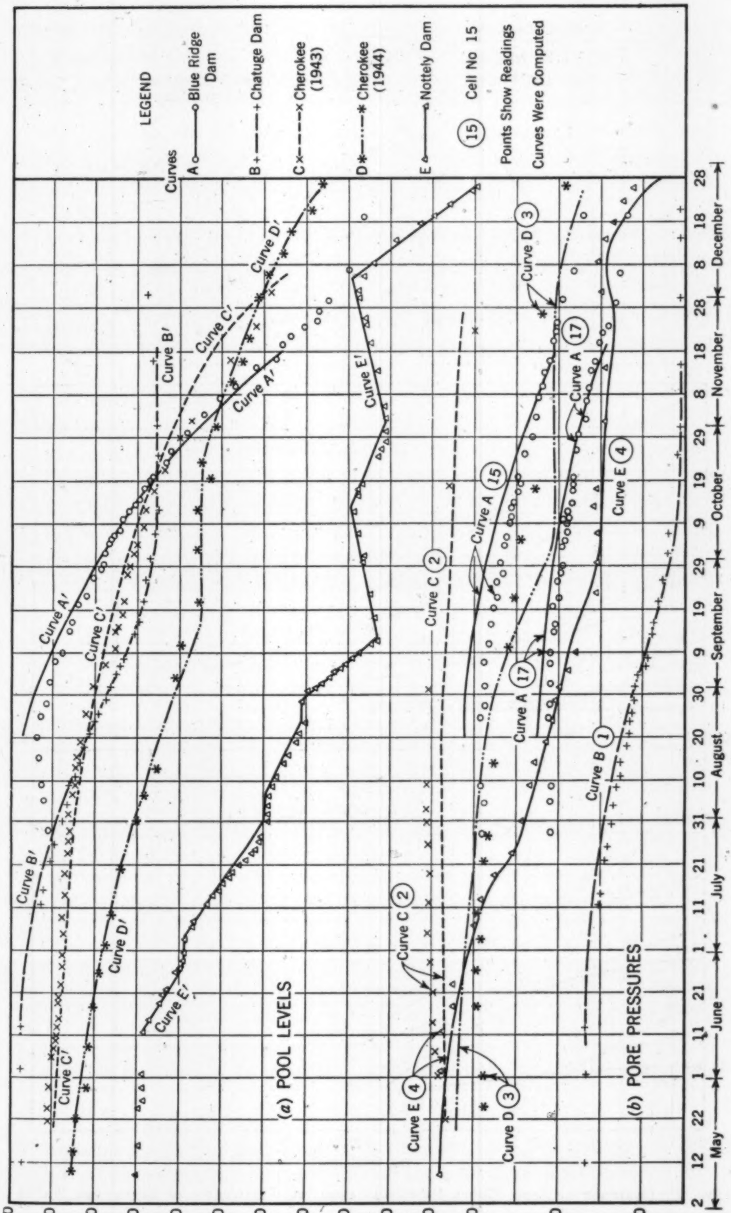

FIG. 1.—COMPARISON OF COMPUTED AND OBSERVED PORE PRESSURES

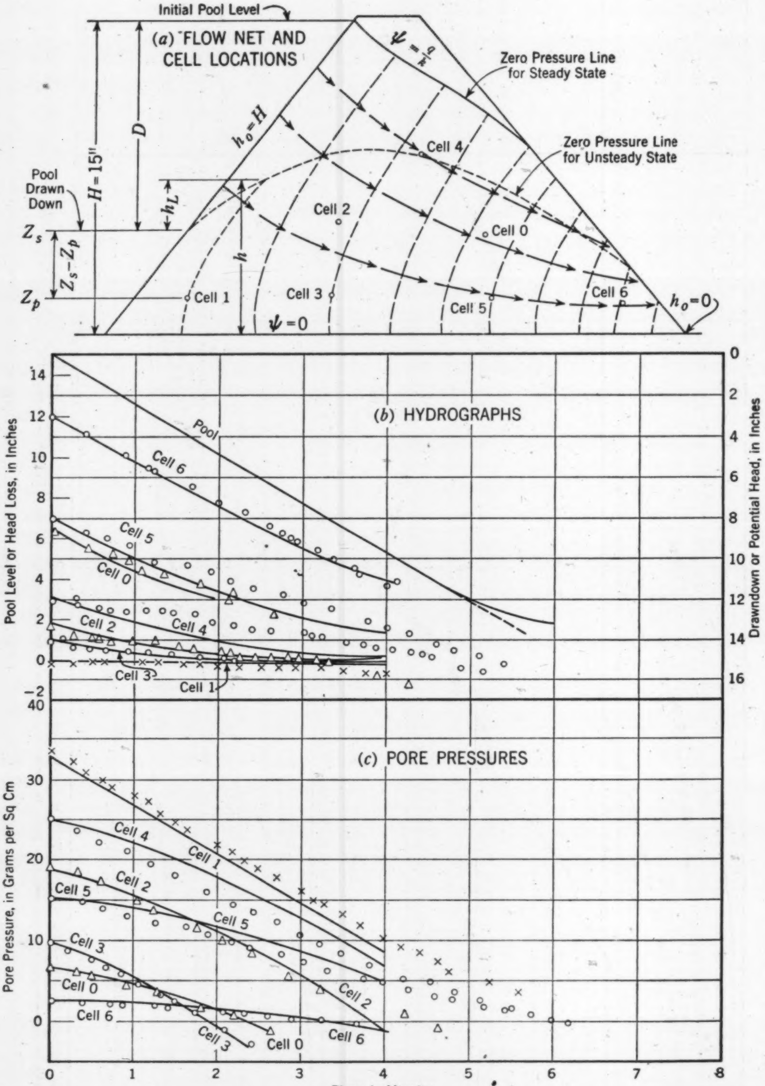

FIG. 2.—DRAINAGE OF SAND MODEL RESULTING FROM THE DRAWDOWN OF IMPOUNDED WATER

were so little as to be negligible, but the empirical rule holding for them could not be extended very far. After following various statistical studies "around a circle," such methods were abandoned in favor of a physical analysis of the problem.

Analogy Between Seepage and Heat Flow.—An analogy between unsteady state heat flow and flow of pore water squeezed from the pores of a clay during consolidation has been described in some detail by Professor Terzaghi and O. K. Froelich.[10]

In the structures involved in the present investigation, however, no definite evidences of consolidation were found, either from settlement measurements or from pore pressure observations. This section of the paper therefore refers to the problem of drainage from pore spaces, the volume of which is assumed to remain essentially constant. As one working hypothesis, the assumption has been made that under this condition analyses of drainage similar to those used in problems involving heat flow and consolidation can still be used, at least within limits.

In seepage, Darcy's law states that the average velocity is proportional to the hydraulic gradient, from which it follows, as shown in Appendix II, that the net quantity of water flowing in time dt out of an element of porous material having a volume $dx\ dy\ dz$ is $k\nabla^2 h\ dx\ dy\ dz\ dt$, in which h is the drop in head across the element and k is the permeability coefficient. In heat flow, the Biot-Fourier law states that quantity of heat per unit area is proportional to the temperature gradient, so that the net quantity of heat flowing out of an element in time dt is $k'\ \nabla^2\ T'\ dx\ dy\ dz\ dt$, in which k' is the coefficient of heat transmission and T' is the difference in temperature across the element. This quantity can also be expressed in another way: Specific heat is defined as the ratio $q_s : q_w$, in which q_s is the quantity of heat required to raise 1 g of transmitting substance 1° C and q_w is the quantity required to raise 1 g of water 1° C. Since this latter quantity may be considered as one calory, specific heat multiplied by unity gives the number of calories required to raise 1 g of conducting medium 1° C. In a volume $dx\ dy\ dz$, of this medium, there are $\rho\ dx\ dy\ dz$ grams, in which ρ is density in grams per cubic centimeter. Therefore, calling specific heat c', the quantity of heat required to raise an element of conducting medium dT' degrees is $c'\ \rho\ dx\ dy\ dz\ dT'$. If this quantity flows in time dt, then:

$$k'\ \nabla^2\ T'\ dx\ dy\ dz\ dt = c'\ \rho\ dx\ dy\ dz\ dT' \quad \text{..............} (2)$$

or

$$\frac{k'}{c'\ \rho}\ \nabla^2\ T' = \frac{\delta T'}{\delta t} \quad \text{.........................} (3)$$

Eq. 3 is the basis of the classical analyses of heat flow in the unsteady state. The factor $\frac{k'}{c'\ \rho}$ is called the "diffusivity" of the conducting medium. If a relationship similar to Eq. 3 could be demonstrated for seepage, a wealth of analytical technique would be available for problems of drainage. For such an analogy to exist, there must be a constant w_d such that

---

[10] "Theorie der Setzung von Tonschichten," by K. Terzaghi and O. K. Fröhlich, F. Deuticke, Leipzig 1936.

$$\frac{k}{w_d} \nabla^2 h = \frac{\delta h}{\delta t} \qquad (4)$$

or

$$k \nabla^2 h \, dx \, dy \, dz \, dt = w_d \, dx \, dy \, dz \, dh \qquad (5)$$

The quantity $k/w_d = c_d$ would then be a constant characteristic of the porous medium in which drainage takes place, expressing potential speed of drainage. It will be designated as the "drainability" of the material, to emphasize the analogy with diffusivity in heat transmission.

Transposing Eq. 5,

$$\frac{k \nabla^2 h \, dx \, dy \, dz \, dt}{dx \, dy \, dz} = w_d \, dh \qquad (6)$$

If "yield" is defined as the volume of water drained without replacement from a unit volume of porous material, then the left-hand side of Eq. 6 represents the yield in time dt. Designating yield w_y, Eq. 6 may be written

$$\frac{dw_y}{dh} = w_d \qquad (7)$$

The constant w_d must therefore be defined as the volume of water that can be drained from a unit volume of porous material by a unit change in head. It will be designated as "specific drainage."

In Appendix II, various solutions of Eq. 4 are given. Values of pore pressures and yields computed from these solutions have been compared with field and laboratory observations. After these comparisons are summarized, the significance of the factors designated as drainability and specific drainage will be discussed further.

Procedure for Checking.—Observations of pore pressures were first made on earth dams that had been in operation for some time. Then, to check the conditions found and to extend them under controlled rates of drawdown, studies were made of model embankments in which a steady state was allowed to develop before applying drawdowns at uniform rates. Finally, to check the methods of computation against some factor other than pore-water pressure, sand samples were saturated and permitted to drain, the yield at various times being measured. In these samples, horizontal drainage and vertical drainage were observed separately. Also, both drainage under gravity alone and drainage under constant air pressure held at one end of the sample were studied.

For dams and model embankments, pore pressures were computed from Eq. 1, using Eqs. 30 in Appendix II to approximate values of potential head. Eqs. 30 are the result of a very crude analysis, but a rigorous solution of the problem could not be made, and the method used serves to give a fair estimate as long as points in the region of zero or negative hydrostatic pressure are not considered and as long as the drawdown is not so rapid as to leave the largest part of the region of positive hydrostatic pressure above the pool level at the time of computation.

The first steps in the computations were to take the observed pore pressure for one cell and one time and to compute the drainability from Eqs. 30. Next, this value was inserted in Eqs. 30, and the pore pressure for this cell at other times was computed, for comparison with observed values. Finally, using the same value of drainability, the pore pressures at other cells at various times were computed. However, when laboratory tests indicated a considerable variation in materials at different cells, a new value of drainability was determined for each cell.

For sand samples, a drainage index was considered, defined as the yield at any given time divided by the total yield under the conditions considered. Eq. 24 in Appendix II was used for horizontal drainage; and Eqs. 25 and 26 were used for vertical drainage. The drainability was first computed from the drainage index observed at one time, and this value was used to compute the drainage indexes at other times for comparison with observations.

(*c*) NOTTELY DAM

FIG. 3.—TYPICAL SECTIONS OF DAMS

Comparison of Computed and Observed Data.—The operation of the reservoirs impounded by four earth dams was such as to permit the attainment of a steady state of seepage, followed by an unsteady state induced by drawdown. Fig. 3 shows typical cross sections of these dams and the head contours during the initial steady state as determined from readings of pore pressure cells. Fig. 1(*a*) shows reservoir hydrographs for drawdown periods during which pore pressure readings were taken. Fig. 1(*b*) shows a few typical pore pressure-time curves. The curves were computed, whereas the points represent actual observations.

In general, computed pore pressures did not vary from those observed by more than 2 lb per sq in. In one case, where the cell reading was only 2 lb per sq in., and the cell was above pool level at the time of reading, a variation of 5 lb per sq in. was noted. However, since the analysis used becomes invalid at points within the embankment higher than pool level, a check could not be expected.

For Chatuge Dam, in southwestern North Carolina, and Cherokee Dam, in eastern Tennessee, a single value of drainability served to check all cells.

For Blue Ridge and Nottely dams both in northwestern Georgia, a value which would check observations at a given cell for one time would agree for other times, but not for other cells. A considerable variation in permeability was found in these two dams. Table 1 gives test data which serve to describe the materials in the various dams.

TABLE 1.—TEST VALUES FOR MATERIALS IN OBSERVED DAMS

Structure	Sand[a] (%)	Clay[a] (%)	Liquid limit	Plasticity index	Permeability coefficient[b]
Blue Ridge Dam (Georgia):					
Shoulder	73	5	....[c]	....[c]	0.3 to 3.0
Foundation	....	....	....[c]	....[c]	2.0 to 6.0
Core	52 to 73	5 to 17	30 to 42	2 to 9	0.003 to 0.007
Chatuge Dam (North Carolina)	64 to 76	4 to 8	45 to 47	4 to 15	0.0003 to 0.005
Cherokee Dam (Tennessee)	15 to 32	28 to 51	41 to 66	20 to 41	0.000008 to 0.00008
Nottely Dam (Georgia)	55 to 94	5 to 39	35 to 43	4 to 23	0.0003 to 0.2

[a] Percentage of the total sample, by dry weight. Particles with equivalent diameter greater than 0.05 mm are classified as sand and those with equivalent diameters less than 0.005 mm are classified as clay. [b] Feet per day. [c] Nonplastic.

Nine model embankments were studied, three of which were made of standard Ottawa sand, three of graded Ottawa sand, and three of a fine, micaceous sand. Four different linear rates of drawdown were used for each model. Fig. 2(*a*) shows a cross section of one of the models, with cell locations and a theoretical flow net. The material is assumed to be isotropic. Fig. 2(*b*) shows the typical hydrograph for one drawdown, and hydrographs for six pore pressure cells during that drawdown. The points represent observations. The curves are plotted from Eqs. 30, Appendix II, using the following data:

Specific drainage w_d	0.23
Permeability k, in inches per minute	0.8
Initial head H, in inches	15
Ratio of head loss to arc length $\Delta h_o/\Delta s_f$	0.6
Drainability, c_d	41.7
B	0.66

In the foregoing—

$$B = \frac{\pi^2 c_d}{H} \left(\frac{\Delta h_o}{\Delta s_f} \right)^2 \qquad \text{(8a)}$$

and

$$c_d = \frac{k}{w_d} \qquad \text{(8b)}$$

In Fig. 2(*b*) w_d is the specific drainage.

The value of the hydrograph of each cell at zero time represents the observed potential head during the initial steady state. Cells 2 and 3 show appreciably different initial values from those indicated by the theoretical flow net of Fig. 2(*a*). In Fig. 2(*c*), the hydrographs of the cells have been converted into pore pressure-time curves by Eq. 1. Results for other observations of model embankments are quite similar to those shown in Fig. 2, and to the results obtained from field observations on dams during drawdown.

The computed values shown in Figs. 1 and 2 have been obtained on the basis of steady state flow nets derived from readings of pore pressure cells. The question naturally arises as to how these computations would have checked had theoretical flow nets been used as a basis. The head distribution shown in Fig. 3 for Blue Ridge Dam is obviously unlike any that could be obtained theoretically. Since the dam is a semihydraulic fill with a fairly pervious foundation and considerable variation in the permeability of the flow system, this condition is not surprising. The flow nets for Chatuge, Cherokee, and Nottely dams are somewhat different from the corresponding theoretical flow nets for isotropic embankments. By assuming various values of anisotropy for each dam (calling "anisotropy" the ratio of permeability in a horizontal direction to that in a vertical direction), a fair agreement between observed and theoretical heads could be obtained for one particular value. The highest value of anisotropy that had to be used to obtain agreement between theoretical and observed flow nets was 50 at Guntersville Dam (in northern Alabama), but, usually, the value was between 1 and 4. Ordinarily, a theoretical flow net is made assuming an anisotropy of 1 or some other arbitrarily chosen value. Under such conditions, pore pressures computed for the unsteady state could be considerably in error.

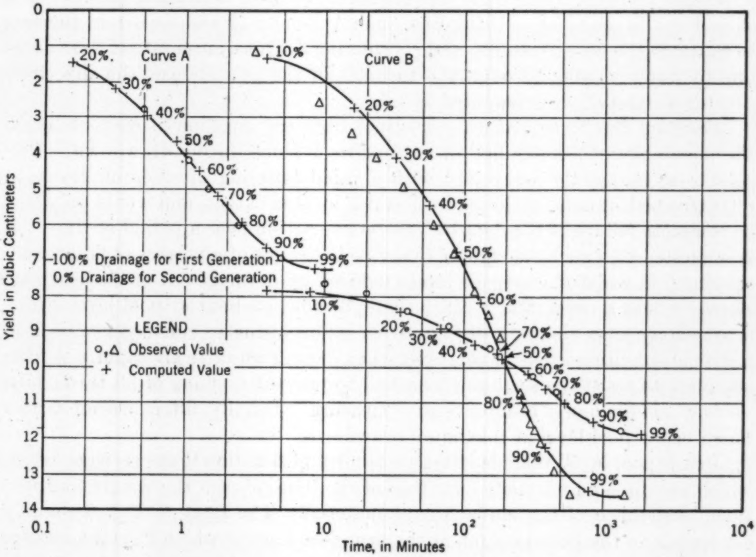

FIG. 4.—COMPARISON OF OBSERVED AND COMPUTED YIELDS

Fig. 4 shows the volume of water drained from a sand sample by gravity alone, plotted against time. Drainage occurred through vertical planes at each end of the sample. Curve A represents results for graded Ottawa sand, and curve B those for a micaceous sand, all of which passes United States standard sieve No. 30, and is retained on a No. 200 sieve. The curves were computed by Eq. 24 in Appendix II, and the points represent actual observations. The two generations of drainage indicated by curve A seem to be characteristic of medium-grained to coarse-grained sands, and indicate that there may be several independent flow systems in a sand, of which the most permeable is the only one of practical significance.

Similar comparisons were obtained when all water flowed vertically, draining from the base of the sample. Drainage was induced in this case by gravity plus a constant external stress, maintained by applying a constant air pressure at the top of the sample. The curves were computed from Eqs. 24 and 25 applied to Eq. 26 in Appendix II.

APPLICATIONS

Slope Stability.—The stability of a slope against mass sliding may be estimated by the "slip circle" method. Field evidence indicates this method is satisfactory for analyzing slope stability if the pore pressures are known.[2] In the case of an earth dam subjected to drawdown of its impounded reservoir, the pore-water pressures are frequently considered as those that would exist if no drainage whatsoever were to occur. Under such an assumption, the "factor of safety" for Blue Ridge Dam was computed as 0.95, indicating that the dam should not be standing. Using Eqs. 30 in Appendix II and Eqs. 1 in the text to estimate the pore pressures, and considering the maximum rate of drawdown due to water passing through the turbines in the powerhouse, the slip circle "factor of safety" was computed as 1.5.

Flotation Due to Drawdown.—Distinct from the question of mass sliding is the possibility of "sloughing" of the upstream slope during drawdown. This condition, frequently associated with a rapid lowering of reservoir levels, is distinguished from mass sliding in that it is local in extent, and would only lead to complete failure of the dam by progressive action over a period of time. It is suggested that such "sloughing" may be the result of a process of flotation or "piping," in which the seepage forces induced by drainage out of the upstream slope produce a quicksand. Since the hydraulic gradient at pool level during a drawdown may theoretically approach infinity, due to convergence of flow, a critical condition exists at this level when drawdown rates are rapid. A filter adequate to resist the seepage forces and to prevent washing of fill through its voids would obviously be a preventive measure. Usually, filters are not carried much below pool level at maximum drawdown.

Below pool level, there is still a possibility of flotation if the seepage forces, which are directed normal to the face of the dam, exceed the weight and frictional resistance of the embankment material. The inset in Fig. 5 shows a conception of the force polygon at the upstream face, in which F_i is the seepage force; F_ϕ is the frictional force; W is the buoyed weight; and ϕ is the angle of internal friction. The vector F_i represents the seepage force required for equilibrium. The actual seepage force at the end of a given period of drawdown may be expressed as $\gamma\, i$, in which γ is the unit weight of water and i is the hydraulic gradient at the upstream face at the time considered. Eq. 36 in Appendix II has been derived to express the approximate value of i for a constant rate of drawdown. Knowing this value, a factor of safety against flotation can be expressed as

$$S = \frac{F_i}{\gamma\, i} \qquad (9)$$

For Blue Ridge Dam, such a factor of safety was computed for a drawdown of 90 ft at 2 ft per day as 2.23. Similar computations indicated that a quick condition would be imminent at the upstream face when the rate of drawdown increased to 5.3 ft per day. Actually, the rate has been increased from the old limit of 5 ft per week to 2 ft per day without harmful effects. The additional water supply made available by such an increase represents an appreciable monetary value.

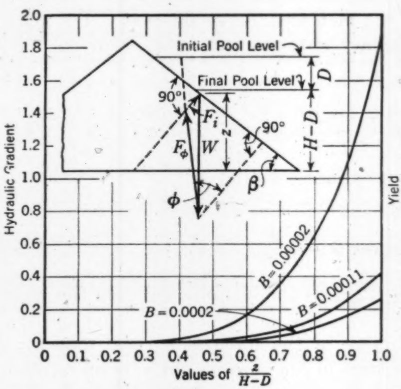

FIG. 5.—FACTORS THAT AFFECT THE PIPING RESULTING FROM DRAINAGE

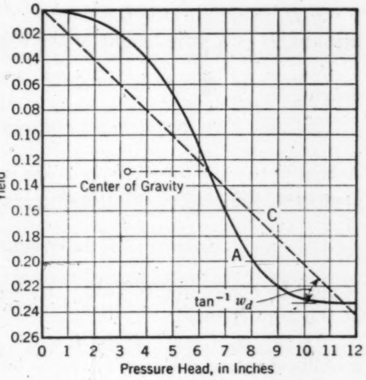

FIG. 6.—YIELD-PRESSURE CURVE (GRADED OTTAWA SAND)

The distribution of hydraulic gradient along the upstream face at points below minimum pool level is shown by the curves in Fig. 5 for materials of three different drainabilities. These curves suggest the desirability of filter protection below minimum pool level when the embankment material is not obviously free draining and the drawdown rate is appreciable.

SIGNIFICANCE OF DRAINAGE CONSTANTS

Pore Pressures in Media of Low Permeability.—Field observations of pore-water pressures in dams composed of relatively impervious materials indicate pressure drops quite similar to those that would be expected for nearly free draining media—contrary to the usual assumption that a relatively impervious material develops high excess hydrostatic pressures which dissipate very slowly. In this section, an effort will be made to explain such behavior.

Consider a porous body, such as an embankment, submerged in a pool of water so that its top is level with the water surface and imagine this body to be completely saturated. The body can be visualized as a plexus of intercommunicating capillary channels of varying cross section. If the level of the pool is now lowered slightly, the water will remain in these capillary channels, and a meniscus will form at the top of each channel. The pore water is held above the surface of the pool by capillarity.[7] To idealize for a moment, if the channel were a circular cylinder, the upward force holding the water above pool level would be $2\,\pi\,r\,\sigma_w \sin\beta$, in which r is the radius of the channel; σ_w is the surface tension of water; and β is the angle made by the meniscus with the horizontal. Resisting this force would be the weight of water above the pool, $\pi\,r^2\,\gamma\,D$, in which D is the height of the meniscus above the pool. For equilibrium, $D = h_c$, the height of the capillary water column, and

$$2\,\pi\,r\,\sigma_w \sin\beta = \pi\,r^2\,\gamma\,h_c \qquad (10)$$

Solving for h_c:

$$h_c = \frac{2\,\sigma_w \sin\beta}{r\,\gamma} \qquad (11)$$

Actually, the capillary channels are not cylindrical; they are not even uniform. However, the general relationship—

$$h_c = \text{constant} \times \frac{\sin\beta}{L} \qquad (12)$$

—may be considered to hold. In Eq. 12, L is the distance between the walls of the pore channel.

As the pool level drops further, more of the force of surface tension is mobilized to resist a drop of the water level in the pore channels by an increase in the curvature of the meniscus which increases the value of the angle β in Eqs. 11 and 12. The maximum value of $\sin\beta$ is unity, of course, and at this value the full force of surface tension is brought to resist a drop in pore-water level. In a relatively fine material, the pore width, L of Eq. 12, may be so small that a quite appreciable drawdown may occur with no drop in pore-water level ($D = h_c$). For example, in Cherokee Dam, at a distance of 70 ft above the free surface of the water, negative pore pressure and complete saturation (within the limits of accuracy of the tests used) were observed. Under such conditions (barring consolidation), the pore pressures vary from $-D$ at the top of the embankment, to zero at pool level, to $+h$ at a distance h below pool level (expressing pressure as equivalent head), and decrease as rapidly as the pool is drawn down. Thus, a relatively impervious embankment could show rates of decrease of hydrostatic pressure during drawdown similar to those exhibited by a free draining structure. In terms of Eq. 4, the permeability k is low and the yield per unit head w_d is zero; therefore, the drainability k/w_d is infinite.

Suggested Limitation of Analysis.—Eq. 12 represents a condition of equilibrium in which the pressure head created by the weight of water in the capillary channel h_c balances an equivalent force, expressed as head, which is created by surface tension. For equilibrium, the drawdown D is equal to the capillary head h_c, and the maximum value of D or h_c for this equilibrium in a channel of given width occurs when $\sin\beta = 1$. When $D > h_c$, Eq. 12 may be expressed as

$$D - \frac{\text{constant}}{L} = D - h_c = h \qquad (13)$$

in which h is the head available to produce flow in the capillary channel. The value of L is obviously not constant, but varies over a wide range, possibly similar to the variation in sizes of grains. Therefore, during a drainage due to drawdown, the largest pore channels will drain first whereas, in the smaller channels, there will simply be increases in curvatures of the menisci without appreciable loss of water. Thus, each increment of drawdown will drain water from successively smaller channels.

To illustrate these relationships, a cylinder of sand, 4 in. in diameter and 5 in. high, open at the top and base, was saturated and its base submerged. The air pressure at the top was adjusted so that the sand would remain saturated without flow. Then the pressure at the top was increased by an equivalent of 2 in. of hydrostatic head and the sand was allowed to drain until no additional water was added to the yield during a 24-hour period. This procedure was repeated at 2-in. head increments until no more water could be forced out of the sand. The total yield at the end of each pressure increment was plotted against the pressure head as shown in Fig. 6.

Although the equilibrium conditions in this experiment are different from those expressed in Eqs. 10 to 13, the principle that there is a capillary head, varying inversely as the width (or "diameter") of the capillary channel at the air-water interface (which head must be overcome by a greater force to produce drainage) holds in either case. In either case, when the pressure head is zero, there is no yield. Furthermore, the yield approaches a maximum value, beyond which there is no additional drainage. This value is called "specific yield" in ground-water hydrology;[11] and the test for specific yield is similar to that for the centrifuge moisture equivalent of a soil. Moreover, since pressure is a function of pore size, and yield, of pore diameter, the yield-pressure curve can be considered as a rough example of a pore-size distribution curve. Then, if there is any truth in the assumption that grain size is an index of pore size (as implied in the "effective size" hypothesis), the yield-pressure curve should have the same general characteristic shape as does a grain-size distribution curve—that is, it should suggest a probability curve, as does the curve in Fig. 6.

To apply the concept of the yield-pressure curve to the analyses in this paper, it is necessary to consider the draining mass as homogeneous, or better, as uniformly heterogeneous. In any element, the grain-size distribution and the pore-size distribution must be considered the same as in any other element. Consider an element at the top of the draining medium, containing pore spaces of every size in the range of the material. In any one of these pore channels, if there is a force F_d promoting drainage, and an equal capillary force, h_c, resisting drainage, there is no flow. If the force F_d is increased by an infinitesimal amount, dF_d, there is an increase in capillary resistance to $h_c + dh$ in those channels too small to permit flow, and seepage under a head not greater than $dh = dF_d$ in the larger channels. The yield increases by an amount dw_y. This increase eventually becomes smaller as successively smaller pore spaces are drained by additional increments of drawdown. Eventually, as the total yield approaches the value of specific yield, dw_y approaches zero. Therefore, the relationship in Eq. 7 ($dw_y/dh = w_d$) can at best be only an approximation. At the value of the specific yield, $dw_y/dh = w_d = 0$, and Eq. 4 becomes

---

[11] "The Occurrence of Ground Water in the United States," by O. E. Meinzer, *Water-Supply Paper No. 489*, U.S.G.S., U. S. Govt. Printing Office, Washington, D. C., 1923.

$$\nabla^2 h = 0 \quad (14)$$

which is the differential equation for steady state flow.

Since, as a material becomes finer, the specific yield becomes less and the pressure at which the value of specific yield is approached becomes greater, the curve is better approximated by a straight line, $dw_y/dh = w_d$, as indicated by the dashed line in Fig. 6. As the value of specific yield is exceeded, the straight line approximation becomes untenable. It is concluded, therefore, that analysis of drainage problems by methods analogous to those used for determining the unsteady state of heat flow is an approximation that can hold only as long as drainage water can be taken from the capillary zone. After all drainable water has been removed from the porous body, air must enter the entire surface of the porous body; and, from Eq. 14, the ensuing drainage follows the laws of the steady state. It is suggested that, in such a steady state, the source is the surface of the draining mass, the inflowing material is air, and the process is similar to one analyzed by Mr. Muskat for the rate of advancement of an oil-water interface.[6]

Since this study was made in connection with a specific problem relating to production rather than as a research project, sufficient data to support or refute the suggestions given herein as to the limitations of the analysis were not obtained. This treatment has been included only in the hope that additional information may be available which will better define the range of validity of the analysis.

CONCLUSIONS

Ordinarily, when an earth dam is subjected to drawdown of its impounded reservoir, it is assumed that the internal hydrostatic pressures will decrease very slowly, if at all, unless the slopes of the dam are composed of relatively permeable material. Such a slow decrease would materially reduce the stability of the dam. Therefore, substantial sums of money have been spent in securing large quantities of pervious materials for the upstream shoulders of earth dams, or in constructing dams with very flat slopes.

Field observations summarized in this paper indicate that, in materials of relatively low permeability, the hydrostatic pressures may decrease about as rapidly as in pervious materials, with little or no reduction in stability. These observations were in fairly good agreement with hydrostatic pressures computed from analyses similar to those used in problems of heat transmission and consolidation of clays. Such computations also agreed fairly well with observations made in the laboratory on model embankments and on volumes of water drained from sand samples under both gravity and induced pressures. Materials observed included clays, silts, and sands.

The analyses indicate that speed of drainage depends not only on permeability, but also on the volume of water that can be drained. For example, standard Ottawa sand is more permeable than graded Ottawa sand, but requires more time to drain because more water can flow out of the same volume of sand. The potential rate at which a given material can drain is expressed by a constant designated as "drainability," which is the quotient of the permeability coefficient over the volume of water, per unit head, that can be drained from a unit volume of the material. If this latter quantity should be zero, as it would be in a fine material in which all water is held in the pore spaces by capillarity, the drainability would be infinite, regardless of the magnitude of the permeability coefficient, and the pore pressures would decrease during a drawdown just as fast as they would for a material with a permeability coefficient of infinity. Of course, if the fine material were not well consolidated, so that the capillary forces transmitted to the grain structure resulted in consolidation, the pore pressures would be higher and their rates of decrease would be slower.

Silts and fine sands, which have neither permeability sufficient to permit drainage by a rapid escape of water from the pores, nor yields low enough to offset this drainage, are considered the most difficult materials to drain, and the least desirable materials for the upstream shoulder of a dam.

The data given in this paper indicate that earth slopes subjected to drawdown are more likely to develop local failures from flotation or "piping" action of water draining out of the face of the slope, than to fail by mass sliding. The likelihood of flotation decreases with distance below the surface of the pool, but under certain conditions, it could occur at appreciable distances beneath the surface of the pool, if not protected by an adequate filter.

Although this investigation has not been extended far enough to determine the limits of the analyses, it is tentatively suggested that the analyses will hold as long as the total head inducing drainage does not exceed the head required to remove all drainable water from the material considered. An alternative method of attack for cases beyond this limit has been suggested but not developed. From a practical viewpoint, it is considered that cases beyond this limit would be confined to pervious sands subjected to drawdowns of considerable magnitude.

Acknowledgment

The experimental work described in this paper was done under the auspices of the Tennessee Valley Authority (TVA). The views expressed are those of the writer, and do not necessarily reflect those of the TVA.

APPENDIX I. NOTATION

As far as consistently possible, the following letter symbols conform with "Soil Mechanics Nomenclature," ASCE Manual of Engineering Practice No. 22, and with American Standard Letter Symbols for Hydraulics (Z10.2—1942) and for Heat and Thermodynamics (Z10.4—1943):

B = a simplifying exponent defined by Eq. 29*b*;
b = rate of drawdown;
c_d = drainability analogous to diffusivity or specific heat c'; $c_d = k/w_d$;

D = distance of drawdown at any given time, the total drawdown being designated D';

d = drainage index, expressed as the ratio of the volume drained to a given time to the total volume drained (see Eq. 26):

  d_1 = drainage ratio due entirely to gravity;

  d_2 = drainage ratio due entirely to pressure;

e = base of Naperian logarithms;

F = force—

  F_i = seepage force required for equilibrium, the "actual" or general seepage force being $F'_i = \gamma i$;

  F_d = a force that promotes drainage;

  F_ϕ = internal friction force;

f = any function, as defined in the text; distinction between functions, are designated f_1, f_2 (Eq. 16*b*), or f' (Eqs. 30);

H = total head;

h = head at a given time or section; potential head:

  h_c = height of capillary rise;

  h_L = head loss due to flow;

  h_o = potential head during the initial steady state;

i = hydraulic gradient at the upstream face at a given time;

k = permeability coefficient analogous to the coefficient of heat transmission k';

L = any distance, as defined in the text;

n = an integer having successive values 1, 2, 3, $\cdots$;

q = flow during the initial steady state, between a given point and any convenient fixed datum such as an impervious base;

q_s = quantity of heat required to raise 1 g of transmitting substance 1° C;

q_w = quantity of heat required to raise 1 g of water 1° C;

R = time ratio, t/t_d (Eqs. 30);

r = radius; polar coordinate (see θ);

S = safety factor;

s = length of arc:

  s_f = length of arc, measured along a flow line;

  s_h = length of arc, measured along a head contour;

T = temperature; T' = difference in temperature across an element;

t = time; t_d = duration of drawdown;

u_w = pore pressure reading;

V = volume;

v = velocity of flow;

W = weight;

w = volume of water drained:

  w_d = specific drainage (Eq. 7); the volume that can be drained from a unit volume of porous material by a unit change of head;

  w_y = yield; the volume that is drained, without replacement, from a unit volume of porous material;

x = Cartesian coordinate;

y = Cartesian coordinate;
z = vertical coordinate, or elevation above an indicated base:
  z_d = elevation of drain or outlet;
  z_p = elevation of pore pressure cell;
  z_s = elevation of reservoir surface at any given time;
β = angle with the horizontal, as the slope angle in Fig. 5;
γ = unit weight of water;
θ = polar coordinate of arc (see r);
λ = a substitution factor used to simplify the typography of a complex exponent (see Eq. 23*b*);
ρ = density, in grams per cubic centimeter;
σ_w = surface tension of water;
τ = substitution factor used to simplify the typography of a complex exponent (see Eq. 23*a*);
ϕ = angle of internal friction;
ψ = a parameter equal to q/k; and
∇ = an operator.

APPENDIX II. MATHEMATICAL TREATMENT

Coordinate System.—For a system of any given geometry there is a characteristic flow net; therefore, it would be convenient to consider this flow net as a curvilinear coordinate system, in which the position of any given point is fixed by the intersection of a head contour with a flow line. The coordinates of the point would then be designated by the parameters h_o and ψ, h_o being the numerical value of the head contour during the initial steady state and ψ being equal to q/k—in which q is the flow between the point considered and any convenient datum such as an impervious base (during the initial steady state) and k is the permeability of the medium considered.

The lengths of arc along these curvilinear coordinates are

$$ds_f = dh_o \sqrt{\left(\frac{\delta x}{\delta h_o}\right)^2 + \left(\frac{\delta z}{\delta h_o}\right)^2} = \frac{dh_o}{f_1} \qquad \text{(15a)}$$

and

$$ds_h = d\psi \sqrt{\left(\frac{\delta x}{\delta \psi}\right)^2 + \left(\frac{\delta z}{\delta \psi}\right)^2} = \frac{d\psi}{f_2} \qquad \text{(15b)}$$

From Darcy's law,

$$d\psi = \frac{dh_o}{ds_f} ds_h \qquad \text{(16a)}$$

Therefore:

$$ds_f \, ds_h = \frac{dh_o}{f_1} \frac{d\psi}{f_2} = \frac{(dh_o)^2 \, ds_h}{f_1 \, f_2 \, ds_f} \qquad \text{(16b)}$$

and

$$(ds_f)^2 = \frac{(dh_o)^2}{f_1 \, f_2} = \frac{(dh_o)^2}{f^2_1}; \quad \text{and} \quad f_1 = f_2 \qquad \text{(17)}$$

It can be shown[12] that, in a curvilinear coordinate system of two dimensions, the operator ∇^2 becomes

$$\frac{\delta^2}{\delta x^2} + \frac{\delta^2}{\delta z^2} = f_1 f_2 \left(\frac{\delta}{\delta h_o} \frac{f_1}{f_2} \frac{\delta}{\delta h_o} + \frac{\delta}{\delta \psi} \frac{f_2}{f_1} \frac{\delta}{\delta \psi} \right) \ldots\ldots\ldots\ldots (18)$$

or, from Eq. 17: In one dimension—

$$\frac{\delta^2}{\delta x^2} = f_1 \frac{\delta^2}{\delta h^2_o} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19a)$$

in two dimensions—

$$\frac{\delta^2}{\delta x^2} + \frac{\delta^2}{\delta z^2} = f^2{}_1 \left(\frac{\delta^2}{\delta h^2_o} + \frac{\delta^2}{\delta \psi^2} \right) \ldots\ldots\ldots\ldots\ldots (19b)$$

and, in three dimensions—

$$\frac{\delta^2}{\delta x^2} + \frac{\delta^2}{\delta y^2} + \frac{\delta^2}{\delta z^2} = f^3{}_1 \left(\frac{\delta^2}{\delta h^2_o} + \frac{\delta^2}{\delta \rho^2} + \frac{\delta^2}{\delta \psi^2} \right) \ldots\ldots\ldots\ldots (19c)$$

Derivation of Differential Equation.—In a rectangular element, $dx\, dy\, dz$, in which v_x, v_y, and v_z are velocity components parallel to the x-axis, y-axis, and z-axis, respectively, the volume of water flowing in time dt is:

Flow	Formula	
Inflow parallel to the x-axis........	v_x	$\times\, dy \times dz \times dt$
Outflow parallel to the x-axis......	$\left(v_x + \frac{\delta v_x}{\delta x} dx \right)$	$\times\, dy \times dz \times dt$
Net Flow—		
Parallel to the x-axis............	$\frac{\delta v_x}{\delta x} dx$	$\times\, dy \times dz \times dt$
Parallel to the y-axis............	$\frac{\delta v_y}{\delta y} dx$	$\times\, dy \times dz \times dt$
Parallel to the z-axis............	$\frac{\delta v_z}{\delta z} dx$	$\times\, dy \times dz \times dt$
Total volume of flow.............	$\left(\frac{\delta v_x}{\delta x} + \frac{\delta v_y}{\delta y} + \frac{\delta v_z}{\delta z} \right) dx$	$dy\, dz\, dt$

Since Darcy's law may be expressed as

$$v = -k \nabla h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

this total volume can be written as

$$V = -k \nabla^2 h\, dx\, dy\, dz\, dt \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

From the definition of specific drainage, this volume can also be expressed as

$$V = -w_d\, dh\, dx\, dy\, dz \ldots\ldots\ldots\ldots\ldots\ldots (20c)$$

[12] "Higher Mathematics for Engineers and Physicists," by Ivan S. Sokolnikoff and Elizabeth S. Sokolnikoff, McGraw-Hill Book Co., Inc., New York, N. Y., 1934, pp. 361–363.

Equating the two expressions, Eqs. 20*b* and 20*c*, and assuming $k/w_d = c_d$,

$$c_d \nabla^2 h = \frac{\delta h}{\delta t} \tag{21a}$$

From Eqs. 19, Eq. 21*a* becomes, in curvilinear coordinates:

$$c_d f^2_1 \left(\frac{\delta^2 h}{\delta h^2_o} + \frac{\delta^2 h}{\delta \psi^2} \right) = \frac{\delta h}{\delta t} \tag{21b}$$

Solution for Horizontal Drainage.—Consider a saturated porous body with length much greater than height—that is, $x \gg z$, and allow it to drain at the ends, $x = 0$ and $x = L$. Then $\frac{\delta h}{\delta z} = 0$ and Eq. 21*a* becomes

$$c_d \frac{\delta^2 h}{\delta x^2} = \frac{\delta h}{\delta t} \tag{21c}$$

The boundary conditions are: $h = 0$ when $x = 0$, $x = L$, $t = \infty$; and $h = H$ when $t = 0$. The solution is analogous to that used for consolidation tests and is

$$h = \frac{4\,H}{\pi} \sum_{n=1}^{n=\infty} \frac{1}{2\,n - 1}\, e^{-\lambda \tau} \sin \frac{(2\,n - 1)\,\pi\,x}{L} \tag{22}$$

in which, to simplify typography:

$$\tau = \frac{4\,c_d\,t}{L^2} \tag{23a}$$

and

$$\lambda = \frac{(2\,n - 1)^2\,\pi^2}{4} \tag{23b}$$

In Eqs. 22 and 23, n is an integer having successive values 1, 2, 3, $\cdots$. The drainage ratio is the ratio of the volume of water removed up to any given time to the total volume of water that can be drained under the existing conditions. For this case, by analogy with settlement computations,

$$d = 1 - \frac{8}{\pi^2} \sum_{n=1}^{n=\infty} \frac{1}{(2\,n - 1)^2}\, e^{-\lambda \tau} \tag{24}$$

In the solution of Eq. 24, settlement tables may be used to simplify computations.

Solution for Vertical Drainage.—Consider a saturated porous body draining vertically through its base. For this case,

$$d = 1 - \frac{16}{\pi^3} \sum_{n=1}^{n=\infty} \frac{(2\,n - 1)\,\pi + 2\,(-1)^n}{(2\,n - 1)^3}\, e^{-\lambda \tau} \tag{25a}$$

$$\frac{u_w}{\gamma} = f(t, z) - \frac{1 - d}{d}\, z \tag{25b}$$

and

$$f(t, z) = \frac{4\,H}{\pi^2} \sum_{n=1}^{n=\infty} \frac{(2\,n - 1)\,\pi + 2\,(-1)^n}{(2\,n - 1)^2}\, e^{-\lambda \tau} \tag{25c}$$

Now suppose that a constant air pressure is applied at the upper end of the porous body, amounting to a pressure head F_d. Disregarding the effect of gravity, the drainage ratio due to this pressure only can be found from Eq. 24, with z substituted for x. The drainage ratio for the case of gravity drainage alone is given by Eqs. 25. Then, by reasoning analogous to that used in settlement problems, the drainage ratio for the combined pressure and gravity drainage is

$$d = \frac{H\, d_2 + 2\, F_d\, d_1}{H + 2\, F_d} \qquad \text{.....................(26)}$$

in which d_1 is the drainage ratio due to gravity alone and d_2 is that due to pressure alone.

Drainage of an Earth Dam.—In the preceding section, all flow is assumed to take place along straight lines. Then the boundary conditions could be expressed in terms of x-coordinates and z-coordinates, so that solutions of Eq. 21*a* could be expressed as series that would converge to the initial head distribution when the time $t = 0$. In most drainage problems of practical significance, the lines of flow are curved, with curved boundaries, as, for example, the "line of seepage" in an earth dam. Therefore, the coordinate system formed by the resulting flow net is curvilinear. In such a case, f_1, which appears in Eq. 21*b* and is defined in Eqs. 15, is no longer a constant, but varies with h_o and ψ. Hence, Fourier series solutions will no longer satisfy the differential equation. In heat transmission problems, where there are usually boundaries of elementary geometry, polar or elliptical coordinates can be used to express the boundary conditions. Then series converging to $h = h_o$ when $t = 0$ can be obtained by use of Bessel functions or Lamé functions. Unfortunately, flow nets for most drainage conditions of practical significance cannot be so idealized. Often, they defy analysis, and are determined by successive approximation or graphical estimate. Hence, the following approximation method has been used to compute rates of drainage of earth dams.

Consider the condition:

$$f_1 \sim \frac{\Delta h_o}{\Delta s_f} \qquad \text{.........................(27)}$$

in which Δh_o is the head drop between two adjacent equipotential lines in a steady state flow net derived by graphical methods, and Δs_f is the length of a flow line between them. A glance at any of the flow nets in Figs. 2 or 3 will show that, over considerable sections of an earth dam, the ratio is nearly constant. The greatest variations occur near the drain and near the upstream slope, and the greatest errors involved in assuming f_1 as constant will be at these boundaries. However, any equation used to approximate the value of h and conforming to the boundary conditions, $h = 0$ when $h_o = 0$ and $h = H - D$ when $h_o = H$, must approach the same numerical values as these boundaries are approached. Furthermore, the observations described in the text indicate that (at least at appreciable distances below the free surface), $\delta h/\delta\psi = 0$, for earth dams subjected to drawdown. Hence, if the approximate differential equation—

$$c_d \left(\frac{\Delta h_o}{\Delta s_f}\right)^2 \frac{\delta^2 h}{\delta h^2_o} = \frac{\delta h}{\delta t} \qquad \text{...................(28)}$$

—is used to express drainage from an earth dam, the maximum error resulting from the assumption that $f_1 = \Delta h_o/\Delta s_f$ = constant occurs in the boundary regions where the values of h must approach the correct values anyway, as long as the solution satisfies the boundary conditions.

Under these assumptions, the following boundary conditions may be considered: When $t = 0$, $h = h_o$ (initial steady state); when $t = \infty$, $h = \frac{H - D'}{H} h_o$ (final steady state); when $h_o = 0$, $h = 0$; and when $h_o = H$, $h = H - D'$. Considering the drawdown, D', as instantaneous, a solution of Eq. 28 is

$$h = \left(1 - \frac{D'}{H}\right) h_o + \frac{2\,D'}{\pi} \sum_{n=1}^{n=\infty} \frac{(-1)^{n+1}}{n} e^{-n^2 B t} \sin \frac{n\,\pi\,h_o}{H} \quad \text{.....(29a)}$$

in which

$$B = \frac{\pi^2\, c\, (\Delta h_o/\Delta s_f)^2}{H^2} \quad \text{.....(29b)}$$

Actually, of course, the drawdown of a reservoir is never instantaneous, but varies as function of time, $D = f(t)$. Still, it can be imagined as the net result of a series of infinitesimal instantaneous drawdowns which immediately follow one another. The magnitude of each of these drawdowns may be considered as $d(D) = f'(t)\,dt$. If any one of these drawdown increments occurs at time t, if t_d is the time during which all of them occur, and if $R\,t_d$ is the time for which a value of h is desired, the drawdown D' in Eq. 29a can be replaced by $f'(t)\,dt$; and t, by $R\,t_d - t$ (the time interval during which the drawdown increment was effective). Thus, the head due to this increment can be computed. The sum of the heads, due to all such increments occurring up to time t_d (or up to time $R\,t_d$, if $R\,t_d < t_d$), is then the head resulting from the gradual drawdown. Hence, when $R \leqq 1$:

$$h = \left[1 - \frac{f(t)}{H}\right] h_o + \frac{2}{\pi} \sum_{n=1}^{n=\infty} \frac{(-1)^{n+1}}{n} \left(\sin \frac{n\,\pi\,h_o}{H}\right) \times \int_0^{R t_d} e^{-n^2 B (R t_d - t)} f'(t)\,dt \quad \text{....(30a)}$$

and, when $R \geqq 1$:

$$h = \left[1 - \frac{f(t)}{H}\right] h_o + \frac{2}{\pi} \sum_{n=1}^{n=\infty} \frac{(-1)^{n+1}}{n} \left(\sin \frac{n\,\pi\,h_o}{H}\right) \times \int_0^{t_d} e^{-n^2 B (R t_d - t)} f'(t)\,dt \quad \text{....(30b)}$$

Flotation Due to Drawdown.—Assuming that an adequate filter protects the upstream face of an earth dam down to the lowest elevation which the reservoir will reach, then only that part of the face which is always below pool level need be considered. In this region, as suggested by readings of pore pressure cells and as confirmed by watching the flow of dye in models subjected to drawdown, the flow is directed upstream and normal to the face. Therefore, the force polygon is as shown in Fig. 5. The value of the vector F_i in Fig. 5 represents the seepage force at equilibrium. Since the actual seepage force is $\gamma\, i$, in which i is the hydraulic gradient at the upstream face, Eqs. 30 may be used to compare the seepage force induced by a given drawdown of the reservoir with that required for equilibrium.

For zero time, corresponding to an initial steady state, the distribution of head near the upstream face of an earth dam resting on an impervious base may be computed from a conjugate function transformation.[13] The appropriate solution is

$$h_o = H - \frac{2\,\beta}{\pi}\left(\frac{r \sin \beta}{H}\right)^{(\pi-2\beta)/(2\beta)} \cos \beta \cos \frac{\pi\ \theta}{2\,\beta} \ldots\ldots\ldots (31)$$

in which h_o is the potential head referred to the impervious base; H is the maximum potential head; β is the angle made by the upstream face with the horizontal; and r and θ are the polar coordinates of a point referred to the upstream toe as an origin.

The hydraulic gradient along the upstream face is therefore the normal derivative of the head,

$$\text{Gradient } h_o = \left(\frac{r}{H} \sin \beta\right)^{(\pi-2\beta)/(2\beta)} \cos \beta \ldots\ldots\ldots\ldots (32)$$

or, if i is the hydraulic gradient and z is the distance of any point along the upstream face from the impervious base, $r = z \csc \beta$ and

$$i_{t=0} = \left(\frac{z}{H}\right)^{(\pi-2\beta/(2\beta)} \cos \beta \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

During a drawdown, the hydraulic gradient at the upstream face at any time is gradient $h = \frac{dh}{ds_f} = \frac{\delta h}{\delta h_o} \frac{dh_o}{ds_f}$; or:

$$i = \left(\frac{z}{H}\right)^{(\pi-2\beta)/(2\beta)} (\cos \beta) \frac{\delta h}{\delta h_o} \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

The value of $\frac{\delta h}{\delta h_o}$ may be obtained from Eqs. 30. If the drawdown proceeds at a constant rate, $D = b\,t$, then $f'(t)\,dt$ in Eqs. 30 may be replaced by $b\,dt$. Integrating as indicated in Eqs. 30 and then differentiating with respect to h_o, for the upstream face (where $h_o = H$):

$$\frac{\delta h}{\delta h_o} = 1 - \frac{b\,t_d}{H} - \frac{2\,b}{B\,H} \sum_{n=1}^{n=\infty} \frac{1}{n^2} (1 - e^{-n^2 B t_d}) \ldots\ldots\ldots\ldots (35)$$

Placing Eq. 35 in Eq. 34, the hydraulic gradient is

$$i = \left(\frac{z}{H}\right)^{(\pi-2\beta)/(2\beta)} (\cos \beta) \left[1 - \frac{b\,t_d}{H} - \frac{2\,b}{B\,H} \sum_{n=1}^{n=\infty} (1 - e^{-n^2 B t_d}) \right] \ldots (36)$$

In numerical computations, the hydraulic gradient obtained from Eq. 36 is positive when flow is directed away from the upstream face and negative when directed into the dam. Eq. 36, like Eqs. 30, from which it was derived, is not valid above pool level at any given time.

[13] "Flow of Homogeneous Fluids through Porous Media," by Morris Muskat, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., 1937, p. 343.

DISCUSSION

Harry R. Cedergren,[14] Assoc. M. ASCE.—In this basic paper the author has introduced a subject of considerable interest to the designer of earth dams. Not only has he presented data regarding the development of pore pressures within several operating earth dams, but he has developed a mathematical analysis that should be of considerable value to research engineers. Very few data on the actual performance of earth dams have been made available to the engineering profession as a whole, and any contribution in this direction is a significant step forward.

Too often extremely elaborate investigations are made for the design of earth dams, but only meager observations (or none at all) are made of pore pressures within the completed structure. Frequently observation systems and schedules are set up and observed for a short time and then abandoned. It is difficult to convince many persons and agencies responsible for the operation of earth dams that relatively small sums of money spent in observing water pressures in earth dams and their foundations over long periods of time can pay dividends. In order that such observations may be of maximum value, careful field measurements of water pressures should be accompanied by dependable summaries of the soil properties having an important bearing on the rate of movement of the saturation line or changes in pressure within the water phase.

In engineering computations highly refined mathematical theory is often applied to situations in which the possible degree of accuracy of the mathematics is far greater than the limitations imposed in fitting the mathematics to real situations. Although the theory may be capable of a high degree of refinement, factors controlling the practical application of the problem generally can be determined only approximately. Nevertheless the theory can be helpful in establishing probable limits within which the prototype can be expected to perform.

The author has based his mathematical derivation on Darcy's law and consideration of the quantity of water flowing out of an elemental volume of porous soil, with simplifications introduced to make his mathematical treatment possible. Since about 1940 the writer has used a graphical method based on Darcy's law and the flow net to obtain approximate solutions to certain nonsteady seepage problems encountered principally in earth dams. The method can be used in the study of falling saturation lines within embankments subjected to drawdown and other situations in which the position of a saturation line is changing. Although it must be considered only approximate, it is believed to have many practical applications.

Darcy's law provides a method of determining the velocity of a moving saturation line and, when used with the flow net, makes possible a study of the shape of a saturation line at successive positions in a structure. The flow net is derived for conditions of steady seepage, but in the following analysis it is assumed that the flow net can be used to obtain approximate solutions to certain nonsteady seepage problems by considering the moving seepage boundaries to be fixed momentarily. The analysis presented herein is based on the assumptions that no lag in flow or water pressure is caused by inertia or consolidation, and that changes in boundary conditions are transmitted quickly throughout the soil mass. To simplify the discussion, capillarity has been neglected. However, as indicated by the author, negative pore-water stresses, as set up by capillary forces in fine soils, cause an immediate lowering in the effective position of a falling saturation line by an amount not exceeding the effective capillary height. In this discussion, determination of the velocity of a saturation line will be reviewed prior to a discussion of application of the flow net in determining the shape of a saturation line at successive positions within a structure.

[14] With U. S. Corps of Engrs., Portland Dist., Portland, Ore.

Darcy's law expresses the relationship between the average, or discharge velocity, v_D, the permeability of the soil, k, and the seepage gradient, i, as indicated by Eq. 37:

$$v_D = k\,i \qquad (37)$$

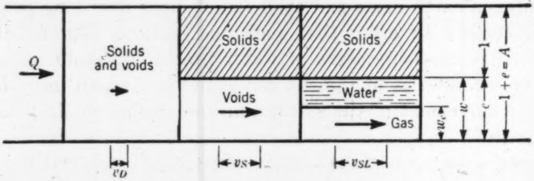

FIG. 7.—SEEPAGE RELATIONSHIPS

The discharge velocity represents the mean velocity in the entire cross section of a soil mass, including both solids and voids (see Fig. 7). The discharge velocity multiplied by the cross-sectional area, A, gives the seepage quantity per unit of time, as follows:

$$q = v_D\,A \qquad (38)$$

The effective velocity in the soil voids (the seepage velocity, v_S, Fig. 7) must be greater than the discharge velocity. Since the quantity of water flowing in the confined tube (Fig. 7) must be constant throughout the length of the tube, it follows that:

$$v_D\,(1 + e) = v_S\,e \qquad (39a)$$

and

$$v_S = v_D\,\frac{1 + e}{e} = k\,i\,\frac{1 + e}{e} \qquad (39b)$$

The seepage velocity, v_S, represents the effective velocity in the soil voids in the direction of flow lines for steady seepage conditions. When considering the rate of movement of a saturation line into or out of a soil mass, the quantity of water required to fill voids already partly filled, or the quantity of water draining out leaving the voids partly filled, must be considered. If the zone of saturation is moving into moist soil, less water must flow in to fill the voids than would be required if all the voids were empty. Likewise, if the zone of saturation is receding in a soil mass, leaving part of the voids filled, the saturation line can drop more rapidly than if all water must be removed. This factor was discussed by the author in terms of "drainability."

The velocity of a moving saturation line (v_{SL}, Fig. 7) is related to the seepage velocity in the following manner:

$$v_{SL}\, w_e = v_S\, w \quad \text{(40a)}$$

and

$$v_{SL} = v_S \frac{w}{w_e} = k\, i\, \frac{1+e}{e} \frac{w}{w_e} \quad \text{(40b)}$$

Grouping all terms dependent on the quantity of water flowing into or out of a soil mass in a drainage factor, *C*, Eq. 40*b* is simplified as follows:

$$v_{SL} = k\, i\, C \quad \text{(41)}$$

in which

$$C = \frac{1+e}{e} \frac{w}{w_e} \quad \text{(42)}$$

In Eq. 42 w is the saturated water content and w_e is the change in water content caused by a change from the moist to the saturated state, or vice versa.

From Eq. 41 the velocity of a moving saturation line can be estimated at any point at which the seepage gradient is known, provided the permeability and drainage factor are known. Knowing the velocity of the saturation line, the time required for a given length of movement may be determined from

$$L = v_{SL}\, t \quad \text{(43)}$$

in which L is the distance traveled in time, t, and v_{SL} is the velocity of the saturation line. For conditions existing during the drainage of water out of an embankment, or during saturation of an embankment, the seepage gradients are in a state of flux, and the seepage velocities are constantly changing. A rigorous solution for these conditions would be highly complex, but approximate solutions can be made by determining the velocity at finite increments of distance in a structure, and summing up the times required for all increments, as follows:

$$\Delta L = v_{SL}\, \Delta t \quad \text{(44a)}$$

and

$$L = \Sigma v_{SL}\, \Delta t \quad \text{(44b)}$$

By use of Eqs. 41 and 44*a* studies may be made of the velocity of a moving saturation line, the time required for a given length of movement, or the distance moved in a given time. Studies of this kind for earth dams can be made in conjunction with determination of the shape of a moving saturation line with the flow net. From the flow net the relative velocities of different points along a moving saturation line at any given moment can be approximated, since the velocities are proportional to the seepage gradient, i, and the gradient can be determined at any point in a flow net from the following fundamental relationship:

$$i = \frac{\Delta H}{\Delta L} \quad \text{(45)}$$

in which ΔH is the drop in head in distance ΔL in the direction of flow.

Application of the foregoing principle to the drainage from an embankment subjected to drawdown is illustrated by an analysis of the cross section in Figs. 8 and 9, which show the same shape as the model in Fig. 2. It is assumed that the section has been subjected to steady seepage with a full reservoir until equilibrium has been established, and the reservoir was lowered instantly to the minimum pool level. Recognizing that the flow net may only represent the approximate true seepage conditions within embankments subjected to nonsteady seepage, a flow net is drawn for the initial steady seepage boundaries (Fig. 8(*a*)). The seepage gradient is then determined at a number of points along the saturation line (points A_1, B_1, and C_1, Fig. 8(*a*)), and the saturation line is moved ahead a moderate amount, with the relative distances moved proportional to the seepage gradients at the various points along the original line. A new flow net is constructed for the new saturation line (Fig. 8(*b*)), a new set of gradients determined, and the saturation line moved to a third position shown by a dashed line in Fig. 8(*b*). This procedure is repeated a sufficient number of times to define the shape of the saturation line over the range desired. Having established the position of the saturation line at a number of intervals, the time required for a given length of movement can be examined in any part of the drawdown zone with the aid of Eqs. 41 and 44*a*. When using Eq. 44*a*, Δt is the time required for movement of the saturation line a distance ΔL, as for example—from the first to the second position in Fig. 8. This procedure, illustrated by a determination of the theoretical time required for the saturation line to move vertically downward at the center of

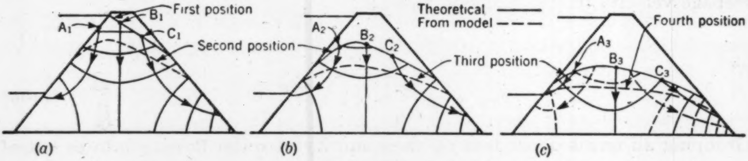

FIG. 8.—FLOW NETS FOR VARIOUS POSITIONS OF THE SATURATION LINE

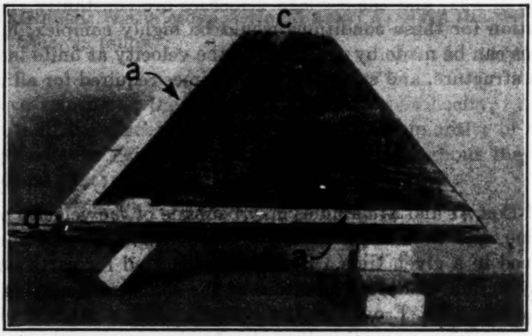

FIG. 9.—SIMPLE VISCOUS FLUID MODEL USED IN DRAWDOWN TESTS

the section in Fig. 8, is shown in Fig. 10. The seepage gradient at the center line is first determined for each position of the saturation line for which a flow net has been constructed, and the downward velocity of the saturation line at the center line computed from Eq. 41, using a drainage factor, *C*, and a permeability coefficient, *k*, which have been determined to be representative of the cross section. The velocity and time curves in Fig. 10 were computed for a small, viscous fluid model having the same shape as the cross section in Fig. 8 (see Fig. 9). The base width of the model was $10\frac{1}{2}$ in.

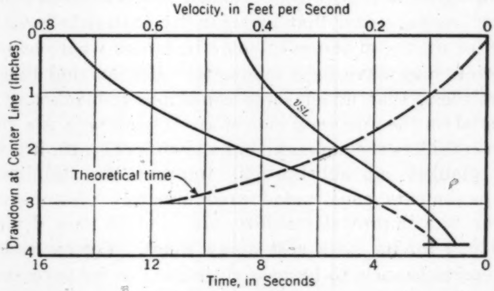

FIG. 10.—DETERMINATION OF THE THEORETICAL TIME FOR DRAINAGE FROM A MODEL

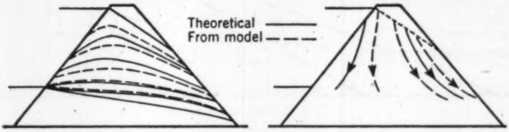
Viscous fluid models provide a valuable supplement to the flow net in studying moving saturation lines. The model shown in Fig. 9 was constructed from plywood and the shape of the saturation line and its direction of movement compared with theoretical determination of these factors. The plywood cross section designated b–b, Fig. 9, is separated (by strips a) about 0.1 in. from a glass plate that can be clamped on the front side of the model (not shown in photograph). The reservoir (c) is filled with a relatively viscous fluid, such as glycerine, which flows through the narrow space simulating flow through an embankment. Drawdown of the reservoir in the model is readily produced by pulling the slide (d) at the left. Determination of the shape and direction of the saturation line from flow nets agreed almost exactly with observations of the model, as indicated by Figs. 11(*a*) and 11(*b*). To the knowledge of the writer, A. Casagrande, M. ASCE, first proposed viscous fluid models for the study of seepage. Professor Casagrande and W. D. Shannon, Jr., have used this type of model extensively in nonsteady seepage studies.



(*a*) Shape of saturation line during drainage

(*b*) Paths followed by random points on saturation line during drainage

FIG. 11.—DETERMINATION OF THE SHAPE AND DIRECTION OF THE SATURATION LINE

The principles outlined herein are useful not only in studying changes in the position of a saturation line following reservoir drawdown, but also in obtaining approximate solutions to many other nonsteady seepage conditions. If water is flowing into a soil mass (as, for example, during saturation of an embankment), the same basic method[15] can be used; but the drainage factor, C, should be computed using w_c to designate the increase in water content accompanying a change from a moist to a saturated condition.

The author has suggested that high quality materials have been used for the protection of upstream slopes in some instances where less pervious, and cheaper materials may have been adequate. Recognizing this possibility, it is true, nevertheless, that under some conditions a blanket of high quality, pervious material on the upstream face of an embankment is a valuable investment. If one considers the embankment shown in Fig. 12, it is evident that a free draining blanket can substantially improve the stability of upstream slopes of embankments constructed predominately of impervious soil. In some instances, the improved stability provided by free draining, granular material may pay for its extra cost many times. For example, in locations requiring expensive tunnels to by-pass river flow, or for permanent operation, steepened embankment slopes (permissible with the use of free draining blanket material) may permit substantial reduction in the cost of the outlet works. In such locations, a stable, free draining blanket may be a highly valuable investment. To be of maximum benefit, the blanket should be free draining to the extent that the saturation line can closely follow a lowering reservoir.

FIG. 12.—INFLUENCE OF PERMEABILITY OF BLANKET ON THE STABILITY OF THE UPSTREAM SLOPE OF A DAM AFTER RAPID DRAWDOWN

An approximate solution for this special drawdown problem was developed by the writer in 1940 using the aforementioned principles.

In studying drainage out of thin blankets similar to that shown in Fig. 12, the criterion was established that the saturation line must closely follow the lowering reservoir, lagging on an average slope, S, that remains essentially constant during drawdown. The slope, S, may be established arbitrarily, or it may be the maximum allowable slope of the saturation line established by stability analysis. On the basis of the foregoing criterion a flow net and viscous fluid model study was made. These studies led to the conclusion that simplified conditions (see Fig. 13) could be used in obtaining reasonably accurate solutions to this problem. In the first place, it was found that a straight line could be substituted with little error, for the slightly curved saturation line, and the slope of this line could be used as a measure of the average seepage gradient within the blanket with little error. Also, for thin blankets similar to those shown in Figs. 12 and 13, the mean direction of flow within the blanket is approximately coincident with a line bisecting the two sloping boundaries of the blanket (for example, line x–x, Fig. 13), intersecting the horizontal base line at an angle α. Substituting these simplified conditions, the velocity of the saturation line, v_{SL}, in the direction of line x–x may be determined from the following equation derived from Eq. 41:

FIG. 13.—RELATIONSHIPS USED IN DETERMINING MINIMUM PERMEABILITY

$$v_{SL} = k\,S\,C \qquad \text{or} \qquad k = \frac{v_{SL}}{S\,C} \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

in which k is the coefficient of permeability of the soil and S is the average slope of the saturation line. The relationships involved are illustrated by the diagrams in Fig. 13.

Generally the maximum velocity of drawdown is established by the discharge capacity of outlet works, and it is desired to determine the minimum permeability of a protective blanket that will permit the saturation line to drop within a blanket, closely following the elevation of the reservoir. The velocity of drawdown of the reservoir, v_R, is related to the mean velocity of the saturation line, v_{SL}, in the following manner (see Fig. 13(*b*)):

$$v_{SL} = \frac{v_R}{\sin \alpha} \qquad (47)$$

Hence, the permeability that will permit the saturation line to follow the reservoir, with a specified small slope, S, can be approximated by combining Eqs. 46 and 47 as follows:

$$k = \frac{v_{SL}}{S\,C} = \frac{v_R}{S\,C \sin \alpha} \qquad (48)$$

Eq. 48 is proposed only as an approximate solution for the relationship between permeability and drawdown velocity for blankets having the general shape shown in Fig. 12. This expression provides a quick method of determining the approximate permeability required if the maximum benefit is to be derived from protective blankets. If available materials are considerably less pervious than the minimum calculated from Eq. 48, drainage from the blanket can be neglected in stability studies. If the available materials, either natural or processed, are several times more pervious than the minimum indicated, the improved conditions within the blanket, as typified by Fig. 12(*b*), should be considered in the stability analysis. For cases in which the permeability of available materials is either several times more pervious than required, or several times less pervious, errors inherent in the method should be relatively unimportant. Hence, an approximate solution such as Eq. 48 should have many useful applications. Doubtful cases will require individual analysis.

The graphical method outlined herein for the approximate analysis of moving saturation lines requires a knowledge of the construction of flow nets. However, this requirement should be no serious handicap, as reasonable skill in their construction can ordinarily be developed with moderate effort. New situations may require appreciable time for the development of satisfactory solutions; but once the general flow pattern for a given type of condition has been established additional flow nets are obtained with diminishing effort. After an engineer has developed reasonable skill in the construction of flow nets he finds that many apparently new problems are closely related to situations with which he is already familiar; hence, he encounters fewer and fewer new conditions. Also, if he studies accurate flow nets constructed by other engineers he can benefit considerably.

The author has stated that the probable danger of major slides of upstream slopes of dams subjected to rapid drawdown has been overemphasized, and he has indicated the manner in which capillary forces may cause a reduction in pore pressures in earth dams constructed of fine-grained soils. Although laboratory experiments may be helpful in establishing the probable effective height of the capillary zone in proposed embankment materials, observation of actual dams under operating conditions is believed the final answer to the study of this factor. Also, pore pressures caused by the sudden increase in effective weight of large soil masses in embankments subjected to drawdown are factors about which few factual data have been published. Dependable observational data for existing earth dams are needed for an evaluation of the combined result of the many factors effecting pore pressures in embankments.

Ross M. Riegel,[16] M. ASCE.—In the design of earth dams it has been the practice of the Tenessee Valley Authority (TVA) to compute a "factor of safety" for the slope exposed to the reservoir water by the method described by the author (under the heading, "Applications"); that is, it is assumed that the pore-water pressures which would exist under conditions of drawdown would be those due to a complete lack of drainage. (It is assumed also that the pore pressure head existing at any point within the dam is the static head existing at that point, measured either to the surface of the fill, to the saturation line, or to the surface of the reservoir water—as the case may be.) Under these conditions the minimum factor of safety prescribed in the design of new structures has been about 1.25. This rather low factor has been used largely because it has been believed that the assumed criterion of no drainage was actually more severe than the probable true condition; the information necessary for a more accurate appraisal of true conditions was wanting. The author's paper remedies this deficiency to a high degree, and enables the problem of design to be approached with more confidence.

It has also been the practice of the TVA to design the downstream slope, which was usually relatively free from uncertainty as to the effects of drainage, with a factor of safety of at least 1.5. This is an index of a more proper value when the drainage conditions are well understood and can be evaluated through the methods developed by the author. The effect of more accurate drainage treatment on the computed factor is strikingly illustrated by the application to Blue Ridge Dam in northwest Georgia, cited by the author.

The determination of the slope of major earth structures has also been subject to the review of the Board of Consulting Engineers (TVA) whose experience and judgment have been material factors in the final determination of slopes. It is suggested that the factor of safety must still have a material value, even after the most accurate design methods available have been employed. Some allowance must be made for two points. The material actually placed in the fill may depart in its characteristics from those determined from the occasional samples examined in the soils laboratory. The construction process, to some degree, may also fail to develop the anticipated characteristics as to compaction, moisture content, friction angle, and cohesion, which are set up in the laboratory investigation and design assumptions.

The author is to be complimented on shedding much light upon an obscure subject. His investigations of full-size structures have been based on embankment materials which may be generally classified as clays, whereas his model experiments have employed relatively coarse sand. He points out that, from the standpoint of drainage, soils classified as silts and fine sands are probably the least satisfactory embankment materials; yet, embankments have been built from them. It would be most interesting if the application of the author's methods of experiment and analysis to existing conditions in such structures would be undertaken, and it is suggested that such an investigation would be a valuable addition to this subject.

[16] Head Civ. Engr., Design Div., TVA, Knoxville, Tenn.

T. W. Lambe,[17] Jun. ASCE.—The method of computing rates of drainage and the magnitudes of total water head in the draining soil mass, based on an analogy of drainage with heat flow or consolidation, is an interesting approach to the drainage problem. In this discussion the writer will present comparative studies of the author's method, and various other theoretical methods, with the results from laboratory tests (made during a research program carried out by the writer which furnished material for a thesis to be submitted in partial fulfilment of the requirements for the degree of Doctor of Science at Massachusetts Institute of Technology in Cambridge), in which a soil was actually drained. Also presented will be a rigorous theoretical derivation of the author's method for vertical drainage, so as to show more clearly some of the assumptions and conditions involved.

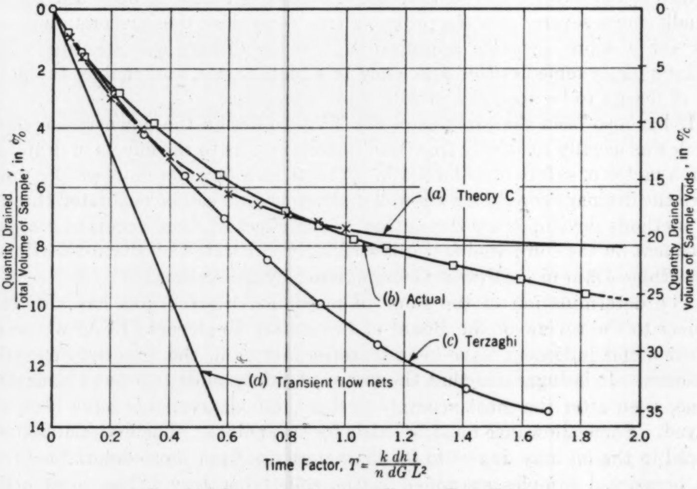

Fig. 14.—Drainage Quantity Versus Time Factor

Fig. 14 is a plot of drainage quantity, expressed as a percentage of both total soil volume and soil void volume of the draining mass, against time, expressed as a dimensionless time factor, T, for a laboratory test and for various theoretical solutions. The methods used to obtain the separate curves are explained first briefly and later analyzed after the theory has been presented so that the meaning of their respective assumptions can be more fully appreciated. Curve (*b*) was plotted from data taken during the bottom drainage of a 6-ft vertical tube of a natural fine, uniform, saturated sand. Theory C is a solution of Eq. 21*a* with a more reasonable assumption of initial total head distribution than that used by the author in obtaining Eq. 25*a*. Curve (*c*) was obtained by use of equations developed by Karl Terzaghi,[18] Hon. M. ASCE. Curve (*d*), for transient flow nets,[19] was plotted using steady state flow nets at the various positions of the falling line of saturation.

---

[17] Instr., Soil Mechanics, Civ. Eng. Dept., Mass. Inst. Tech., Cambridge, Mass.

Eq. 25*a* was not plotted in Fig. 14 because the writer knew no reasonable way to compute the ultimate drainage quantity due to the initial total head assumption used to derive Eq. 25*a*. This point is explained more fully later. However, in Fig. 15, Eq. 25*a* is compared with theory C, for both methods, by plotting T against the percentage of drainage, where the percentage of drainage is assumed equal to the percentage of the average total head which has been dissipated. An examination of Figs. 14 and 15 shows that: (*a*) Theory C more nearly approximates the actual flow curve than does Eq. 25*a*; and (*b*) none of the theoretical methods correctly takes care of the actual time lags that exist.

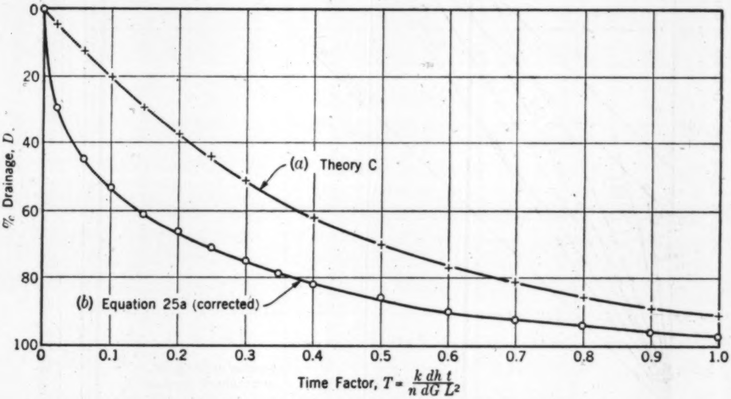

FIG. 15.—PERCENTAGE OF DRAINAGE VERSUS TIME FACTOR

Before considering the theoretical methods, a brief description of the true drainage process is given so that the validity of the various assumptions which are made to obtain solutions can be better evaluated. Fig. 16 is a plot of total heads in the sand sample at various times during drainage. (The datum for measuring elevation heads was taken at the bottom of the soil, which is also the atmospheric pressure line. The convention is followed throughout this discussion.) The times are represented by the dimensionless time factor, T, used in Figs. 14 and 15; T is the same as the author's τ (Eq. 23*a*), without the term 4. These total heads were obtained using a pore pressure measuring system with the same general principle as the one used by D. W. Taylor,[20] Assoc. M. ASCE, in his pore pressure work on undrained shear of clay. Since the pore water pressures were less than atmospheric pressure, it was necessary to prove that the measuring device correctly obtained the true pressures. This proof was secured by measuring the pore pressures for systems in which the values of pressure could be checked by an independent method.

[19] "Retaining-Wall Design for Fifteen-Mile Falls Dam," by Karl Terzaghi, *Engineering News-Record*, May 17, 1934, p. 632.

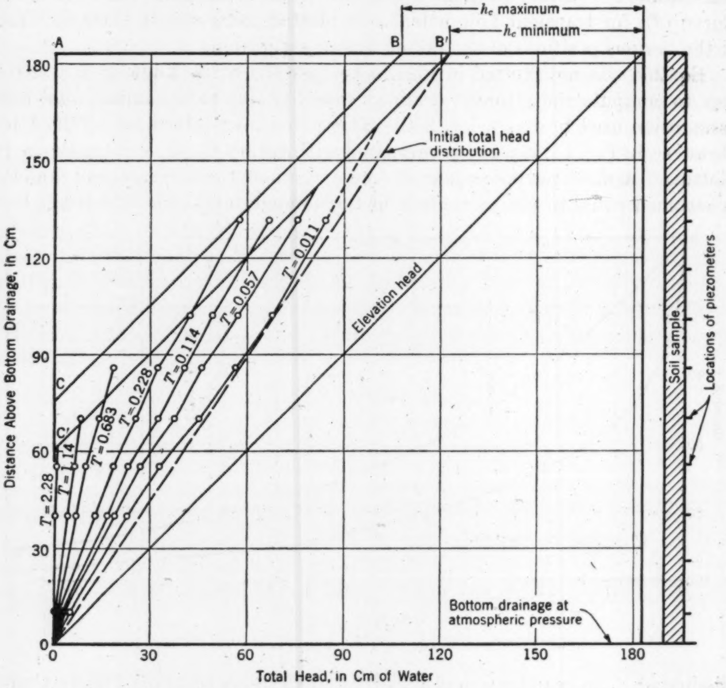

FIG. 16.—PORE PRESSURE DURING DRAINAGE OF SAMPLE

If, at the start of the test, the level of the water is an infinitely small distance above the top surface of soil in the tube, the total water head at every point is equal to its elevation head as shown in Fig. 16. As soon as the water level drops below the top of the soil, menisci are developed, causing the soil to exert a tension (based on a zero pressure of atmospheric pressure) to the water. This tension is transmitted throughout the water and gives the initial total head distribution shown in Fig. 16. As drainage takes place, the total head at all points becomes smaller; at any time the total head distribution has a characteristic shape, as shown in Fig. 16, of smaller gradients at the lower elevations. When the water tension in any small element exceeds the capillary head, h_c, more water is removed than flows into the element and the degree of saturation becomes less than 100%. In Fig. 16, the line BC, or the line B′C′, represents the maximum water tension that can exist at any point. Thus, at any time factor, line B′C′ is the boundary between the partially saturated soil above, and the completely saturated soil below, the line. Drainage from the partially saturated zone, represented by AB′C′, is a large percentage of the drainage and proceeds at a very slow rate because of the greatly lowered permeability.

---

[20] "Shear Research," 10th Rept. to U. S. Engr. Dept., Massachusetts Institute of Technology Soil Mechanics Laboratory, Cambridge, Mass., May, 1944.

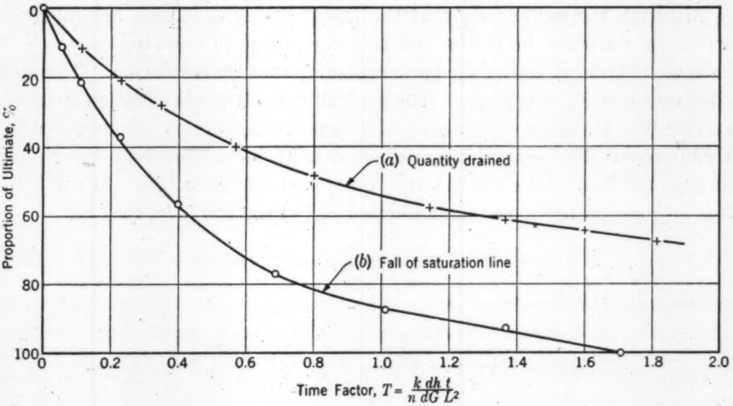

FIG. 17

The time lag of drainage from the partially saturated zone can also be noted in Fig. 17, which is a plot of the percentage of drainage and the relative fall of the line of "saturation" versus T for the laboratory test. The line of "saturation" fall was obtained by observation of the boundary line between the completely saturated and the partly saturated zones. There is some air present just below the visual boundary line, but this has little effect on the plot of fall of line of saturation since it is put on a percentage basis. Fig. 17 shows that the line of saturation has fallen to its final position when only 66% of the

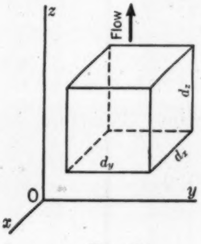

FIG. 18

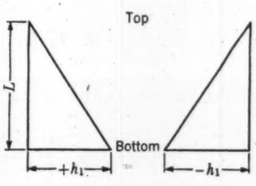

FIG. 19

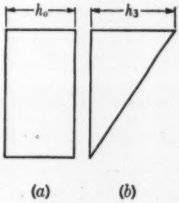

FIG. 20

drainage has taken place, thus 34% of all drainage takes place from the partly saturated zone after the line of saturation has reached its final position; also, while the line of saturation is falling, a large percentage of the water comes from above the line of saturation.

Although the writer feels that the use of analogies is very helpful for instructional purposes, he thinks that true derivations of analytical methods are desirable in order to clarify the various assumptions that are made. Therefore, a derivation of Eq. 4 is given. The general hydrodynamic equation governing laminar flow in soils is set up first. To save space, only one-dimensional flow is considered: The general equation can easily be extended to cover three-dimensional flow. The net flow into the element *dx dy dz* (Fig. 18) will be the flow into the bottom face minus the flow out of the top face; that is,

$$\text{Net } q = \Delta q = q_{\text{bottom}} - q_{\text{top}} \tag{49a}$$

in which, by Darcy's law,

$$q_{\text{bottom}} = k_{\text{bottom}}\, i_{\text{bottom}}\, A = k_z \left(- \frac{\partial h}{\partial z} \right) dx\, dy \tag{49b}$$

and

$$q_{\text{top}} = k_{\text{top}}\, i_{\text{top}}\, A = \left(k_z + \frac{\partial k_z}{\partial z}\, dz \right) \left(- \frac{\partial h}{\partial z} - \frac{\partial^2 h}{\partial z^2}\, dz \right) dx\, dy \tag{49c}$$

In these equations q is the rate of flow; k is the coefficient of permeability; A is the cross-sectional area of soil; h is the total head; and i is the hydraulic gradient.

Substituting Eqs. 49*b* and 49*c* in Eq. 49*a* and combining terms,

$$\Delta q = \left(k_z \frac{\partial^2 h}{\partial z^2} + \frac{\partial k_z\, \partial h}{\partial z^2} + \frac{\partial k_z}{\partial z}\, dz\, \frac{\partial^2 h}{\partial z^2} \right) dx\, dy\, dz \tag{50}$$

In the element *dx dy dz*, the volume of water present is

$$V_w = \frac{G\, e}{1 + e}\, dx\, dy\, dz \tag{51}$$

in which G is the degree of saturation; and e is the void ratio. Therefore,

$$\Delta q = \frac{\partial}{\partial t} \left(\frac{G\, e\, dx\, dy\, dz}{1 + e} \right) = \frac{dx\, dy\, dz}{1 + e} \frac{\partial}{\partial t} (G\, e) \tag{52a}$$

or

$$\Delta q = \left(e \frac{\partial G}{\partial t} + G \frac{\partial e}{\partial t} \right) \frac{dx\, dy\, dz}{1 + e} \tag{52b}$$

Equating Eqs. 50 and 52*b*,

$$\left(k_z \frac{\partial^2 h}{\partial z^2} + \frac{\partial k_z\, \partial h}{\partial z^2} + \frac{\partial k_z}{\partial z}\, dz\, \frac{\partial^2 h}{\partial z^2} \right) dx\, dy\, dz = \frac{dx\, dy\, dz}{1 + e} \left(e \frac{\partial G}{\partial t} + G \frac{\partial e}{\partial t} \right) \tag{53a}$$

or

$$k_z \frac{\partial^2 h}{\partial z^2} + \frac{\partial k_z \, \partial h}{\partial z^2} + \frac{\partial k_z}{\partial z} dz \frac{\partial^2 h}{\partial z^2} = \frac{1}{1+e}\left(e \frac{\partial G}{\partial t} + G \frac{\partial e}{\partial t} \right) \ldots\ldots (53b)$$

—which is the general hydrodynamic equation for laminar flow in soils. By making various assumptions, several of the familiar formulas of soil mechanics can be obtained, for example:

(*a*) If it is assumed that k is constant and $G = 100\%$, Eq. 53*b* becomes

$$k_z \frac{\partial^2 h}{\partial z^2} = \frac{1}{1+e} \frac{\partial e}{\partial t} \ldots\ldots (54)$$

—which is the consolidation equation.

(*b*) If it is assumed that k, e, and G are constant, Eq. 53*b* becomes

$$k_z \frac{\partial^2 h}{\partial z^2} = 0 \ldots\ldots (55)$$

—which is the Laplace equation for one-dimensional steady flow.

To obtain the author's formula (Eq. 4) it must be assumed that k is constant, e is constant, and

$$\frac{e}{1+e} \frac{\partial G}{\partial t} = w_d \frac{\partial h}{\partial t} \ldots\ldots (56a)$$

Assuming the relation expressed by Eq. 56*a*,

$$w_d = \frac{e}{1+e} \frac{\partial G}{\partial h} = n \frac{\partial G}{\partial h} \ldots\ldots (56b)$$

in which n is the porosity of the soil. Eq. 56*b* agrees in principle with the author's paper (under the heading, "Analogy Between Seepage and Heat Flow"), since $n \, \partial G$ is the water drained per unit volume. The writer prefers to use $n \frac{\partial G}{\partial h}$ instead of w_d, as both n and G are widely used terms in soil mechanics literature. If a vertical tube of soil is drained and the degree of saturation, G_z, of the drained soil is obtained at various heights above the atmospheric pressure line, a plot of z versus $n\,(1 - G_z)$ can be made. This is the true curve the author is attempting to plot in Fig. 6. There is some question as to the use of air to obtain the various hydrostatic heads, since it is difficult to know whether or not all the air pressure is carried by the water and whether or not the air picks up water in passing through the sample. Air pressure to obtain plots of $n\,(1 - G_z)$, which is also known as "effective porosity," versus z has been used by other experimenters.[21,22] As recognized by the author, $n \frac{\partial G}{\partial h}$ (or w_d) may be far from constant.

The writer would like to point out that w_d and c_d have units. It would be helpful if the units were given to the values of w_d and c_d listed in the section,

---

[21] "Capillarity of Soils," by Hsien-Hsiang Ku, thesis presented to Purdue University at Lafayette, Ind., in 1940, in partial fulfilment of the requirements for the degree of Bachelor of Science.

[22] "Subsurface Drainage Investigation," New England Div., Corps of Engrs., Dept. of the Army, Boston, Mass., 1947.

"Comparison of Computed and Observed Data," so as to enable the procedure to be better followed. For example, without units, the writer finds it difficult to discover how, by using Eq. 8*b*, the author obtains $c_d = \frac{0.8 \text{ in. per min}}{0.23} = 41.7$.

Making the three assumptions previously mentioned as necessary to obtain Eq. 4, by replacing $\frac{k_z}{n} \frac{\partial h}{\partial G}$ by c_d in Eq. 53*b*,

$$c_d \frac{\partial^2 h}{\partial z^2} = \frac{\partial h}{\partial t} \qquad (57)$$

—which is the author's equation (Eq. 21*a*) for vertical drainage.

Formulas for draining a saturated soil mass vertically through the base are next developed—because it is this flow condition for which the comparison is presented in Figs. 14 and 15.

The solution of Eq. 57 involves the assumption of an initial distribution of total head, *h*. As in the theory of consolidation for the initial distribution of hydrostatic excess, there are many initial total head distributions for which solutions can be obtained. By using boundary conditions of bottom drainage only and of zero total head at the bottom immediately after start of flow, by assuming an initial total head distribution as shown in either Fig. 19(*a*) or in Fig. 19(*b*), and by solving in a manner similar to the solution for the consolidation theory,[23]

$$d = 1 - \frac{16}{\pi^3} \sum_{n=1}^{n=\infty} \frac{(2\,n - 1)\,\pi + 2\,(-1)^n}{(2\,n - 1)^3}\, e^{-\frac{1}{4}\lambda\tau} \qquad (58)$$

—which is Eq. 25*a*, with a correction of 4 in the exponential term. The boundary conditions of bottom drainage and of zero total head at the bottom are in complete agreement with what takes place. On the other hand, the assumption of either initial total head distribution as shown in Fig. 19 is questionable. A solution based on Fig. 19(*a*) gives an infinite initial gradient at the bottom, also, according to this solution, during the early stages of drainage there is upward flow in the upper sections of the soil. Examination of Fig. 16 shows that both these conditions are untrue. A solution based on Fig. 19(*b*) gives water flow into the soil sample and, therefore, has no place in drainage equations.

It is interesting to note that the solution of Eq. 58 can be obtained by substitution of the initial condition of Fig. 19 in Eq. 57, or by correctly combining the better known solutions for initial conditions as shown in Fig. 20.[23] In view of the actual initial total head distribution in Fig. 16, the writer suggests that a solution based on an initial total head distribution as shown in Fig. 20(*b*), in which $h_3 = L - h_c$, is superior to that presented by the author. This solution is given by K. Terzaghi and O. K. Fröhlich[10] and will be called theory C for the comparison in Figs. 14 and 15. The time curves for theory C are given in Fig. 21. A comparison of the theoretical time curves of Fig. 21 with the actual time curves of Fig. 16 shows: (*a*) The theoretical initial total head distribution is correct; (*b*) in the early stages, the actual head dissipation is faster than in theory C (later the reverse is true); and (*c*) the theory does not take into account the partly saturated zone. As one might expect, theory C agrees fairly well with the actual test, as noted in Fig. 14, until the effects of the partly saturated zone become important.

---

[23] "Fundamentals of Soil Mechanics," by D. W. Taylor, John Wiley & Sons, Inc., New York, N. Y., 1948.

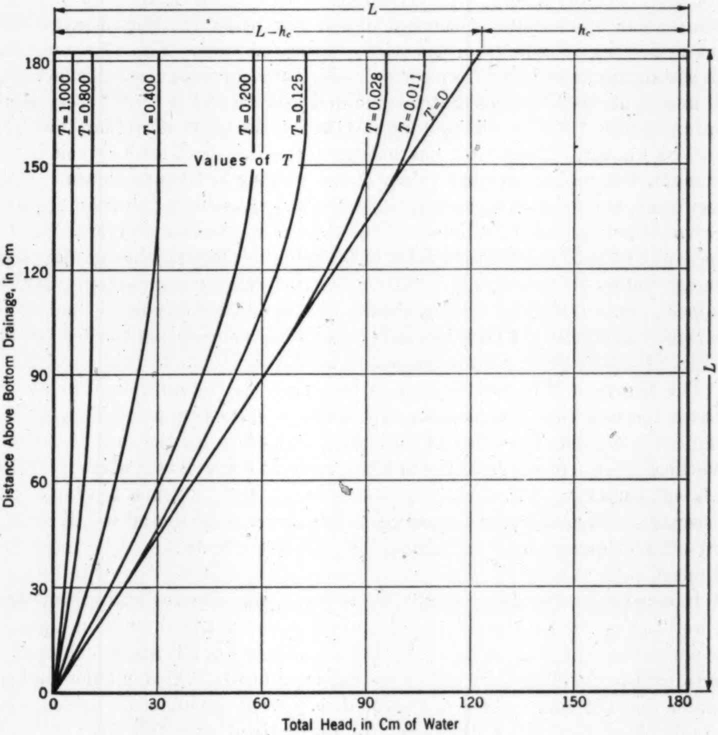

FIG. 21.—TOTAL HEAD AS A FUNCTION OF HEIGHT AND TIME FACTOR

The ultimate total water drained can be computed for theory C by: (1) Setting up the expression for total head as a function of time and distance; (2) differentiating the head expression with respect to z to obtain the gradient and substituting $z = 0$ to obtain the gradient at the bottom; and (3) putting the gradient in Darcy's expression for rate of flow and integrating with respect to time from time = 0 to time = ∞. For the case studied, the ultimate total water obtained by this method was only 57% of the actual. This result is not surprising in view of the fact that the theory does not approximate the actual head dissipation in the partly saturated zone. The ultimate quantity drained was not computed using the author's initial head distribution because the gradients obtained have little meaning. Since the bottom gradient is infinite immediately after starting drainage, a solution, like that applied to theory C, using the author's initial total head distribution, would give an infinite quantity. It would be helpful if the author were to explain how the ultimate quantity can be computed in a manner consistent with his theory, if such a method exists.

The remaining two theoretical solutions plotted in Fig. 14 also require discussion. In his theory, K. Terzaghi assumes that all drained water comes from a small cross-sectional element of soil just below the line of saturation, thus neglecting all flow from the partly saturated zone. Fig. 17 shows that this assumption may be far from correct. K. Terzaghi recognized this fact himself and in his book[24] states that this method may be only a "* * * very crude approximation * * *." In applying this theory, the value of capillary head, h_c, must be known. The writer has not used the definition of h_c given by K. Terzaghi, but he has selected values of the varying h_c from test data. More specifically, the value of h_c used in the gradient expression is the value required to give the actual initial gradient. (This value of h_c was also used for theory C.) The capillary head and the final value of G chosen to compute the quantity were average values so that $A\, n\, (1 - G)\, (H - h_c)$ equaled the measured quantity drained. Such selections of values of G and h_c would not be possible had actual drainage test results not been available; they were made so that the comparison in Fig. 14 would be on a more consistent basis.

The transient flow net solution is based on the assumption that at any instant the flow can be represented by a steady state flow net. The solution completely neglects the effect of capillarity and, thus, for the case of draining a vertical column of soil from the bottom, assumes a constant gradient of unity. It is not surprising, therefore, that this solution gives a much too large rate of seepage. The difference between this solution and the actual would be even larger for a finer-grained soil where the capillary effects would be more pronounced.

In conclusion, the writer would like to emphasize that the author's method, as well as the other theoretical methods considered in this discussion, does not recognize the changing permeability that appears in Eq. 53*b* and which must be considered in draining soils with large capillary heads. Also, all the methods assume that the void content of the soil does not change under the added intergranular load caused by drainage. In fine-grained soils this assumption of constant void content may be questionable.

W. L. SHANNON,[25] Assoc. M. ASCE.—In connection with the design of a rolled fill earth dam in New Hampshire in 1945, the writer became interested in investigating the time required for the drainage of the pervious upstream shell section of a rolled earth fill dam following drawdown of the upstream pool. This problem is of general interest because most earth dams of modern construction contain substantial upstream pervious shell sections. To investigate the stability of such dams it is usually necessary to make some assumption regarding the drainage of this shell section for the condition of drawdown of the upstream pool.

---

[24] "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., New York, N. Y., 1943, p. 310.

[25] Research Associate in Soil Mechanics, Graduate School of Eng., Harvard Univ., Cambridge, Mass.

At the writer's suggestion an approximate solution for the drainage of an upstream shell section of a dam was developed by A. Casagrande, M. ASCE, and presented in an unpublished report, dated May 23, 1945, to the Boston (Mass.) District, Corps of Engineers, Department of the Army. Professor Casagrande assumes that the upstream pool elevation is suddenly drawn down the depth D (Fig. 22). This is a reasonable approximation providing the time for a small percentage of drainage of the shell section is much greater than the actual time for full drawdown of the pool. It is further assumed that the free water surface during drainage may be approximated by inclined straight lines passing through the toe of the shell. This approximation has been found to be reasonable where the seepage quantity is of interest and the shape of the free surface is not. At the start of drainage the free water surface is at the upstream face of the shell; at any time after drainage starts the free water surface is the line designated t_U in Fig. 22.

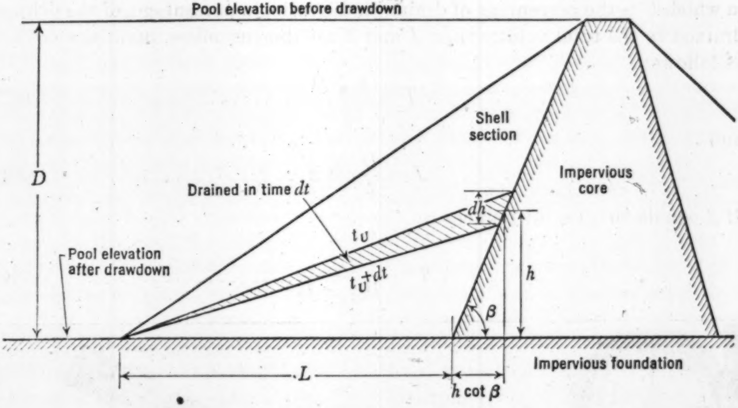

FIG. 22.—DRAINAGE OF UPSTREAM SHELL SECTION OF AN EARTH DAM

The volume of water which will drain from the shell in the time dt (Fig. 22) is equal to the volume of the triangular slice times the yield, w_y:

$$dq = -\frac{dh}{2}(L + h \cot \beta)\, w_y \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

Based on Darcy's law and making Dupuit's assumption,[28] which is reasonable for slopes of the upstream face less than 30°, the quantity of flow per unit of time may be approximated by

$$\frac{dq}{dt} = k\, a\, i = k\left(\frac{h}{2}\right)\left(\frac{h}{L + h \cot \beta}\right) \ldots\ldots\ldots\ldots\ldots (60)$$

---

[28] "Seepage Through Dams," by A. Casagrande, "Contributions to Soil Mechanics 1925–1940," Boston Soc. of Civ. Engrs., Boston, Mass., 1940, p. 304.

Eqs. 59 and 60 when solved and integrated may be reduced to the following form:

$$T = \frac{U}{100 - U} + J \log_e \frac{100}{100 - U} + J^2 \frac{U}{100} \dots\dots\dots\dots (61)$$

in which U is the percentage of drainage, the ratio, in percentage, of the volume drained to the total volume; and J and T are dimensionless quantities defined as follows:

$$T = \frac{t_u \, k \, D}{w_y \, L^2} \dots\dots\dots\dots (62)$$

and

$$J = \frac{D}{L} \cot \beta \dots\dots\dots\dots (63)$$

If β equals 90°, Eq. 61 reduces to

$$T = \frac{U}{100 - U} \dots\dots\dots\dots (64)$$

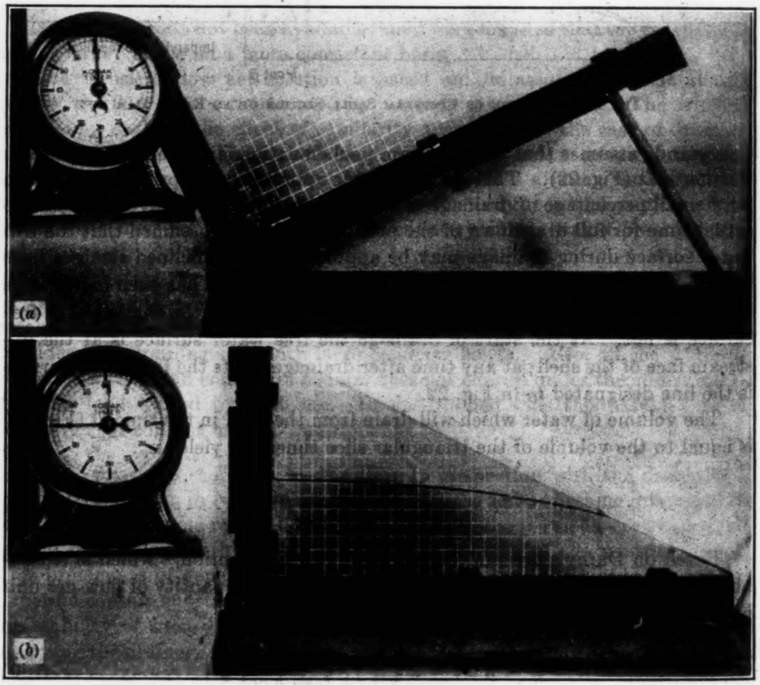

Fig. 23.—Viscous Fluid Model

(a) Inclined for Filling
(b) During Drainage Test

It was suggested by Professor Casagrande that viscous fluid models could be used advantageously to check this theoretical solution. Viscous fluid models have several important advantages over sand models, such as those used by the author, for the study of nonsteady flow problems. In a viscous fluid model all the fluid is drained, whereas in sand models there is a variable quantity of water retained by capillarity. The coefficient of permeability of the viscous fluid model is the same in every direction and at every point. Different coefficients of permeability for different elements of a structure may be obtained by varying the plate spacing. In sand models it is difficult to place the sand so that it has the same coefficient of permeability throughout. To obtain two or more sands having desired ratios between their coefficients of permeability usually is extremely difficult.

A viscous fluid model was designed and constructed at Harvard University (Cambridge, Mass.) and tests were performed under the supervision of the writer at the Soil Mechanics Laboratory of the Boston District, Corps of Engineers. The model, as shown in Fig. 23, represents the upstream shell of a dam resting on an impervious horizontal foundation and having an impervious core with a vertical upstream face. The upstream face of the shell has a slope of 1 vertical and 2 horizontal. The model consists of two triangular parallel glass plates 0.28 cm apart and held in a frame which provides the impervious horizontal and vertical boundary. To fill the model with fluid the frame was tilted so that the sloping open edge was horizontal, as shown in Fig. 23(*a*).

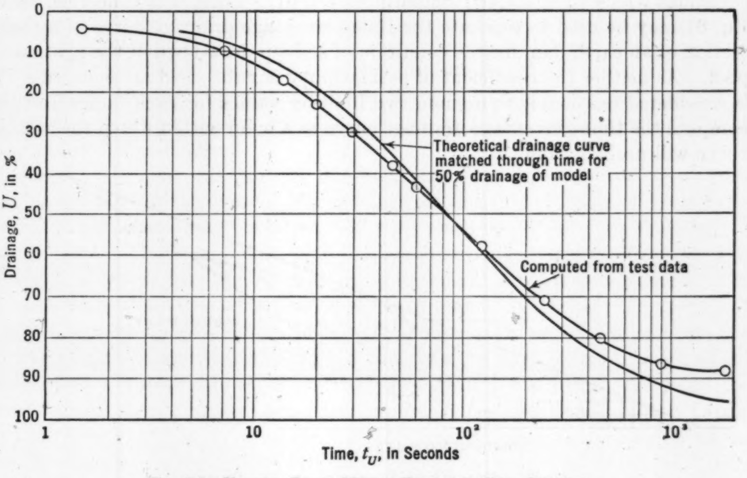

FIG. 24.—VISCOUS FLUID MODEL DRAINAGE TEST RESULTS

The fluid used was glycerine, which is sufficiently viscous to insure laminar flow between the plates. Glycerine has an affinity for glass, and hence, as drainage of the fluid occurs, a thick film will cling to the glass plates in the drained area unless precautions are taken to reduce this affinity. In these tests, the glass plates were given a very thin coating of paraffin, which reduced to a negligible amount the quantity of glycerine clinging to the plates.

A drainage test consists in suddenly tilting the model filled with fluid from the position shown in Fig. 23(*a*) to that shown in Fig. 23(*b*). Periodic observations of the position of the free surface were recorded photographically. In Fig. 23(*b*) the dark line at midheight of the model is the free surface of the glycerine at 45 sec after start of drainage. The results of a drainage test on this model are shown in Fig. 24.

In order to determine a value for the coefficient of permeability of the glycerine flowing between the two paraffin coated glass plates, measurements of the fluid viscosity are necessary. For the model tests performed, measurements of fluid viscosity were not obtained; hence, a direct comparison between Eq. 64 and the model test results is not possible. However, it is possible to match a theoretical curve based on Eq. 64 through any desired point on the drainage curve for the model. In Fig. 24 a theoretical curve has been matched through the time for 50% drainage of the model. The good agreement between the test data and the matched theoretical curve indicates that the derivation is reasonable as far as shape of the time-drainage curve is concerned.

In connection with an extensive viscous fluid model investigation of a very similar problem, a good agreement, both with respect to the shape and the position of drainage curves, was obtained between curves determined from viscous fluid model tests and drainage curves computed from theoretical equations which were derived similarly to Eq. 61. Thus, it is concluded that Eq. 61 may be used to estimate the time-percentage drainage curve of a shell section of an earth dam for the condition of sudden drawdown of the upstream pool. As neither the coefficient of permeability nor the yield are constants, it is considered reasonable to assume two limiting values for each factor and to compute the time-percentage drainage curve as a band within which the actual curve will probably fall.

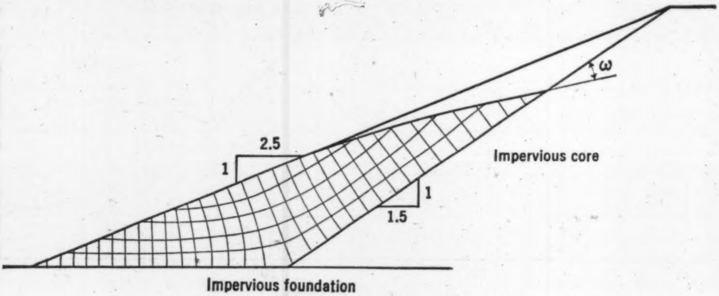

FIG. 25.—EXAMPLE OF FLOW NET AT 16% DRAINAGE

From such a solution, the percentage of drainage corresponding to any desired time after sudden drawdown of the upstream pool may be estimated. This value for percentage of drainage will be reasonable only if the percentage of drainage which occurs during the actual time required for pool drawdown is small.

By making several trial flow nets, one net may be constructed for a desired value of percentage of drainage. Fig. 25 is an example of a flow net representing seepage conditions in an upstream shell of a dam which has drained to $U = 16\%$.

According to Professor Casagrande, the problem of constructing a flow net for the condition of drainage is more complicated than the ordinary steady flow seepage problem, because the free surface is neither a flow line nor an equipotential line. The free surface must fulfil the condition that the intersections with the equipotential lines are all vertically equidistant. In addition, the free surface must be tangent to the upstream slope and must meet the slope of the impervious core at an angle ω which is dependent on the velocity v_β with which this point moves down the slope. This velocity must fulfil the conditions:

$$v_\beta = \frac{k \sin(\beta - \omega)}{w_y \cos \omega} \dots\dots\dots\dots\dots (65)$$

and

$$v_\beta = \frac{k}{100\, w_y \sin \beta} \left(\frac{D}{L}\right)^2 \frac{\partial U}{\partial T} \dots\dots\dots\dots\dots (66)$$

Eq. 65 follows from considerations of the flow net at the point where the free surface meets the impervious boundary of the core, and Eq. 66 represents the rate of progress of drainage.

F. H. KELLOGG,[27] M. ASCE.—The discussions of this paper indicate several of the methods being used in the study of drainage without replacement from an external source. They should point the way toward a rational analysis of this type of ground-water flow which would lead to a much more intelligent use of local experience.

Mr. Cedergren outlines the method of attack by graphical flow nets. As pointed out at the close of Mr. Lambe's discussion, this completely neglects capillarity, which should not invalidate the analysis for pervious shoulders of dams, ground-water supplies, and similar conditions where capillary head is considerably less than the head inducing drainage. Just why the free surface of the water should be considered a source does not seem clear; the volume of water available there is infinitesimal. It appears more rational to consider the unsaturated boundaries of the drained body as a constant source through which air enters, the drains as constant sinks through which water escapes, and the free surface as a transient air-water boundary, as mentioned in the paper. Thus, distinction may be made between free draining materials, in which capillarity plays a minor role, and slow draining materials, in which capillarity plays a major role. The boundary between the two would depend on the ratio of effective capillary head to head inducing drainage, and would thus be variable, just as the boundary between turbulent and laminar flow, as defined by the Reynolds criterion, is variable.

---

[27] Chairman, Dept. of Civ. Eng., Univ. of Mississippi, University, Miss.

Mr. Lambe gives an excellent resume of the mechanics of drainage. He questions the validity of Eq. 25*a*, doubtless because of lack of clarity in the basic paper. The writer hastens to add that he did not fail to plot this equation because he "* * * knew no reasonable way to compute the ultimate drainage quantity * * *"; in support, Fig. 26 is presented, plotting the computed curve, together with observed points for comparison. The test was made for standard Ottawa sand, so that any interested investigator may verify these results.

To clarify Eq. 25, it should be mentioned that it was derived for an initial condition of static saturation. The initial head distribution represents maximum potential head, L, minus maximum capillary head for equilibrium h_c. Because capillary channels are of a variety of sizes, and intercommunicate, the initial value of h_c was taken as varying from zero at the base to L at the top. As drainage proceeds, water flows from smaller into larger channels, accounting for increased net heads at the top of the sample. No flow of water into the sample is involved. An infinite hydraulic gradient occurs for an infinitesimal time at the beginning of drainage, making the volume of drainage during the first instant of flow indeterminate, not infinite. This analysis is similar to one for consolidation under its own weight of clay resting on sand.[28] As the initial head distribution for Mr. Lambe's "theory C" requires initial steady state flow, there is no comparison between this condition and that for which Eq. 25 was derived.

Mr. Riegel moves the discussion from the science of physics to the art of engineering. The importance of the modifying factors he has mentioned has been amply confirmed by field observations, including those of the writer. In fact, until sufficient field observations are available to serve as bases for working hypotheses, the usefulness of models and pure analysis is questioned.

---

[28] "Theorie der Setzung von Tonschichten," by K. Terzaghi and O. K. Fröhlich, F. Deuticke, Leipzig, 1936, p. 115, section 57.

It is emphasized that the tests described in this paper were performed after field observations to secure a variety of checking conditions, and not to try to duplicate any field conditions.

Mr. Shannon presents an interesting description of drainage study by viscous fluid models. Although these are certainly a technical improvement on sand models, they do not give the heterogeneity of capillary channels leading to a true unsteady state condition in which every point of the body is a source. Like transient flow nets, they illustrate a steady state in which one boundary varies with time—air flowing steadily in at the top and fluid flowing out at the drain. This is not the condition described in the basic paper, nevertheless it is one that is extremely important, particularly in the field of ground-water supply, where the yield w_y, as assumed in Mr. Shannon's equations, is essentially constant. The viscous fluid models described in this discussion should have valuable potentialities under such conditions.

In conclusion, the author wishes to express his appreciation of the discussions submitted, which should be valuable additions to the scanty literature on unsteady state drainage.

APPLICATION OF GEOLOGY TO TUNNELING PROBLEMS

By Ernest E. Wahlstrom,[1] Esq.

With Discussion by Messrs. Berlen C. Moneymaker; Robert S. Mayo; F. A. Nickell; R. H. Keays; Jacob Feld; Thomas W. Fluhr; Portland P. Fox; Hyde Forbes; Roger Rhoades, A. B. Reeves, and W. H. Irwin; and Ernest E. Wahlstrom.

Synopsis

Geological examination of tunnel sites prior to and during tunneling operations has become established procedure. The geologist should study and appraise carefully all surface and subsurface features having any bearing on the engineering problems associated with the drawing of the tunnel. Particular attention should be given to the following: (1) Internal structures, physical characteristics, and distribution of the rocks and overburden; (2) secondary structural features such as folds, faults, and joints; (3) chemical alteration of the rocks; and (4) the distribution and flow of ground water.

Suggestions for overcoming or minimizing difficulties presented by caving ground and other undesirable conditions in tunnels are given, and the causes and effects of caving in selected examples are discussed in detail.

Introduction

Geological investigations play an increasingly important part in the planning and completion of certain types of engineering projects. Geological examination of dam sites, bridge and building foundations, and tunnel sites prior to and during construction has become an established procedure that has yielded substantial or even spectacular returns in the form of safety and reduced costs of construction and maintenance.

The writer has spent considerable time as a consultant studying the geological features of several proposed water diversion tunnels, and in connection with this work has examined many existing tunnels and adits in an effort to discover and evaluate the various geological factors that are important in economical tunneling operations. Mine tunnels yield the most valuable data because, in general, these tunnels follow or cut across ore bodies formed where faulting,

[1] Dept. of Geology, Univ. of Colorado, Boulder, Colo.

fracturing, and alteration are at a maximum. However, much pertinent information has been obtained from railroad tunnels, drainage tunnels, and existing water diversion tunnels.

THE FUNCTIONS OF THE GEOLOGIST

The functions of the geologist in tunneling operations are manifold. Generally, he is called upon to examine the proposed site for a tunnel to determine if it is located to the best advantage. Such an investigation entails a geologic study of the portal areas and the surface over and adjacent to the line of the tunnel. The results of the study may lead to one of several conclusions:

(1) The tunnel is favorably situated and little or no difficulty should be experienced in driving it.

(2) There are geologic indications of the presence of sections of bad ground in the course of the tunnel. (It is the geologist's responsibility to indicate the probable location and nature of the bad ground in these sections.)

(3) The tunnel site is unfavorably situated, and the cost of driving the tunnel will be very high if not prohibitive.

If the location of the tunnel cannot be changed or if conditions demand that the tunnel be driven in spite of the unfavorable prognostication, then the geologist is faced with the responsibility of predicting to the best of his ability the extent and character of the various undesirable conditions that will be encountered.

Many tunnel sites are in areas partly or wholly covered by concealing alluvium or overburden. In covered areas the geologist must decide to what extent and by what methods the subsurface should be explored. Frequently, trenching or drilling is needed, which should be supervised by the geologist with attention to minute detail. Exploratory work of this type is expensive and the geologist generally must be satisfied with a bare minimum of information even though the facts he obtains do not begin to solve the host of unanswered problems that are associated with regions of thick or widespread blanketing deposits. Under certain conditions geophysical investigations yield pertinent information, and the geologist's duty is to determine which geophysical method or methods should be employed and to what extent.

Once the tunnel is started, the geologist should make periodic examinations of the completed sections and the face. He should maintain a detailed written account and a map showing the geological features of the tunnel as well as the day-by-day progress. The study of the rocks and structures encountered in the tunnel may lead to an increase in the accuracy with which the geologist may predict the changes in the rocks or structures beyond the tunnel face. The geologist may give advice as to the type and the amount of support needed in bad sections and as to the most effective manner of drilling and blasting at the face—giving due consideration to the relationship between the structure of the rock and the ease with which it is mined. In the event that unexpected difficulty is encountered because of extremely bad ground, he may offer counsel as to the best method of overcoming the difficulty.

The importance of a detailed geologic map of the tunnel cannot be overemphasized. This map not only should show the geologic structures and rocks encountered, but it also should serve as a lasting record to indicate the location of bad sections, which may require attention many years after the tunnel is completed.

The geologist should act in an advisory capacity to the engineer in charge of the tunneling operation. Too often the geologist's advice does not carry the weight it should because either the engineer does not understand what the geologist is attempting to do or he feels that the geologist's predictions are too vague and indefinite. However, this situation is gradually becoming less serious and the engineer and the geologist are reaching an amicable understanding based on mutual respect and profitable cooperation. A geologist should not attempt to assert authority in any problems facing the engineer except those which bear directly upon, or are the outgrowth of, the geological study. On the other hand, the engineer generally is not qualified by training or experience to make a critical appraisal of the findings of a trained geologist and must accept the advice of the geologist as the best that can be offered.

Physical Characteristics of Consolidated Rocks

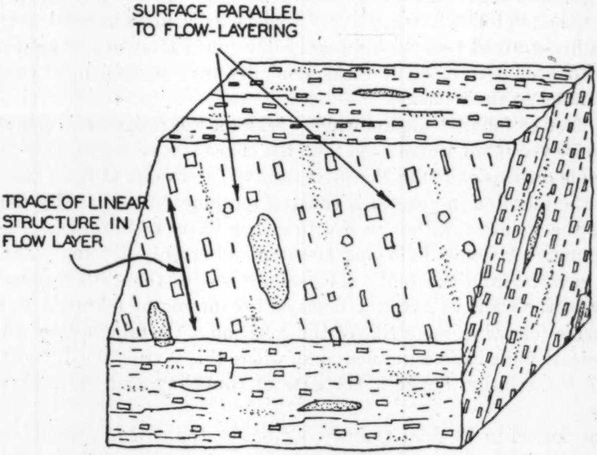
Consolidated rocks are those in which the constituent particles or fragments are bound together strongly enough to produce an aggregate with moderate to considerable strength. The rock or mineral components may be held together with a cementing material as in certain clastic sediments, or the contacts of the mineral grains may be interlocked or intermeshed as in igneous rocks and in most metamorphic rocks.

Certain rocks are massive or isotropic. The physical characteristics of these rocks, from the points of view of the geologist and the tunnel engineer, are the same in all directions within the rock. There is no preferred orientation of the mineral particles, and the ease of tunneling in such a rock is the same irrespective of the direction of the tunnel. In this category belong igneous rocks such as certain types of granite, sedimentary rocks such as certain limestones, and metamorphic rocks such as certain marbles and quartzites. Completely isotropic rocks are relatively rare.

Most rocks possess directional structures as a result of the parallel to subparallel orientation of many or most of the mineral particles. Such rocks are anisotropic and show distinct variations in physical properties in different directions. Consideration of the nature of the anisotropy of rocks is important to the tunnel engineer because it has a direct bearing on the cost of driving the tunnel.

In igneous rocks layered or linear structures are commonly present. If the rock contains "platy" minerals such as tabular feldspar or mica, there is a tendency for these minerals to rotate into parallel or subparallel positions during the intrusion and crystallization of the rock. The resulting formation is called "flow layering" or "platy structure." Rocks which show a well-developed platy structure have a gneissoid aspect and commonly contain flat, lenticular, dragged-out inclusions of foreign rocks called "schlieren." Generally, such rocks show a strong tendency to split or break along planes paralleling the flow layering, and they part or break with difficulty in directions at right angles to the layering.

Rocks containing minerals of prismatic or needle-like habit tend to develop a unidirectional formation which is described as "linear structure" or "flow lineation." This formation results from the parallel to subparallel alinement of the prismatic minerals during the intrusion and crystallization of the rock. It is not uncommon to find both platy and linear structures in the same rock.



SURFACE PARALLEL TO FLOW-LAYERING
TRACE OF LINEAR STRUCTURE IN FLOW LAYER

Fig. 1.—Block Diagram Showing Flow Layering and Linear Structure in an Igneous Rock; Stippled Areas Are Inclusions of Foreign Rock

If both are present, the needles or prisms lie in the plane of the platy structure Linear structure may be emphasized by the presence of elongated, spindle-shaped inclusions of foreign rocks. Igneous rocks in which linear structure is well-developed generally break easily parallel to the lineation and break with difficulty at right angles to the linear structure.

Fig. 1 is a block diagram of an igneous rock showing platy and linear structures. When the geologist describes these features, he generally gives the strike and dip of the platy structure and the direction of the trace of the linear structure on a horizontal plane. These data permit the easy calculation of the pitch angle of the flow lineation. Where flow lineation and flow layering are steeply inclined, lineation is of slight practical importance in the tunnel operation. However, the direction of the tunnel with respect to the flow layering merits careful consideration. A tunnel being driven across the flow layering probably will have the following characteristics: The face will advance relatively rapidly because in the blasting operation the rocks will break cleanly and easily away from the planes of weakness paralleling the flow layering. The walls, floor, and roof will tend to be rough and blocky. On the other hand, if the tunnel is parallel to the strike of steeply dipping flow layering, the forward progress of the tunnel will be slowed because the tunnel is parallel to a direction of maximum strength and toughness in the rock. The walls of the tunnel will probably be relatively smooth; the floor and roof, more or less irregular.

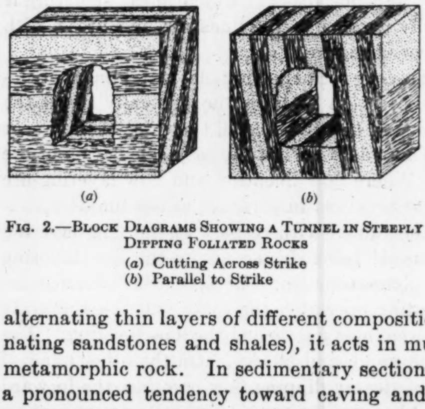
The irregularity of the walls increases with a decrease in the angle of dip of the layering.

In metamorphic rocks the layering is commonly called "foliation" and is well developed in gneisses and schists. A typical gneiss consists of alternating layers of granular rocks of differing mineral composition and physical properties. A schist, although foliated, is relatively homogeneous in its mineral composition. Slate is a fine-grained rock with a highly developed tendency to split into thin plates. Foliated metamorphic rocks generally tend to split most easily along planes parallel to the foliation.

The effect of foliated metamorphic rocks on the progress of the tunneling operation is even more pronounced than the effect of layering in igneous rocks—for the same reasons and with the same results. A tunnel at right angles to the strike of the foliation in general is constructed much more rapidly than is one following the foliation, although the tunnel is likely to be much more blocky and irregular. A tunnel following the strike of steeply dipping foliated rocks tends to cave in from the roof. The smoothness of the walls lessens and the tendency of the walls to cave increases as the dip of the foliation decreases, if the tunnel is following the strike of the foliation. Certain gneisses and schists are complexly folded and crumpled; and, where this is true, the difficulty of prediction of the relation between the ease of tunneling and the rock structure increases.

In one tunnel in Boulder County, Colorado, the cost of driving the tunnel was as much as 25% greater in the sections paralleling the foliation than in the sections cutting across the foliation. However, the overbreak in the latter was about 20% greater than in the first instance because of the irregularity of breakage along the walls and roof.

Typical conditions are illustrated in Fig. 2, which shows one tunnel cutting across steeply dipping, foliated rocks, and another following the foliation of steeply inclined layers. The latter condition should be avoided if possible.



(a) (b)

Fig. 2.—Block Diagrams Showing a Tunnel in Steeply Dipping Foliated Rocks

(a) Cutting Across Strike
(b) Parallel to Strike

In sedimentary rocks bedding or stratification may be conspicuous, but the strength of an individual layer parallel to the bedding is not much different from the strength across the bedding. However, if the rock is thinly stratified or consists of alternating thin layers of different composition (for example, thin-bedded alternating sandstones and shales), it acts in much the same manner as a foliated metamorphic rock. In sedimentary sections where shale is abundant, there is a pronounced tendency toward caving and slumping, and considerable supporting timber may be required as the tunnel is driven.

If a tunnel is driven through inclined layered rocks at right angles to their strike, an additional factor should be considered—that is, the direction in which the tunnel is being driven relative to the dip of the layers. Preferably, the tunnel should be driven so that the layers will dip away from the heading. If this is done, drilling and blasting operations will be expedited because the cleavage in the rocks tends to produce an overhanging face rather than one which is sloping back toward the already completed section of the tunnel. This suggestion applies equally well to tunnels being driven in faulted or strongly jointed rocks. In general, the tunnel should be headed in the down dip direction of the planes of weakness in the rock.

These conclusions purposely are generalized. No attention is paid to the modifying effects of fracturing, alteration, and other features because these are considered separately. It is not claimed that the generalizations noted are without exception because various conditions have modifying effects.

Folds, Joints, and Faults

Folding in layered rocks requires consideration by the geologist because, if folded structures are present, a correct interpretation permits prediction of the attitudes of the layers in different sections of the tunnel. In foliated metamorphic rocks, particularly, the prediction of variation of the attitudes of the layers at the tunnel level may call for detailed surface studies and all the ingenuity, skill, and experience at the command of the geologist.

Actual or incipient fractures are present in all rocks. Fractures along which there has been little or no movement are called "joints." "Faults" are fractures along which there has been appreciable to considerable movement. Joints result from various causes, most important of which are expansion or contraction of the rock due to thermal, chemical, or mechanical causes, or fracturing of the rock in response to deformation by stresses accompanying movements in the outer part of the earth's crust. Faults show relative displacement of the rocks on either side of the fault plane. Fault displacements range from a few inches to several miles. A fault may be very narrow and sharply defined or may involve rocks in a zone hundreds of feet wide.

Joints and faults are a major cause of bad, caving ground in tunnels and deserve careful consideration. Joint surfaces commonly are rough and irregular in coarsely granular rocks, particularly if the joints developed as a result of shrinkage or decompression. Blocks bounded by such joints rarely cause trouble because friction along the rough surfaces prevents disengagement of blocks from the walls or roof of the tunnel. However, if the irregularities of the joint surfaces have been smoothed by slight movements between adjacent blocks or if the joints are smooth for other reasons, the tendency to cave is increased. Moreover, if water has permeated closely jointed rocks and has resulted in alteration and formation of clay minerals along the joints, a particularly bad, "running" or raveling type of ground is produced.

A careful study of a rock mass may show that several joint systems are present and, moreover, that certain of the joint systems are better developed than others. If possible, the tunnel should be located so that its direction is at right angles to the most prominent, most steeply inclined joint system. This course should be chosen because in drilling and blasting the ease of breaking the rock in the heading away from joints or "slips" is advantageous. Moreover, if a tunnel follows a major joint system, the danger of overhead caving is constantly present. In igneous rocks showing flow layering it has been observed that a very prominent joint system commonly parallels the flow layering.

Engineers and geologists have developed a real fear of faults in tunnels, and justly so. Of course, a tunnel should not be driven through or along an active fault; but, fortunately, most faults are not active. The fear of encountering a fault in a tunnel should be justified or tempered by a detailed study of the faults in the region where it is proposed to drive the tunnel. Some faults offer no difficulty, others present distressing problems.

Among the faults which cause little or no trouble are those which show a sharp, clean offset of the rocks and are not accompanied by decaying alteration of the wall rocks. Certain faults or fault zones have served to localize the circulation of mineralizing solutions and examples are known where the substances deposited from the solutions have produced a tight, well-cemented rock stronger than the original rock. However, mineralizing solutions may produce the opposite effect, and a broad zone within and on either side of the fault may be converted into rotten, swelling, or squeezing ground. Alteration of feldspars to clay minerals or micaceous minerals often produces a weak, slippery rock which will cause considerable trouble.

Fault movements commonly develop selvages of weak, pulverized rock flour or "gouge." In wide fault zones where the gouge is present in weaving, crisscrossed, or braided fractures, extensive caving is likely to result. In some faults the rock are brecciated into loose, porous aggregates. Additional movements may cause the rounding of the angular fragments. Generally, such faults are filled with water and the combination of loose rock and water under hydrostatic pressure has caused more than one tunnel to be rerouted or even abandoned. Such fault zones were encountered in the Elton tunnel under the Oquirrh Range in Utah and in the Leadville drainage tunnel in Colorado. Fig. 3 shows typical joints and Fig. 4 shows several common types of faults.

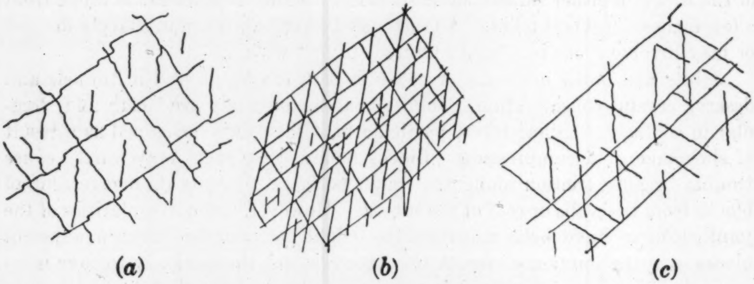


Fig. 3.—Typical Joint Patterns; Joint Surfaces
(a) Rough and Irregular, Minimum Caving
(b) Smooth Surfaced, Maximum Caving
(c) Smooth and Rough, Considerable Caving

In summary, it may be stated that a study of the joint systems and faults in an area where it is proposed to drive a tunnel should be included in the geological investigations over the line of the tunnel and in the area adjacent to it.

Altered Rocks and Swelling Ground

In the preceding section brief reference was made to altered rocks in the vicinity of joints and faults. It was suggested that alteration might produce effects of a serious nature in tunneling operations.

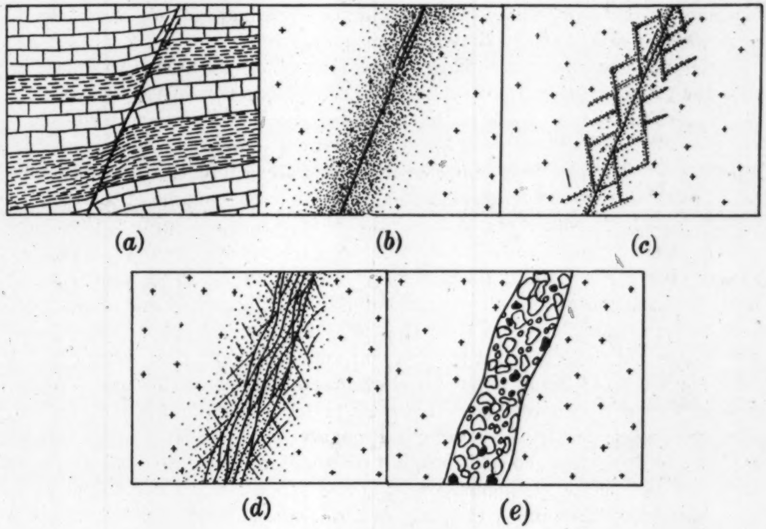

Fig. 4.—Types of Faults

(a) Clean Sharp Break, No Alteration of Wall Rocks
(b) Sharply Defined, No Subsidiary Fractures, Pervasive Alteration
(c) Sharply Defined, with Subsidiary Fractures, Localized Alteration
(d) Braided, with Subsidiary Fractures, General Alteration
(e) Open, Porous, Filled with Breccia

One of the minerals most susceptible to alteration in rocks is feldspar. Attack on feldspar by reactive solutions of surface origin or of deep-seated derivation may cause feldspar to be converted from a fresh, physically strong substance to a weak, pulverulent aggregate of clay minerals or micaceous minerals, and of fine-grained silica. This change, essentially a chemical one, generally is most pronounced in and near zones of intensive jointing or faulting, where altering solutions move with maximum freedom.

Grain size controls the amount of alteration to a certain extent. Fine-grained feldspathic rocks in general alter more readily than coarse-grained rocks, probably in part because fine-grained rocks may be more closely jointed than coarse-grained rocks and in part because the small size of each grain promotes more rapid, pervasive alteration. Fault movement may pulverize the rocks along the fault and cause the development of a multitude of tiny fractures in the rocks in the vicinity of the fault, thus producing ideal conditions for rock alteration. Moreover, faulting causes the minerals in the rock along the fault to be strained and, in general, strained minerals decompose more readily than do unstrained ones.

If the altering solutions are of deep-seated origin, alteration may not change the strength of the rock. For example, hydrothermal solutions commonly deposit condiderable silica in the wall rocks of fissures, and the silicified rock will stand in the tunnel as well or even better than the original rock. Sulfides deposited in fractures or in the wall rocks along fractures tend to oxidize on exposure so that mineralized areas containing abundant sulfides have a tendency to swell slowly and to slough after exposure to air.

Swelling or squeezing ground in tunnels is much to be feared. In squeezing rock the tunnel cross section is reduced by the plastic flow of very weak rocks in response to the pressure of the overlying rocks. Rocks that act in this manner generally are highly altered, are rich in clay minerals, and contain considerable water. The plasticity increases with the water content.

In swelling ground there is an actual increase in the volume of the rock resulting from hydration or chemical reaction or from a combination of these processes. Certain clay minerals and anhydrite have a remarkable affinity for water. If rocks containing these minerals are encountered in the tunnel, water from the atmosphere and other sources tends to be absorbed and swelling results. Tunnel sections have been studied where the rock when first encountered appeared to be reasonably fresh and unaltered; but, after being exposed for a short time, it began to swell and eventually was converted into a sticky, plastic mass of clay minerals. This same material broke down on the dump into an almost impalpable powder. Probably, the rock was partly altered at depth by hydrothermal solutions, but the confining pressure of the overlying rocks did not permit complete hydration and expansion. When the pressure was released by the tunnel, the rock, in a metastable state, rapidly reached a state of chemical equilibrium in response to the release of the confining pressure. Pressures as high as 20 tons per sq ft have been encountered in swelling ground.

The most spectacular example that has come to the writer's attention was the swelling of a dike of fine-grained porphyry cut by a tunnel in a gold mining operation. Within a few days after exposure, the originally fresh looking rock had almost completely filled the tunnel with sticky, relatively cohesive mud. In the Moffat tunnel water bore (in Colorado), a deceptively fresh looking granite irresistibly splintered Oregon fir timbers, 12 in. by 18 in. Many similar examples may be cited.

Rocks in a metastable condition may swell by chemical reaction as well as by simple hydration. It is an established principle that the release of pressure on a rock tends to produce a new mineral assemblage which is in equilibrium with the new environment. Fortunately, however, chemical changes in response to pressure changes in most rocks are so slow that they are of no importance in tunneling operations.

UNCONSOLIDATED ROCKS

The range of composition, texture, and structure in unconsolidated rocks is extreme. Texturally these rocks grade from the finest muds to coarse aggregaates such as are found in rock slides and bouldery glacial deposits. Unconsolidated rocks are characterized by the lack of interlocking contacts between adjacent grains or by the lack of a strong, binding cement or matrix. Some rocks, as, for example, certain sandstones, have been converted into loose aggregates of mineral grains through the removal of the cement by dissolution.

In tunnel operations unconsolidated rocks generally are encountered at the portals, where the bedrock is blanketed with rock waste or alluvium. Loose sand and gravel, wet or dry, present a considerable obstacle as does loose material consisting of large, round, or angular boulders with no cementing material. The difficulty of tunneling through unconsolidated rocks consisting partly or largely of very fine-grained or clayey materials increases in direct proportion to the amount of water present. Dry or slightly moist clayey aggregates stand fairly well in portal areas; and, despite a slumping tendency, the walls and roof generally will stand long enough to permit support and lining to be set before caving starts. As the water content increases, however, the plasticity and mobility of the clay mineral aggregate increase, and considerable difficulty may be experienced in excavating and supporting such ground.

One of the most vexing situations arises when a tunnel is driven through water-saturated volcanic ash beds. In wet ash beds a mobile, gelatinous slurry is generally present which is held with only the greatest of difficulty. On the other hand, if the material is compact and dry, it offers little trouble except that it may swell on exposure to water.

A railroad tunnel near Leadville, Colo., was driven through dry, bouldery glacial till without mishap. The clayey matrix of the till was dry enough to have considerable strength and to serve as a reasonably strong binding medium. On the other hand, a near-by drainage tunnel driven through water-saturated glacial deposits encountered so many difficulties that part of the tunnel had to be abandoned and the cost of the tunnel greatly exceeded the most pessimistic cost estimates.

GROUND WATER

Prediction of ground-water conditions in tunnels is one of the most baffling problems confronting the geologist. Any prediction must be based on a consideration of the porosity and permeability of the rocks and the availability of ground water. Rapid movement of water in rocks generally is determined by the presence of connected open joints, fissures, or faults. It is a common experience of the tunnel engineer to drive through a fault containing little or no water and then to encounter a narrow crack or a section of jointed ground from which water issues in great volume and with destructive velocity. This phenomenon is explained in terms of relative permeability. Many faults, but not all of them, contain abundant clayey gouge which effectively prevents the rapid movement of water. Joints and small fractures, however, generally are not clogged with impermeable material and will permit the easy flow of water.

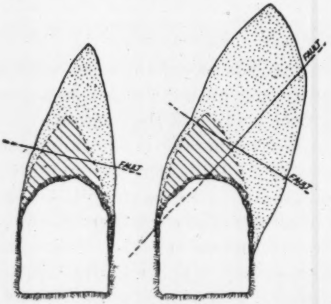
Faults characterized by abundant breccia and open spaces generally are permeable and contain ample water. Tunnels driven in limestone are likely to encounter underground caverns filled with water. The location of these caverns commonly is determined by the presence of fractures which have permitted the easy circulation of water with a consequent dissolution of the limestone.

A knowledge of the configuration of the ground-water table is useful; but, in general, the accurate determination of the depths of the upper surface of the saturated zone is obtained only by extensive drilling or geophysical study. In compact, consolidated, relatively impermeable rocks, the configuration of the ground-water table is of no great significance, because impermeable rocks do not permit the circulation of water. In alluvium or any permeable or unconsolidated rock, however, the story is quite different.

The Tunnel Cross Section

Too little attention has been paid to the relationship between the tunnel cross section and the ease or difficulty with which rocks of the wall and roof cave. In certain tunnels, much time and expense can be saved if careful consideration is given to details of rock composition and structure and to methods of preventing or reducing the hazard of caving ground. It is the purpose of this section briefly to describe the nature of the caving and to suggest a remedy in certain selected examples. The generalizations do not apply to tunnel sections in squeezing or swelling ground.

The caving tendency is present in all tunnels, but the extent of caving depends on the strength and structure of the rocks. It is well known that in average caving ground the caving tendency does not extend for a great distance above the tunnel unless the ground is almost completely without strength and is of the free running type. Observations in hundreds of caved sections of rock tunnels indicate that the caved area commonly extends to a height above the roof nearly equal to the width of the tunnel. If the rock is highly fractured or altered, the caved section may involve a mass of rock above the tunnel roof with a height equal to as much as twice the width of the tunnel. As the caving proceeds, the tunnel tends to assume a cross section similar to that of a Gothic arch. When the arch is finally developed, it acts to support the walls and roof of the tunnel and to prevent further collapse. Except in shallow tunnels or in tunnels in free running ground the caving effects almost never extend to the earth's surface. In supporting the average tunnel roof, then, the maximum strength of the supporting structure, even in the worst kind of caving ground, in general need not exceed that necessary to support an arch-shaped block of ground above the tunnel roof having a maximum height equal to twice the width of the tunnel. For average rock the potential dead weight on the roof of the tunnel is considerably less than in very bad ground. However, this dead weight needs support only when the rock has small strength. In massive, unaltered rocks, the potential dead weight of the roof rocks is more than compensated for by the inherent strength of the rock, the rock load is reduced to zero, and little or no support is necessary. Also, if the caving is not allowed to begin, even in bad ground, the ground may be held by a relatively weak supporting structure because the caved arch can develop only by progressive slumping starting at or near the roof of the tunnel and extending upward.



(a) (b)

Fig. 5.—Tunnel Sections Showing How Faults May Affect the Caving Tendency

The shape assumed by the arch resulting from caving is to a certain extent a function of the geologic structures in the roof rocks. In general, the height of the caved area is greater in faulted and highly fractured or altered rocks than in rocks in which these features are absent or poorly defined. Fig. 5 shows the effects of faults on the upward extension of caving ground in two selected examples from tungsten mines in Boulder County, Colorado.

In driving tunnels through caving ground special attention should be paid to the tunnel cross section. Much time and effort can be saved by arching the roof in such a manner as to utilize what strength there is in the caving rock until supporting structures can be set in place. Obviously, it is not generally feasible to drive a tunnel in which the height is twice or three times the width; but, nevertheless, it is profitable to arch the roof somewhat and, if possible, to make the arch resemble in shape the Gothic-like arch that will result from caving. In nonlayered rocks the tunnel cross section is made as symmetrical as possible; but, in layered or foliated rocks, an asymmetrical arch may serve the purpose to better advantage.

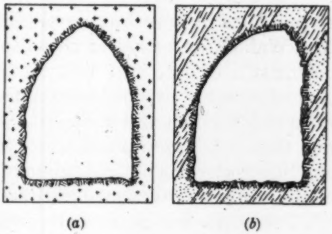


FIG. 6.—SUGGESTED TUNNEL SECTIONS FOR CAVING GROUND IN
(a) Relatively Homogeneous Unlayered Rock
(b) Inclined Layered Rocks

Fig. 6 shows two suggested tunnel cross sections for caving ground. Of course, in spite of all precautions and in spite of the maintenance of an arched cross section, some ground will continue to cave. However, if this caving tendency is offset to even a slight degree, the precautions suggested will pay off in the more rapid forward advance of the tunnel and in the need for less temporary or permanent supporting structure. Of course, if the rock in the tunnel is strong, a cross section is preserved which will be most economical considering the purpose of the tunnel and the immediate requirements of the engineers driving it.

It may be argued that altering the cross section of the tunnel in response to changes in the rocks and rock structures might in the long run cost more than attempting to preserve a standard section and taking a chance on caving ground. However, even a slight concession in the direction of tailoring the tunnel cross section to the rocks will pay dividends. Thus, from a practical point of view, the actual cross section employed necessarily must be a compromise between what is wanted by the geologist and what is desired by the engineer.

In squeezing or swelling ground a circular cross section with closely spaced circular supporting ribs appears to overcome the difficulty to best advantage.

ACKNOWLEDGMENT

The writer wishes to express his appreciation to Prof. W. O. Thompson, Department of Geology, University of Colorado, in Boulder, who read the manuscript and offered several helpful suggestions.

DISCUSSION

Berlen C. Moneymaker,[2] Assoc. M. ASCE.—The application of geology to problems in tunneling, as presented in this paper, is interesting and timely. Mr. Wahlstrom places at the disposal of the engineer and the inexperienced geologist a concise and well-written account of the manner in which certain geologic conditions affect tunneling. The author not only presents a very clear, rather elementary discussion of the characteristics of the more common rocks and their primary and secondary structures, but also indicates several geologic conditions that may affect tunneling adversely and suggests ways of eliminating or reducing the resultant difficulties.

The writer has made both preliminary and final geologic studies of many miles of tunnels, both within and without the United States. Although no issue is taken with either the author's statements (under the heading, "The Functions of the Geologist"), or the facts he states regarding rock characters and rock structures, the paper tends to convey the idea that the geologist has more to do with planning a tunnel than is actually the case. Generally, he has little to do with determining the alinement, and even less to do with determining the size of the bore and the shape of its cross section, especially if the tunnel is for the diversion of water for power, irrigation, or water supplies. In this case the engineer determines the points to be connected by a tunnel and the amount of water to be carried and then calculates the size and the shape of the cross section of the bore which best meet the requirements. In the case of highway and railroad tunnels, the engineer also determines the alinement, the size, and the shape of the cross section. The location of such proposed tunnels may be surveyed and staked before the geologist is asked to make his studies. The geologist may or may not have more to do with the planning of tunnels in mining districts, where the tunnels are for exploration, mine development, or drainage.

In 1937 the writer was asked to make a geologic study of the Garzas tunnel in Puerto Rico. This tunnel, for the diversion of water from the Garzas reservoir for power and irrigation, was already beyond the planning stage and had been surveyed. It is 11,640 ft long and extends in a north-south direction across the rugged Cordillera Central, which forms the insular divide. The ground to be penetrated had not been explored by core borings, test pits, trenches, or any other method and, apparently, no funds were available for exploration. As most of the tunnel was to be from 400 ft to 1,200 ft below the surface, sufficient exploration to yield detailed information was not feasible. There was a good exposure of bedrock at the intake portal and small outcrops in the beds of two of the several small streams crossed by the tunnel line. Elsewhere bedrock was concealed by as much as 200 ft of residuum. The entire tunnel location was covered by a dense jungle of tropical vegetation, except along the cleared parts of the survey line. Under such conditions the geologist is at an acute disadvantage. By a very careful study of the stratigraphy and the orogenic and geomorphic history of the region as a whole, the writer was able to predict accurately the nature of the geologic problems to be encountered. A painstaking study of the residuum along the survey line revealed the character of the underlying rock with a very high degree of accuracy, and a study of the only outcrops on the line revealed the location of a few faults. Although it was believed that hundreds of faults would be crossed by the tunnel, there was no method of determining their location, their magnitude, or their seriousness as tunnel problems.

---

[2] Chf. Geologist, TVA, Knoxville, Tenn.

The tunnel, a 7-ft horseshoe in cross section, was driven from the two portals and was "holed-through" near the midway point. As predicted, the northern 10,486 ft of the bore penetrated water-laid volcanic ash shales and associated limestones; the remaining 1,188-ft section penetrated massive tuff and agglomerate of andesitic composition—both types of rock being cut by numerous intrusions of andesite porphyry. Hundreds of faults were encountered, but most of them presented no serious problems. Many involved sizable zones of closely fractured rock and resulted in considerable overbreakage. These structures required timbering during construction and lining afterward. Two major faults, both apparently active, were crossed with some difficulty and after considerable delay. Both yielded copious quantities of water under considerable head. One resulted in the caving of the heading and the partial filling of the bore with 1,000 cu yd of fine gouge and 500 cu yd of broken rock. This fault zone was 152 ft wide and yielded 1,300 gal of water per min. The other fault also resulted in the failure of the heading and the partial filling of about 40 ft of the bore with broken rock and gouge. The fault zone was only 21 ft wide and yielded 200 gal of water per min under a head of 160 lb per sq in.

The location of the spillway tunnel at Garzas dam was also examined by the writer before its construction was undertaken, but after it was beyond the planning stage and after it had been surveyed. This tunnel, 1,100 ft long, was designed as a large bore of horseshoe cross section. Bedrock was exposed at the outlet portal and near the intake, but it was concealed elsewhere by a thick residuum. The ground to be penetrated was explored inadequately by a few drill holes. Geologic studies, as detailed as could be made under the circumstances, afforded no indication of serious problems, but, as the construction neared completion, a fault zone was encountered and occasioned a long delay and considerable difficulty.

The Apalachia tunnel, constructed by the Tennessee Valley Authority to divert water from the Apalachia reservoir to the powerhouse 12.6 miles downstream, is located on the south side of Hiwassee River in Polk County, Tennessee. Although the terrain to be crossed by this tunnel was thoroughly studied geologically and mapped on a scale of 1 in. to 500 ft before the project reached the planning or designing stage, geologic conditions played little or no part in its alinement and design. It is 43,637 ft long, and was driven as a bore of circular cross section, from 20 ft to 22 ft in diameter. It crosses the strike of the Great Smoky (Thunderhead), Pigeon, Citico, and Wilhite formations, which consist of altered fine to coarse clastic sediments. The geologic structure is moderately complex and is characterized mainly by folds and thrust faults. Exposures of bedrock were sufficiently large, numerous, and continuous in the vicinity of the tunnel alinement to permit accurate projection to the tunnel grade of all formation contacts and changes in lithology and in the larger structural features. Although numerous faults were encountered, no difficulty of any kind was experienced in driving the tunnel.

Another tunnel constructed by the Tennessee Valley Authority in the highly deformed metamorphic rocks of the Southern Applachians is the Ocoee No. 3 tunnel, which diverts water from the Ocoee No. 3 reservoir to the powerhouse 4.2 miles downstream. This 13,000-ft-long tunnel was driven as a bore of horseshoe cross section. From a geologic study of the surface along the survey line, all the larger geologic structures and changes in lithology were projected accurately to the tunnel grade. Even though the geologic structure was characterized by numerous folds, faults, and joints, no problems were encountered. There were a small amount of weathered rock and a few zones of shattered rock which required support, but these conditions presented no difficulties.

In all previously mentioned tunnels, and numerous others on which the writer has done geologic work, it would not have been feasible to follow some of the author's recommendations. First, the alinements were determined by engineering and other requirements. Moreover, the direction of strike and dip of the strata and foliation changed so many times in each of the tunnels that it would have been impossible to keep the bore advancing normal to such structures and as stated (under the heading, "Physical Characteristics of Consolidated Rocks") "* * * so that the layers will dip away from the headings." The rocks penetrated by these tunnels are cut by numerous joints and in most cases the most prominent joints are dip joints, which are parallel to the dip and normal to the strike. Where the most prominent joints are dip joints, a tunnel normal to the layers will be parallel to the joints That no tunnel could be driven normal to two structures which intersect at right angles is obvious. Furthermore, in spite of the advantages of altering the cross section of a tunnel, as Mr. Wahlstrom suggests (under the heading, "The Tunnel Cross Section") "in response to changes in the rocks and rock structures," it would not be practicable to do so in the case of tunnels where hydraulic considerations are important.

In large diameter tunnels, especially those constructed for use in hydroelectric projects, such features as bedding planes, flow lineation, foliation, joints, and minor faults are of relatively minor importance. Large faults and fault zones of badly weathered and weak rock, swelling ground, large flows of water under high head, and high temperatures are much more serious. In a great majority of cases, some of these conditions cannot be accurately predicted, even by experienced tunnel geologists.

In pointing out the difficulty of locating and designing tunnels so as to take full advantage of geologic conditions, the writer does not question the validity of the author's conclusions. Rock conditions and rock structures do affect tunneling precisely as he states. Although, generally, it is not possible to meet all engineering and other requirements and at the same time to locate and design the tunnel to the best advantage geologically, an experienced tunnel geologist can undoubtedly contribute substantially to the economy of funds and of time in the planning, design, and construction stages.

Robert S. Mayo,[3] **M. ASCE.**—The field that the geologist should occupy during the planning and construction phases of tunnels is clearly indicated by this excellent paper. Professor Wahlstrom's experience has apparently been gained in the deep mines of the west in connection with the driving of haulage and drainage tunnels. In this type of work, where the tunneling is generally done by company forces, the advice of a trained geologist in selecting the route for the safest and most economical tunnel is of utmost importance.

To the tunnel engineer on the eastern seacoast of the United States, such opportunities for profiting by the advice of the geologist are few. The tunnel route is fixed in most cases—the railroad engineer has his portals all staked out for him, regardless of the intervening ground; in the larger cities, the sewer engineer must run an intercepting tunnel down the center of certain streets from trunk sewers to the sewage treatment plant. Only in the rare case of a diversion or aqueduct tunnel in an unsettled area can the tunnel be shifted an appreciable amount to secure better ground.

This does not mean that the engineer cannot use the services of the geologist. The specifications prepared for the information of bidders would be of much greater value if there were a section in which a trained geologist analyzed the borings and other available information in order to forecast the types of ground to be found, the possibility of encountering faults, and how the rock will break; but this introduces an objection. The engineer has found, by sad experience, that it is rather expensive to hazard a guess to the contractor as to what type of ground he will encounter. In presenting the log of borings in the bidding documents, most engineers specifically state that the findings shown in the log are not guaranteed and that the contractor must make his own interpretation of the borings. To incorporate in the specifications a geologic monograph stating what types of ground are likely to be encountered, what difficulties might be expected, and what overbreak to anticipate, would result in a lower bid by the contractors in most cases. The courts have been extremely liberal in interpreting implied geologic data in the contractor's favor and, therefore, many engineers would be hesitant to include such forecasts in the specifications, when it might implicate the owners in expensive lawsuits, if the geologist's opinion were wrong.

This an unfortunate situation, but it does not lessen the value of geologic advice during the planning and bidding stages of a job. Consultation with the geologist would certainly enable the designing engineer to establish the "A" and "B" lines of the tunnel more intelligently. These lines govern the thickness of the concrete lining, and at present they are established by "rule of thumb."

The writer has stated that, in the past, the routes of tunnels are selected by factors other than geological ones; but, nevertheless, should the geologist indicate that extremely bad ground is to be expected, in most cases the engineer would call for a re-examination of the entire project with major relocation of the tunnels to secure better ground.

---

[3] Proprietor and Chf. Engr., Mayo Tunnel Equipment, Lancaster, Pa.

In spite of the present legal pitfalls that make it unwise for the engineer to add to the bidding specification the opinion of a trained geologist, the geologist can be of great value to the owner's engineer. By reading the daily reports of earlier tunnels, he can deduce the type of rock penetrated. He can forecast, with fair accuracy, the results of the drilling, the type of ground to be penetrated, and the difficulties (particularly "swelling ground") to be anticipated. He can be of real help in setting the "A" and "B" lines, in addition to recommending whether grouting should be specified and just what quantity of grout each type of ground will take.

The geologist can be of immense value on all tunnel projects, not only to the engineer, but to the contractor. To the end that every job can benefit from geologic science, it is recommended that, when an organization is not large enough to warrant a full-time geologist, that a consulting geologist be engaged on a part-time basis to visit the tunnel at least weekly to report on the ground and its effect on progress and overbreak. Complete engineering and geological reports on every tunnel job will be of immense value to the next generation.

F. A. NICKELL,[4] ESQ.—The feasibility of tunnels is dependent on numerous factors, and the geological conditions of the area that affect suitability of the rock are of immediate importance. Rarely, however, are special geological features pertaining to an earlier project so similar in detail that methods adopted to overcome them can be applied strictly elsewhere. Unlike engineering, founded on mathematical principles and largely concerned with materials of prescribed physical properties, geology is not an exact science. Its value to engineering projects results from skilful interpretation based on experience in construction problems. Generalization that limits discussion in technical articles leads to oversimplification and the inferences are not always applicable.

Choice of a tunnel in preference to some other structure is usually determined by economic and engineering data in which geological conditions are a consequential, but perhaps not the most significant, factor. Presumably, the plan would be altered only if insurmountable geological difficulties and greatly increased costs can be demonstrated. Nevertheless, geological proof showing superiority of one route over an alternative line, or the occurrence of questionable ground, including active fault zones, would be of major importance.

The foregoing comment leads to the identification of geological effort in engineering projects, a subject discussed in several published articles. The relationship between the engineer and the geologist has grown harmoniously on the basis that the ultimate responsibility for success of the undertaking rests with the engineer, who would want to make decisions on the best information obtainable. The geologist serves in an advisory capacity, responsible for the disclosure and practical interpretation of all pertinent features of bedrock that affect construction.

The significance of many conditions is influenced commonly by nongeological factors. For example, rock suitable for excavation of small tunnels might not stand well if the tunnel were larger. In addition, the seriousness of objectionable items beyond effect on construction must be judged from the viewpoints of repair and maintenance as well as of the magnitude of damage in case of interrupted service. This implies that the geologist ought to know and to evaluate related aspects of the problem.

---

[4] Cons. Geologist, Pasadena, Calif.; formerly Head Geologist, Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

The amount of study needed depends on the geological complexity of the area, as well as on the length and the size of the tunnel. Investigation is customarily done in stages, starting with general regional examination as a proper background in explanation of local conditions. Detailed mapping of formations along the tunnel line almost always proves valuable providing as it does facts on the distribution of rock types, the nature of doubtful features, and the geologic structure. These can then be projected into approximate position at tunnel level.

Special features are explored by pits, drifts, and core drilling, particularly in the cases of portal locations and of conspicuously bad zones. Ordinarily, the cover of rock above grade is too great for an elaborate program of core drilling down to the tunnel level. In fact, mechanical difficulties, slow progress, and diminished core recovery with depth limit the number of holes that will be drilled.

In most cases, surface mapping provides much of the required geological information on which to base plans for construction. Fracture zones, water-bearing horizons, or elevation of bedrock concealed by thick overburden can be located by one or more geophysical methods of investigation, sometimes with very accurate results.

Geological problems revolve around questions of distribution and physical character of rocks, their probable stability during excavation, and the nature of objectionable features. The fields of interest and responsibility for the geologist, engineer, and contractor may overlap. The geologist should not hesitate to give his views to focus attention on construction problems. The value of suggestions, of course, depends on experience and judgment.

Formations free of defect are probably nonexistent. From a practical standpoint, many kinds of materials can be tunneled easily. Nearly all hard, massive rocks, unless disturbed, excavate readily and stand without support. These include the crystalline group (as granite and gneiss); the indurated, fairly thick-bedded sediments (for example, sandstone and limestone); and many of the lavas, although the latter are commonly jointed and may contain bodies of poorly compacted deposits of fragmental origin.

With diminished hardness, and with consequent lower physical strength, formations of a wide variety become less able to stand unsupported. The ease of excavation is offset by problems of stability, by required changes in construction methods, and by need for protective lining or timbering. These rocks belong to or are analogous to the clayey-shaly series. Sweeping generalization is unwarranted. Adequate recognition of physical limitations will permit safe construction, presumably at a higher cost. In such cases, the geologist, besides identifying the rocks, should propose supplemental treatment to insure successful excavation. Timbering, guniting, or spraying with asphalt will protect the fresh surface.

Unconsolidated deposits—including the normal overburden on bedrock in preparing approach cuts to the portals, valley fill, and alluvial side wash; and the scarcely compacted silts, clay, and coarser debris of stream and glacial origin—commonly offer the most difficult problems. The task is simplified by accurate knowledge of the nature of loose materials and selection of suitable tunneling methods. The presence of some interstitial clay in sandy deposits, mentioned by Professor Wahlstrom, adds to stability, but good drainage and close support are usually necessary. It seems reasonable that the better informed the geologist is regarding construction methods, the more dependable will be his opinions. Underriver tunnels are practical through unstable deposits by use of caissons and compressed air; certain loose materials may be consolidated by grouting beyond the tunnel heading; and stage mining is ordinarily successful in clays (and shales), under which only a section of the tunnel face is removed at one time so that support can be replaced immediately.

Physical features that tend to control the pattern of breakage during blasting operations, or that reduce stability of the rock, deserve particular attention. Massive bodies like granite have nearly equivalent strength in every direction. As a result usually of metamorphism with increasing intensity, the rock assumes a foliate structure, passing gradationally from gneiss to schist, to slate, and finally to phyllite, progressively losing uniformity and coherence. Similar conditions arise from the inclusion of abundant platy minerals such as mica or chlorite. Physical properties are varied according to orientation, and the rocks tend to break along the banding or to slacken on exposure to air. The array of additional problems due to the banded character ranges from overbreakage to caving. Such difficulties can generally be limited by controlled excavation and support. Extremely difficult ground may be found in highly micaceous zones, in which the unconfined material will flow if wet.

The laminar structure of shale and, to a lesser extent, the bedding planes of thinly stratified sediments, facilitate parting on exposure. Initially stable rock may cave after prolonged contact with air, so that a protective asphalt coat is helpful. Tunneling methods are successful with adequate support, much in the manner described for unconsolidated materials. The difficulties increase with the diameter of the tunnel.

Joints are fairly universal in all types of rocks, occuring in sets of different orientation and importance. Weathering is facilitated on the surface by admission of water into the cracks, resulting in accentuation of the patterns. At a depth, beyond the immediate effects of atmospheric conditions, joints become tight. Dependent on prominence, joints have a varied influence on tunneling operations generally expressed by slight overbreakage guided by circumstances that permit dislodgment of rock in blocks outlined by intersecting fractures. That section of the paper describing problems related to joints may be needlessly alarming—unless the excavation is chiefly in the zone of weathered rock. It is doubtful that the alinement in any case would be changed merely to cross the joint pattern at a favorable angle. Practically all tunnel problems traceable to jointing can be remedied by timbering the bad sections and trimming loosened rock elsewhere.

Excavation and stability of formations are influenced by the trend and dip of beds in a stratified series cut by the tunnel. It is usually less troublesome to cross the bedding nearly at right angles, whereas the rock is most secure if the dip is steep or vertical. If the strata are gently inclined or horizontal, the tendency for separation of unsupported masses, with consequent caving, is comparable to the experience with fissile or closely jointed rock. Liberal usage of timbering may be required. The difficulties are greater according to the incompetency of the beds and to the size of the tunnel.

Faults are common in many regions as a result of strong movement between crustal masses. Tunnels are subject to extreme difficulty in excavation of badly mashed rock of the fault zone, particularly where the zone consists of plastic material charged with water. If a fault zone is unavoidable in alinement, the tunnel should be located to cross the feature nearly at right angles to minimize the amount of difficult operation.

The hazards involved in tunneling through faults are twofold: The actual difficulties caused by the instability of the crushed rock, and the questions introduced by the prospect of renewed movement. Excavation can be carried on by methods comparable to those used in unconsolidated materials with adequate support, perhaps by steel liners, kept abreast of the heading. In some instances, stage mining yields results. Grouting to consolidate fragmented rock might stabilize the zone sufficiently for normal tunnel operations. The broken area generally carries considerable water, which must be provided for either by grouting or by special drainage features.

In addition to the practical problems, the geologist must consider the seriousness of future disturbance, which may close the tunnel. The time needed for repair in event of rupture could be disastrous for a metropolitan water system, but might be only a calculated risk for a vehicular tunnel, from which traffic can be diverted. These factors enter into the evaluation of the geological significance.

Variation in geological conditions is endless, so particular problems will inevitably escape the discussion. Nevertheless, Professor Wahlstrom outlines many of the common difficulties encountered in excavation for tunnels. A careful geological study prior to final location and design will afford greater assurance of success, and routine inspection of the work during construction allows both a check on surface interpretation and a modification of ideas required by changed conditions underground. A permanent record of geological features disclosed by the excavation should be filed for reference in the event repairs are needed later.

R. H. Keays,[5] M. ASCE.—Greater cooperation between tunnel engineers and geologists and greater respect for the opinions of one another on problems that arise in tunnel construction should result from this valuable paper. Several instances may be mentioned where the lack of correct geological information in regard to the character of the rock has been a great disadvantage in tunnel excavation.

---

[5] Inspecting Engr., Reconstruction Finance Corp., Brooklyn-Battery Tunnel, New York, N. Y.

Reference has been made in the paper to the Moffat tunnel in Colorado. This tunnel has been outstanding in several ways, particularly so, in that the final cost was several times the engineers' preliminary estimate of cost, which was said to be based on the opinion of an eminent geologist that the rock throughout was solid. On the basis of this preliminary estimate of cost the Colorado legislature had authorized a bond issue of $6,720,000, which included the cost of electrification of the tunnel.

The writer, on taking office as chief engineer of the Moffat Tunnel Commission in July, 1923, was asked by the commission to make an estimate of the cost of the tunnel construction on the foregoing assumption, concerning the equality of the rock. No borings whatever had been made, nor had any test pits been dug to verify the statement of cost. Basing costs on past experience with many tunnels, the writer made an estimate of $5,250,000 for the tunnel work alone. This estimate was to serve as a so-called "upset" price in a proposed fixed fee form of contract. The contract was awarded in September, 1923. In the meantime, on the writer's recommendation, the west portal of the tunnel had been moved south a short distance to the only rock outcrop in the vicinity.

A geological report[6] on the tunnel, after its completion in 1928, designated the formation as that of the pre-Cambrian age. The rock itself has been defined as granite, injection gneiss, and metamorphic granite with some pegmatite, quartz monzonite, and schist for two miles east of the west portal. A badly faulted area of the same kind of rock, approximately one half mile in extent, followed. Gray metamorphic granite with quartz monzonite and injection gneiss seams was encountered the rest of the way—about 3½ miles.[7] The rock proved to be excellent on the eastern side of the continental divide, as was to be expected from the inspection of many outcrops. On the western side of the divide, however, where the rock surfaces were buried beneath unknown depths of glacial drift, the quality of the rock could hardly have been worse for tunnel driving purposes, and it was fortunate that at no place did the glacial drift extend downward to the tunnel line. An estimate of the final cost, made after completion of the work, indicated that the work on the eastern half of the tunnel had not cost more than the original estimate,[6] and that all the extra cost had been on the western half of the tunnel, which was heavily timbered, and, on which, heavy steel supports were used for short distances.

The author speaks of squeezing ground and swelling ground. By these terms it is understood that squeezing ground is mainly the result of pressure on plastic materials, and that swelling ground is that due to chemical changes or absorption of water. It is difficult to admit that the pressures that developed on the tunnel support of the Moffat tunnel for the two miles next to the west portal were due to either of these causes. All the rock was badly faulted and broken into blocks. On removal of the support given by the tunnel rock while in place, these blocks tended to slip out of place and deprive further outlying blocks of their support. It was necessary, therefore, to place tunnel support immediately after blasting and to maintain it in place, so as not to allow the rock to start moving. An easily compressible local cordwood, loblolly pine, together with some rock packing, was used to pack the space between the timber support and the rock.[8] This permitted additional movement, and no doubt was the cause of some movement which would not have occurred had better packing been used. The writer was in Europe and not connected with the work later on when the worst of the bad rock was excavated in the tunnel.

---

[6] "Completion of Moffat Tunnel of Colorado," by C. A. Betts, *Transactions*, ASCE, Vol. 95, 1931, p. 334.

[7] "Geology of the Moffat Tunnel, Colorado," by T. S. Lovering, *Transactions*, A.I.M.M.E., Vol. 76, 1928, p. 337.

Another situation wherein a geologist undoubtedly would have been of service occurred on the excavation of the Shandaken tunnel, an important feature of the Catskill Aqueduct.[9] This tunnel was excavated in Hudson River bluestone, a shaly sandstone of excellent quality, and a thin-bedded sandy red shale. These formations were bedded approximately horizontally. In this instance trouble was experienced with the thin-bedded shale which tended to cave up to a point forming a Gothic arch; this type of difficulty was described in the paper (under the heading, "The Tunnel Cross Section").

It was estimated that only a nominal stretch in this 18-mile tunnel would require timbering, but the final result was that nearly 50% of the tunnel length was timbered—practically all due to the thin-bedded shale. This is a result certainly not to be expected in a tunnel which is only 10 ft 3 in. wide and 11 ft 6 in. high inside the concrete lining. This shale was really very dangerous. Construction was carried out by hand methods, mostly using the old top heading and bench system. There were about twelve headings being excavated simultaneously, and the timbering where used had to be kept as close to the heading as possible. This prevented heavy blasting, as the timbering would have been shot out.

The permanent timbering was designed as a three-piece or five-piece set of 10-in. by 10-in. material resting on wall plates which were supported by posts. As an alternate design, a three-piece set was to be supported on hitches cut in the rock walls. Soon both schemes were shown to be impractical, as too much unprotected tunnel existed and progress was altogether too slow. It was a day's job to cut properly the two hitches necessary for one set of timber, and the men cutting them were quite unprotected from rock falls.

At this time the contractor developed a scheme whereby the three-piece set was to be used exclusively, but instead of supporting the timbers on hitches, the inclined legs of the set were each to be supported on a horizontal row of three 1½-in. steel pins set in holes drilled in the rock. On top of these three pins a wooden block was set. The inclined legs of the three-piece timber set were cut on their lower ends in such a way that they would be supported largely by being forced against the rock through wedge action. This was important, as the pins themselves were not intended to take bending moment. The design required that the timbers for each set be specially cut due to the varying width of the tunnel. Those who are familiar with recent developments in tunnel support will recognize that this pin support idea is now in general use, but not for exactly the same purpose as it was originally intended.

---

[8] "Rock Tunneling with Steel Supports," by R. V. Proctor and T. L. White, Commercial Shearing and Stamping Co., Youngstown, Ohio, 1946.

[9] "The Shandaken Tunnel," by Roy W. Gaussman, *Transactions*, ASCE, Vol. 92, 1928, p. 233.

A good example of squeezing ground was an extensive stretch of altered black chlorite schist in the 8½-mile Boyati tunnel of the Athens (Greece) water supply, constructed from 1926 to 1931. Some of the timber support in this small diameter tunnel had to be replaced as many as four times. It was finally replaced by a concrete block lining, reinforced by thoroughly grouted dry rock packing.

JACOB FELD,[10] M. ASCE.—A rock tunnel is one of the simplest engineering structures for the designer and the draftsman, but it often develops into a troublesome job for the field engineers and supervisory staff. As far as the design is concerned, the location is determined by the geometric requirements of the future use of the tunnel (whether for railroad, highway, or water) and sometimes subject to conclusions drawn from geological explorations and analysis. The actual design of the tunnel section is based on assumed empirical or extrapolated experimental values of the physical characteristics of rock, used in formulas derived from mathematical analysis which are based on the assumption of rock uniformity. That such uniformity never exists is admitted—but any assumption of nonuniformity which results in a much more complicated design analysis will probably be just as far from the actual conditions encountered as the assumption of uniformity.

In regard to construction procedure, the matters which must be determined before work is actually started are, as follows:

1. The question whether a full-face section can be drilled and mucked, and whether the progress must be based on a pilot tunnel with either longitudinal or radial enlargement, or on multiple-step benching, must be answered.
2. Having determined the answer to the first question by guesswork or by other means, the drilling support and bracing erection framework must be designed and procured on an estimated amount of use. In addition, it must be flexible enough to permit rapid modification, if the assumed conditions are not found.
3. The general pattern of drilling (and sequence of blasting) is usually the controlling item of ultimate cost in tunneling. Not only all the required excavation must be moved with a minimum of overbreakage, but the pattern must be such that it can be modified from day to day as the feel of the actual rock is obtained.
4. An amount and a type of explosive to insure economical mucking is chosen so that a minimum amount of scaling will be required and still all the rock will fall in the desired position.

If the geological advice carefully described by the author is proposed for use in the design stage, and if such advice can be of use, then, of course, the paper is of great value. However, the information presented can be obtained in greater detail in a textbook by Robert F. Legget,[11] M. ASCE, and in several others of similar, recognized quality. If the author presents his paper as advice to use when tunneling is actually in operation, most men engaged in such work will agree that the information has come too late.

---

[10] Cons. Engr., New York, N.Y.

[11] "Geology and Engineering," by Robert F. Legget, McGraw-Hill Book Co., Inc., New York, N. Y., 1940.

It is difficult for the writer to discount the impression that such statements as the author's, defining the division of work and authority between geologists and engineers (under the heading, "The Functions of the Geologist"), are parallel to the dicta one encounters in the construction field (such as the rule that only a dues-paying electrician holding a proper union card may turn on a switch). Similar advice and instruction was recently published to cover highway design and construction.[12,13]

Such a division of professional control of closely allied fields of endeavor can only lead to chaos and an end to progress. The writer received formal training in mathematics and the physical, chemical, and geological sciences; yet, the fact that he received a college degree in engineering has never reduced his interest in geology nor has it discouraged his study of that field, when related to the work at hand. In common with many other practicing engineers, the writer resents the attempt of similarly trained men, who happened to have received degrees under the sponsorship of geology or some other academic faculty, to circumscribe, or in any way limit, the field of his endeavors. In parallel fashion, he considers that men similarly trained can be of service in the engineering field, even though they do not have engineering degrees.

The main part of the paper (under the heading, "Physical Characteristics of Consolidated Rock") contains informative data and conclusions. It should, however, be read by the engineer with the reminder that it is not written by an engineer. For instance, the statement, "Certain rocks are massive or isotropic," indicates that the two descriptions are synonymous—a policy which is not in accordance with recognized engineering terminology. Certainly, anyone who has worked in seamy granite which was massive did not find any isotropic characteristics.

Fig. 6 summarizes the recommendations of tunnel cross sections in caving rock. In Fig. 6(*a*), apparently a uniform caving material is pictured; any shape can be cut through if properly timbered and no shape is safe if it is not timbered. If the indication is intended to represent a uniform rock with no cleavage or seams, then any shape can be cut without timbering. In Fig. 6(*b*), the recommended shape will result after the blasting and the scaling operations are complete, no matter what pattern of drilling is followed; such a condition is immediately taken advantage of in the next round of drilling.

Finally, every tunnel engineer should carefully read and heed the concluding sentence of the paper:

> "In squeezing or swelling ground a circular cross section with closely spaced circular supporting ribs appears to overcome the difficulty to best advantage."

If the reader has been through a similar operation, he should take his own experience preferably as a guide and install any shape of bracing as fast as possible. For, in such ground, it is not feasible to excavate a full section, circular or otherwise, and to expect to place the recommended closely spaced circular supporting ribs.

[12] "Geology and Highway Engineering," by M. T. Huntting, *Transactions*, ASCE, Vol. 110, 1945, p. 271.

[13] "Engineering Geology and Highway Location and Design," by L. W. Currier, Daniel Linehan, and George H. Delano, presented at a meeting of the Highway Research Board, National Research Council, Washington, D. C., December, 1947.

Thomas W. Fluhr,[14] Assoc. M. ASCE.—In spite of the fact that the works of the engineer are founded on, or pass through, the materials of the earth's crust, papers on geology seldom appear in engineering publications, and too few engineers have sufficient acquaintance with the subsoil and bedrock that concern their projects so vitally. The subsoil and bedrock vary to an extreme degree in quality and condition. The engineer designs his steel and concrete structures with the indicated degree of precision and then founds them on natural materials, the quality and condition of which are known only approximately and, unfortunately, in some cases not at all. This paper therefore serves an extremely useful purpose in that it delineates some of the geological features encountered in tunneling in such a manner as to be easily comprehended by an engineer, and in such form that he may make practical use of them in planning and construction. Since the kinds of rock and soil and their characteristics vary considerably in different locations, opinions may differ on the emphasis to be placed on various geologic features.

The engineering geologist is most valuable to the engineer prior to the beginning of construction. Reconnaissance of a proposed tunnel line often is sufficient to discover the critical points of the line. Geologic mapping and structural studies will permit the geologist to predict subsurface conditions and anticipate difficulties with greater assurance. Programs of test borings, test pits, or other methods of exploration can be devised and their progress guided by geological considerations.

When the subsurface features have been explored, the engineer and the geologist, working together, may find it possible to shift a tunnel line to advantage. For example, one section of the Delaware aqueduct tunnel line was shifted laterally to avoid passing through the intersection of two fault zones. In another case, part of the tunnel was placed much deeper than planned, and thus decayed rock present at the original level was successfully avoided. However, such shifts in position can seldom be made, because they usually involve increasing the tunnel length which results in more expense than would crossing bad ground.

The engineering geologist, by predicting the location, quality, and extent of bad tunneling ground, makes it possible to plan for such eventualities when cost estimates are prepared. His reports are frequently of great service to contractors bidding on proposed work. Geologic forecasts should not be included in specifications. On the other hand, the proper manner of presentation of geologic data is of advantage both to the engineer and to his client, and to the contractor, and the withholding of such geologic data as are available may be construed by a court as evidence of bad faith. One practical aspect of making geological data available to the contractor is the possible elimination of future claims.

Once construction has begun, the geologist can furnish advisory service to the engineer regarding tunneling conditions and can record the geology of the tunnel for future reference, but unless wet or caving ground or serious fault zones are encountered, he can do little to change the course of events.

It would appear that in the paper too much weight has been placed on "flow layering" of igneous rocks. The directions and intensity of the jointing are of much greater importance. Not everyone will agree that a greater amount of overbreak occurs in tunnels driven normal to the foliation or bedding. The overbreak depends to a great extent on the jointing, as well as on the manner of drilling and shooting. Similarly, the problem of driving tunnels so that the layers dip away from the heading is of little practical importance, and can be taken care of by a skilful heading boss.

---

[14] Senior Geologist, Board of Water Supply, City of New York, Downsville, N. Y.

One point emphasized by Mr. Wahlstrom is the effect of ground water on tunneling. In the eastern section of the United States, the writer has observed that less difficulty is usually encountered with the badly decayed central crush zones of faults, than with the jointed and water-bearing zones on each side of the decayed zone. Control of water is of first importance both in hard rock and soft ground tunneling. In general, when an inflow of water is encountered in a tunnel, the average engineer tries to shut it off by grouting, usually without success. Most inflows diminish or disappear if allowed to flow; if shut off, the hydrostatic pressure builds up to that corresponding to the ground-water level, and eventually the water breaks through elsewhere.

When a water-bearing fault, sometimes accompanied by a run-in of soft material is encountered, the contractor, anxious for progress, often feels that he has to take some immediate action, and it is difficult, if not impossible, for the geologist to persuade him to wait until the water has drained off and the soft ground has become stabilized. One must recognize that in underground, as well as in living bodies, nature tries to heal her wounds.

Modification of the cross section of a tunnel to conform with the geologic structure is theoretically desirable, as Mr. Wahlstrom points out. However, tunnel driving today is a highly systematized procedure, and any change in section is expensive in terms of time and progress. Moreover, since a large proportion of tunnels are concrete lined, changing the section would necessitate the use of special and expensive forms for lining, or else the use of excessive amounts of concrete to fill the additional excavation.

One problem, not mentioned by the author, is that of popping or bursting rock, which often necessitates the use of roof support.

Mr. Wahlstrom is to be commended for having presented his material in a form which is simple and direct, as well as technically correct, thus enhancing its value to those engaged in tunneling work.

PORTLAND P. FOX,[15] Assoc. M. ASCE.—Many civil engineers will find this paper interesting and instructive, but experienced engineering geologists will feel that it is somewhat academic. The civil engineer will have difficulty in interpreting many of the geologic structures from outcrops, drill cores, and other explorations. In many regions there are no rock outcrops from which a geologist or engineer can determine the character of the joints and faults and only information obtained from core drill holes will be practical or possible.

If a core drill hole was drilled through faults or fault zones as represented in Fig. 4, few geologists or engineers would be able to recognize the fault (much less appraise its significance) unless a nearly perfect core recovery was obtained, which is rare in such zones. Such fault zones could be represented by a few feet of core loss and pass completely unsuspected until encountered in the tunnel. Geologists may easily classify the faults after they are encountered in the tunnel, but it is difficult to do it before.

---

[15] **Chf. Geologist, Brazilian Traction, Power & Light Co., Ltd., São Paulo, Brazil.**

The author states (under the heading, "Physical Characteristics of Consolidated Rocks") in discussing the relative merits of the geologic structure represented in Figs. 2(*a*) and 2(*b*) that "the latter condition should be avoided if possible." The writer has found, in tunneling in the Brazilian Archean complex, that the structural conditions represented in Fig. 2(*a*) will cause much more overbreakage and many more tunneling problems than those shown in Fig. 2(*b*) if the dip joints are well developed and if there is slight weathering along them. This is especially true if the dip joints strike at an acute angle with the tunnel.

It is not practical in the planning and construction of most tunnels for civil engineering works to aline the tunnel to suit best the geologic structures. The writer assisted in the planning and exploration of the 7,100-ft tunnel for the relocation of the Chicago, Burlington and Quincy Railroad Company in the Wind River Canyon in Wyoming for the construction of Boysen Dam. A detailed geologic study was made of the area and it was immediately realized that several large fault zones would be encountered by the tunnel, but even so the tunnel was more feasible than the alternates.

The author states (under the heading, "The Tunnel Cross Section"):

> "Much time and effort can be saved by arching the roof in such a manner as to utilize what strength there is in the caving rock until supporting structures can be set in place."

Generally speaking, this would not be practical because it would involve a different tunnel section in caving and noncaving ground, and, if the tunnel had to have a permanent concrete lining, the forming of such an arch would be objectionable.

The writer has usually found that coarse-grained rocks alter more rapidly than fine-grained rocks, contrary to the author's statement (under the heading, "Altered Rocks and Swelling Ground"). For instance, in the Wind River Canyon in Wyoming the fine-grained granite gneisses underlying the Flathead sandstone are rarely altered, but the coarse-grained pink granites are usually weathered several feet below the sandstone. Pegmatites are usually more deeply weathered in Brazil than are the adjoining finer-grained wall rocks.

HYDE FORBES,[16] M. ASCE.—This well-considered outline of the application of geology to tunneling problems is directed more to the student geologist or to the geologist employed in such work than it is to the engineer responsible for design and construction. It is to be hoped, therefore, that discussion of this comprehensive paper will yield field experiences so that the engineer, although possibly not fully able to recognize the rock conditions with which he is confronted, will know when to seek the advice of a geologist who is able to do so, and learn how to appreciate the importance of obtaining a geologic interpretation.

---

[16] Cons. Engr. and Geologist, Palo Alto, Calif.

It is true that the preliminary investigation and the actual construction of tunnels involve a most direct and detailed application of the science of geology within the field of activity of the engineering geologist. Unfortunately, however, this is usually limited to the preliminary investigation of ground conditions by interpretation of diamond drill cores, or as revealed through shaft and other type exploration. From these all too limited "peeks" into the subsurface the geologist is supposed to give the engineer a complete geologic cross section of the formations to be bored, and geologic interpretation or determination of the character of the ground as to the occurrence or nonoccurrence of fractured, seamy, or noncoherent rock; water; and gases from point to point. In addition, he must solve the practical problem of the load to be carried by the tunnel support or lining, and the magnitude and distribution of ground or water pressures on which to predicate plans and specifications for the tunnel.

Excavation for tunnels through sound, hard rock has not presented any exceptional features. The section generally can be taken out with a center top heading and one or more benches (depending on the height and width of the section heading) with the spacing and number of drill holes depending on the hardness of the rock. The engineer achieves a confidence in his ability to judge and handle rock. It is, therefore, well to place emphasis on the necessity for "full coverage" through the employment of a geologist throughout the life of a job. In nearly every length of tunnel some modifications of the rock due to geologic processes are to be expected; these may be enumerated as follows:

(1) Heavy ground, wherein hard but "blocky" rock exists with the blocks of hard rock separated by bedding planes, planes of schistocity, and fractures or joints opened either through geologic processes in the zone of surface weathering or through faulting and intense folding, or through blasting in the tunnel itself, subject to fall if not supported;

(2) Seamy ground, wherein the rock walls of fracture or other planes are found separated by varying thicknesses of the products of rock decomposition, produced by the action of water and in which water is encountered;

(3) Swelling ground of fault zones and that due to chemical or physical action when the bore exposes the rock to contact with air and moisture and when it removes retention and support; and

(4) Flowing ground, which includes plastic clay of high moisture content and saturated sand.

Designers and constructors can cope with these types of ground by methods which have been developed through experience. It is the function of the engineering geologist to interpret the field conditions and to provide working data of value for design and construction in the event that these forms of rock weakness, disintegration, and decomposition can be anticipated or found to occur after construction starts.

In discussing the physical characteristics of consolidated rock the author presents a picture too involved with geologic terminology to mean much to the engineer. The writer's contact with the profession has shown him that the civil engineer studied the prescribed geology courses in college, and that the professor generally maintained the position that the science is an end in itself, rather than that it is of extreme value to the engineer as a means to an end; and so the student understood and retained little of the "book thrown at him." The same thing applies to a general discussion of rock structure. Generalities on the subject are of little value and it is difficult to state which particulars have wide application or avoid being misleading if not correctly identified. The writer has found that when rock cores show slickensides when broken, or swell when they are removed from the core barrel, it is an indication that actively swelling ground will be encountered in the tunnel bore. Fractures of any kind that carry gouge seams or oxidized products with more than a minimum thickness require strong support, and probably will carry water when pierced by the bore. The clayey gouge of fault zones and moist kaolinized (clayey) walls of faults and fractures act as viscous fluids under the load pressures produced by overburden. These materials are seldom recovered in the core.

Actively swelling ground due to chemical causes depends on the combination of minerals in the rock with the chemically active substances in the air. Air slacking is the general term used to cover oxidation, carbonization, and hydration. Much can be predetermined in that regard by tests on rock cores. The difference between the density of a rock upon its removal from the core barrel, and after it has stood several days exposed to the oxygen and carbon dioxide of the air, indicates the volume of swell taking place. The action of some rocks upon submergence in water is an indication of the amount of hydration to which they will be subject upon contact with moisture. Swelling ground results from the integration of minute slippages between extremely small fragments or crystals in rock material. This may be due to hydration, as in serpentinization, resulting in a slickensided rock. In driving a tunnel through serpentine under Parker Avenue (San Francisco, Calif.) blasting was necessary to remove the massive rock, but within a short time the further hydration of the rock produced clay which could be scraped from the walls and roof to the extent that the workers classed all the material as clay.

Swelling results from pressure (essentially hydrostatic) in fault zones characterized by crushed and ground-up rock (gouge). The outlet tunnels from the San Andreas reservoir of the San Francisco water department are bored through the San Andreas fault zone, the most extensive and active rift in California. The material making up the zone is gouge and breccia, the latter consisting of blocks of unground rock (called boulders by the miners), which are segments of the original rock that have slid in the finely ground gouge in adjustment to the pressures and have suffered only compression. The gouge is made up of a multitude of minute dry particles, between which slippage occurred as soon as the bore pierced it. The initial swell amounted to as much as 8 in. and the working material developed slickensided planes in the wall and at the contact between gouge and breccia. Swell continued for 36 hours as the pressure acting on the gouge at tunnel level was gradually relieved by the shearing stresses or "arching" developed in the gouge, until a new condition of pressure equilibrium was achieved in the mass around the bore. The material was cut back to line when the swelling ceased and the load was successfully carried by the timbers. When the tunnel was completed and approved for lining, blasting in a near-by quarry regenerated movement as the stress-strain equilibrium was upset by shock waves. The result was a new "working" of the material; new slickensided planes developed, and breccia boulders fell from the roof as shown in Fig. 7.

Rock falls and excessive overbreak due to blocky ground, characteristic of the weathered zone of all formations as well as where folding and faulting has been geologically recent and intense, are well described by the author (under the heading, "Folds, Joints, and Faults"). This can be foretold through a surface geological survey and mapping. A case in point was the Broadway Low Level tunnel in Oakland, Calif., approaching and through the Wild Cat fault zone. The rock formation exposed in road cuts was sheared to the extent that its original structure was hardly recognizable. This led to the conclusion that overbreak in the tunnel would be excessive and rock falls would be a common occurrence.

In this regard, as well as in geologic mapping during the construction of a tunnel, it is well to place emphasis on the employment of a geologist throughout the life of the job. The writer wishes to underscore the author's statement (under the heading, "The Functions of Geologist"):

> "The importance of a detailed geologic map of the tunnel cannot be overemphasized. This map not only should show the geologic structures and rocks encountered, but it also should serve as a lasting record to indicate the location of bad sections, which may require attention many years after the tunnel is completed."

An example of neglecting to provide such a map is found in the Coast Range tunnels of the Hetch Hetchy aqueduct system of San Francisco; nor is the writer aware of such a record for other important tunnels bored in California in the past twenty years.

As to the location of a tunnel, the geologist is rightly limited to the selection of the best of alternate locations which will serve the proposed engineering requirements, and frequently there is no alternative in relation to the purpose of the tunnel. It is seldom possible to change the direction of the tunnel to meet changes in rock structure as the author suggests, but the author briefly mentions (under the heading, "Folds, Joints, and Faults") that the geologist can advise in connection with the important feature of rock structure in relation to blasting. Forty years ago during precollege and college vacations the writer worked in California gold mines. Then, much was learned of tunneling from the experienced, practical miner, but the knowledge of rock and the application made of that knowledge, which was most interesting and impressive to this student of geology, was found in studying the rock to determine its "cleavage." The location, number, depth, and powder charge of drill holes were dictated by this cleavage, and the foot or hanging wall of waste rock would be cleanly stripped from the gold bearing quartz vein without fracturing or damaging the vein in any way. After the tunnel was mucked out, the vein would be drilled and shot down on canvas without breaking into or carrying down waste rock.

The writer has found it difficult in his professional work to impress upon engineers the idea that most rock has incipient cleavage, because of compressive stresses to which it has been subjected in crustal movement, or swell of adjacent igneous masses in geochemical change. In addition, bedding planes of sedimentary formations, planes of schistocity, or other structural features of rock character contribute prominent lines along which rock cleaves. These cleavages should be given consideration as a guide for using powder to break the rock. In considering the dam sites for the State Wide Plan of California (later the Central Valley Project) from 1928 to 1930, the writer endeavored to present specifications covering stripping of the sites. The reaction is best

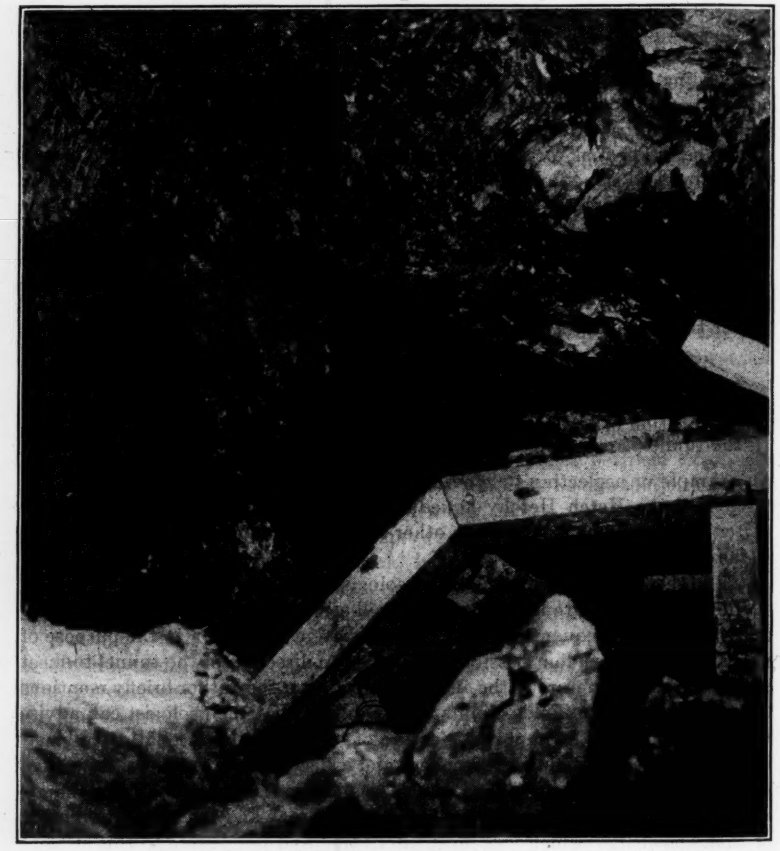

FIG. 7.—ROOF AND WALL OF SAN ANDREAS OUTLET TUNNEL AFTER QUARRY BLASTING

recorded in the remark of one consulting engineer that a contractor will not strip a dam site with a nut pick.

In connection with the sites selected in 1934 for debris dams on the Yuba, Bear, and American rivers to be constructed by the United States Army Engineers in California, the writer presented a definite stripping pattern on maps of the sites, meeting the cleavage of the rock and utilizing the banding due to compressive stress so that a minimum of rock had to be removed to provide a sound, unyielding, strong, watertight foundation and abutment. This was not understood, nor was its significance appreciated by the designing engineer, and it was unwelcome as an unwarranted trespass by the geologist into matters within the prerogative of the designer.

The ruination of good dam sites and the damage to tunnels observed by the writer have been largely due to "poor rock" caused by improper blasting. Much rock in California does not require blasting with the modern excavation equipment now available. In a recent rock excavation project in a built-up area in San Francisco the writer prescribed slopes to meet the rock conditions, based on boring and sampling, and specified that no blasting was required. It was believed by the engineers that bids could not be obtained on that basis, and a compromise was reached permitting the drilling of holes no deeper than 3 ft and loading with not more than 2 lb of powder. The contract is nearing completion without resorting to this limited use of blasting, except in the case of two large rock masses, one rolling down the slope, and another projecting above finished grade.

The observation of the diamond drill operations and the study of (and tests on) core recovered in connection with the prospective Broadway tunnel in San Francisco led to the recommendation that a tunnel be driven without blasting. The "chittering" of the drill so shattered the rock cores that less than 25% core recovery was effected. The recovered cores had a compressive strength ranging from 530 lb to 1,750 lb per sq in. when tested unconfined, but they shattered to small fragments under a percussive force of from only 5 ft-lb to 9 ft-lb. It was clearly shown that cleavages were so numerous that no piece of rock larger than a 1-in. cube would resist a sharp hammer blow. An important function of the geologist is to determine the presence of lines of structural weakness in rock and the methods of treating them in the process of tunneling, as well as in other excavation. It will take considerable persuasion to convince the engineering profession, if the writer's experience is any criterion.

The author states that the prediction of ground-water conditions in tunnels is one of the most baffling problems confronting the geologist. Experience will soon teach the observer that much can be predetermined in relation to the source, occurrence, and effect of water in tunneling. Tunnels driven under lakes, rivers, or other bodies of surface water can be expected to tap considerable volume of flow. Those driven under regions in which wells or springs are used by surface landowners for water supply purposes are found to dry up those sources, and tunnels driven into some formations release highly mineralized stored ground water that contaminates streams into which the tunnel drainage flows. Surface mapping of all water sources in a considerable area on both sides of the tunnel line should be carried out, and the probable water table beneath the area should be plotted. The relation of water bodies or courses to faults or other geologic structural features should be noted on the map. During exploration, drilling notes made of the depths at which water is lost or rises in the drill hole are of value, and measurements of water level in the hole at the end of each day's run and before the next run, to determine the loss or gain, will be found helpful.

Some water troubles occur where fissures filled with water are encountered. These fissures may range in width from hair thickness to several inches, and the water pressures may be the full hydrostatic head to the surface at the highest point of the water table. The Santa Barbara tunnel in California was bored through almost vertical dipping, sedimentary rock beds and water was encountered along bedding planes that had been opened by blast shock; the water pressures were sufficient to cause the rock to "pop" dangerously (fatal to several workmen) before the water seam was reached by the bore.

The city tunnel of Santa Barbara was driven a total of 18,000 ft through sandstone and shale formations characteristic of the Coast Range of California. Because the rock was not of a porous nature, it would have yielded little water except that, as the work progressed, the incipient, closed fractures (due to distortion suffered by the formation in crustal movement) and bedding planes were made crevices through blasting. These opened to the ground surface and filled with water from rainfall and soil water percolation. The tunnel portal is at El. 1500; the range rises to El. 5000. The writer made a survey of the springs that had been dried up by drainage through the tunnel in 1915 and found that the drained area extended approximately 3 miles east and west of the tunnel section at the crest of the range, in the form of an inverted cone with the tunnel at the apex. The tunnel was lined with concrete, but, because of water pressures, weep holes were installed, and the tunnel developed a considerable inflow—ranging up to 250 gal per min with the amount of seasonal rainfall. The flow from the tunnel, since used for city water supply, was fairly constant in that the sections nearer the portals discharged the greatest amount soon after (and during) the winter rains, whereas the flow from sections at greater depth below ground surface increased as that at the portal sections diminished.

The same experience was encountered in the boring of the Lafayette tunnel of the East Bay Municipal Utility District of Oakland, through a geologic formation of the same character. There, wells of dairies located on the ridge were deprived of water, whereas formerly the wells, more than 100 ft in depth, had a water level always standing between 10 ft and 20 ft from the surface—about 800 ft above sea level. The tunnel at El. 370 passed about 1,500 ft south of one well and down the dip of the strata from it, and the blasting within the bore opened the bedding planes beyond the well, as indicated by the drainage of water from the formation.

Similar conditions were brought about in driving the Mono tunnel of the Los Angeles (Calif.) Aqueduct in 1935. The formation through which the tunnel was driven, and from which springs issued at the surface, was volcanic in origin, varying greatly in mineral composition, and occurring as beds of lava, tuff, and agglomerate. It was dislocated by faulting, and the members of the volcanic series had a decided dip from their original horizontal position so that the tunnel penetrated them in succession. The bore, 9 ft by 10 ft, was driven approximately 300 ft below the spring area. Blasting in the tunnel opened the fractures and contact planes in the various formations and drained the water into the tunnel at rates in excess of 100 gal per min, drying up the spring area.

The effect of opening planes of schistocity by blasting was found when a state highway was carried over a tunnel of the Western Pacific Railroad near Keddie, Calif. The tunnel was bored and lined and had been in use several years. The blasting of the rock for the highway cut over the tunnel opened the formation along the planes so that segments of the rock were loosened and slid along the self-lubricating micaceous schist, buckling the tunnel lining. The character of the rock and the dip of the planes directly over the tunnel are shown in Fig. 8. In this instance, lubrication of the sliding plane through moisture was not required to facilitate movement. In tunnels, however, most rock slips occur when clayey or talclike alteration products resulting from the action of ground water on the rock and filling joints, bedding, or fracture planes, or those making up the gouge of fault seams or walls of joints, are softened when tunneling operations allow water to move down the slightly opened crevice.

The author suggests the alteration of the tunnel section to meet the caving of the walls or roof of a tunnel. The walls and roof of the tunnel become unstable due to conditions brought about by the tunnel, after it has been bored through the troublesome formation, and little can be predetermined which would indicate the necessity for a change in cross section, even if the engineering requirements should allow such change. Moist clayey decomposition products form a consequential part of a thoroughly fractured rock mass through which

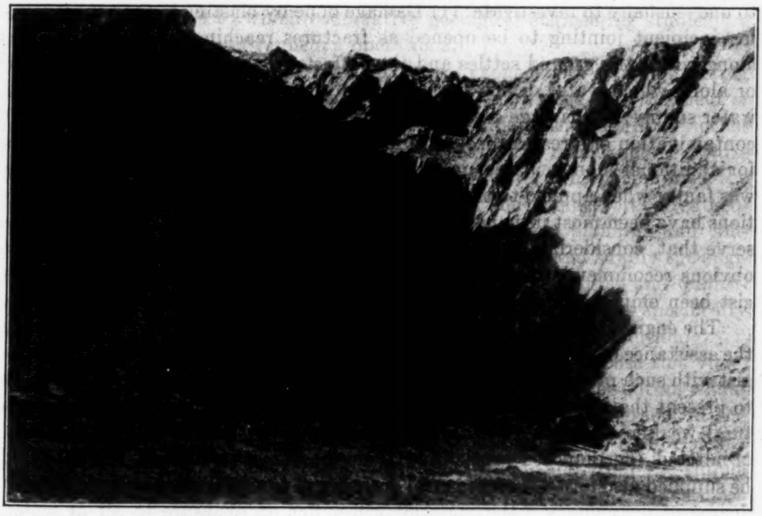

FIG. 8.—FACE OF HIGHWAY CUT EXCAVATION OVER TUNNEL

water has circulated, and the mass will be incapable of withstanding even moderate stresses when restraint is removed by the bore. Faults that carry gouge seams more than a few inches thick in humid regions are usually found to have carried water, even if no water is found in the preliminary drill hole. The rock hydrates to the extent of taking up the water trapped in the fractures, and the presence of water is not revealed. Strong timbers will be required to meet the imposed forces, similar to hydrostatic pressure, as the clay gouge and kaolinized walls of a fault or fracture will act as viscous fluids under the pressures at tunnel level regardless of the cross section.

The author states (under the heading, "The Functions of the Geologist"), that in relation to cooperation between the engineer and the geologist:

> "* * * this situation is gradually becoming less serious and the engineer and the geologist are reaching an amicable understanding based on mutual respect and profitable cooperation."

This is true among the salaried employees or civil service employees, in large corporations and governmental agencies. Nevertheless, the "awareness" of the importance of geological advice from a consultant of broad experience is not so well developed in the administrative head or the engineer in responsible charge. The writer's experience is that he has been employed after a tunnel is constructed, rather than before and during construction, on a ratio of five to one—usually to investigate: (1) Damage done by blasting in the tunnel causing incipient jointing to be opened as fractures reaching to ground surface, along which the ground settles and thus affects the foundations of structures, or along which water drains to the tunnel depriving overlying lands of their water supply; (2) damage done to tunnels due to blasting in their vicinity; (3) contamination of streams through tunnel drainage; and (4) contractor's claims for additional money, based upon the contention that the engineering design was faulty when applied to the particular ground conditions. These investigations have been most instructive, but have also afforded the opportunity to observe that, considering the money involved in the project, only one of several obvious recommendations was needed, had an experienced engineering geologist been employed, to save the cost of the geologist's fee several times over.

The engineer in responsible charge of tunnel projects should insist on having the assistance of an engineering geologist. In turn, he should provide the geologist with such preliminary exploration as he recommends and believes necessary to present the occurrence or nonoccurrence of consequential fault zones, structural weaknesses in the form of extensively jointed, fractured, disintegrated, or altered (decomposed) rock, and their locations. Sufficient funds should be supplied also for tests on material occuring at tunnel level to determine what degree of decrepitation the material will suffer on exposure to air or water. Provision should also be made to take sufficient rock samples or cores representative of the rock profile above the tunnel, from which the pressures at the tunnel arch can be determined, as well as to ascertain such properties of the rock as elastic expansion upon release from restraint, swell, compressive strength, and resistance to percussive force; and such observations and tests should be progressively carried on during the driving of the tunnel as a basis for current recommendations and final record. All these are well worthwhile, to the end that safe and economical tunnel design and construction will be better founded on fact.

ROGER RHOADES,[17] ESQ., A. B. REEVES,[18] M. ASCE, AND W. H. IRWIN,[19] ESQ.—It is now accepted as a truism that geology can contribute helpfully to civil engineering. The author has restated some aspects of the geologist's role in tunneling, has described or mentioned several basic geologic principles which may be applied profitably to tunneling operations, and has alluded to a few specific examples of such application.

The object of this discussion is not to disagree with either the general thesis or the specific content of the paper; it is written soundly, from the geologic standpoint, and, if tunnel engineers uninitiated in geologic matters obtain from it a more sympathetic understanding of the medium—the rocks and soil—with which they work, the author's objective has presumably been achieved, and a useful purpose has been served. However, a large and complex subject is involved and the author, constrained to brevity, has dealt only with the basic fundamentals. The purpose of this discussion is to point out the difficulty of compressing a subject so large into a presentation so brief, and to warn of the danger that the uninitiated—among both engineers and geologists—may fail to comprehend the full extent of the potential contribution of geology to tunneling and the degree to which cooperative geological-engineering studies are being applied currently to tunneling operations.

The extensive and increasing participation of geologists in civil engineering operations in general is now a matter of common knowledge. In the field of tunneling this geologist-engineer partnership should be closer than in any other kind of civil engineering because the problems met by the tunnel engineer arise almost wholly from the rocks, soil, and ground water which comprise the geologist's special field of professional interest. The engineer requires geological information for the most effective and economical planning and construction of tunnels; the geologist is challenged to procure and supply the engineer with the information he needs, in terms that are as precise and quantitative as possible—not in the form of generalizations—and in terms specifically applicable to the engineering problem and directly useful to its solution.

Nothing in Mr. Wahlstrom's paper can be construed to oppose this viewpoint; it may be inferred from the paper's general context that the author would agree fully. However, the paper is brief and is purposely concerned, in the main, with elementary fundamentals; it would be easy to derive the erroneous conclusion (from the few concepts and examples cited, and from the simple geological principles described) that the scope of geology in tunneling is more limited than is actually the case. In reality, the applications of geology to tunneling are manifold and complex; its application to tunneling problems and operations is a matter of long standing, although it has become greatly expanded in the last one or two decades.

---

[17] Chf. Geologist, U. S. Bureau of Reclamation, Denver, Colo.

[18] Head, Structures and Tunnels Section, Canals Design Div., U. S. Bureau of Reclamation, Denver Colo.

[19] Asst. Chf. Geologist, U. S. Bureau of Reclamation, Denver, Colo.

The paper describes, for example, the association of soft or squeezing ground with the geological processes of chemical alteration, and the "arching" effect of caving ground. Nevertheless, if an uninitiated reader is to be protected from gaining the mistaken impression that the geologist can supply no more than such academic explanations of tunneling problems, allusion must be made to other important considerations. For instance, it should be mentioned at least that the mechanics of such matters have been comprehensively analyzed by engineering geologists and engineers. Through these analyses such geological phenomena have been translated into specific stress-strain interpretations, and the interpretations, in turn, have been applied quantitatively to answer such questions as: How much and what kind of support will be required? Will permanent lining be required—what kind and how strong?

Such questions may seem to some to be beyond the proper sphere of a geologist's interest, but it is essential in any description of the relationship of geology to engineering to point out that the engineering and geological aspects of these problems are merged and interlocking and cannot be disentangled. The engineer must, of course, retain responsibility for the decision as to what kind of structure is most appropriate, and how it is to be built.

The geologist is responsible for interpreting the geologic conditions to which the structure must be adapted, and for defining the problems which these conditions will present. The geologist's data and interpretations cannot be pertinent and directly useful unless he has comprehended fully the engineering viewpoint and objective, the design alternatives, and the construction procedures that are available for use—he must understand what can and what cannot be done. The geologist must be conversant at least with the technical facilities and limitations of engineering procedure if the information he obtains is to be of any practical value to the engineer. Similarly, the geologic studies must be intimately coordinated with the economic considerations, which, in the long run, dictate what can or cannot be done within the controlling limits of cost and value.

Simply stated, the geologic studies must be practical as well as scientifically sound. Thus, although the engineering geologist must recognize that the ease or difficulty of tunnel driving may be controlled to a large extent by the relationship between the direction of the tunnel and the direction and inclination of the schistosity, foliation, or stratification of the rocks (as succinctly described in the paper), he must also recognize that, in practice, it is only occasionally practicable to vary the course of a tunnel very much from a predetermined line to take advantage of such factors. Similarly, although the theoretical advantage of skewed or asymmetric tunnel sections shaped to conform with the structure of the rock is well described in the paper, the geologist should be equally aware of possible, serious engineering disadvantages to such shapes.

These disadvantages, even though commonly of negligible importance in mining tunnels, are frequently critical in the tunnels of the civil engineer, where the shape is often predetermined and controlled by factors directly related to the function of the tunnel. For example, in unlined tunnels designed to carry water, overbreak or irregular shape may be seriously detrimental to hydraulic efficiency, and may even so reduce the efficiency that a larger tunnel diameter is required with attendant increased costs. If the tunnel is to be lined, and has been designed with a shape and diameter controlled by the capacity requirements, any overbreak represents so much rock needlessly removed and replaced by expensive concrete and steel. The geologist cannot remain ignorant of these considerations but must take them into account specifically if the geologic studies are to be of maximum practical use to the engineer.

Although the paper acknowledges the desirability of applying geology to actual tunneling operations and recommends periodic geologic examinations and the assembly of geologic records as the work progresses, the reader may get the impression that the author is primarily concerned with the exploration of prospective sites. The experience of the United States Bureau of Reclamation attests to the value of thorough explorations continuously coordinated with the progress of design studies; on the basis of that experience—not only with tunnels, but also on engineering undertakings in general—one could recommend even stronger emphasis on drilling, ground-water testing, geophysical explorations, and the application of any other technique for searching beneath the earth's surface and securing useful reliable data bearing on the engineering plan.

It is difficult to recall a structure site that has been "overexplored"; money spent on judicious exploration is inevitably saved many times over in cheaper and more efficient design and construction. However, the applications of geology during construction are at least as important and, in some respects, more productive of useful results. The preceding comments have stressed the necessity for quantitative geological determinations, but it is recognized that this quantitative ideal is usually unattainable during the stage of exploration—no matter how many holes are drilled, or how exhaustively routine and special investigational techniques are applied. At best, explorations serve only to reduce the guesswork and increase the assurance of advance predictions.

During construction, when the rock is exposed for precise study and when the water flow can be measured and interpreted, the measurements, observations, and tests necessary for quantitative appraisals can be made. Moreover, when precise studies made during construction (particularly if compared closely with the predictions made during the explorations) become the subject of comprehensive records, they serve as the principal method by which the procedures of tomorrow may profit by the experience of yesterday and today. The literatures of both engineering and geology need to be augmented by more "case histories," carefully and fully described.

The paper suffers from two important omissions: No mention is made of the problems of (1) residual rock stress, so important in relation to rock bursts and "heaving ground," which is sometimes critical to the design of tunnel linings, and (2) rock temperature, so important because of its technical and economic implications with respect to ventilation. The extent of recent researches in both problems attests to the current interest of engineers and geologists in these important considerations. Related minor or special problems, such as the occurrence of gas or hot water, should be mentioned even though space limitations have prevented their thorough discussion by both Mr. Wahlstrom and the writers.

There is a dearth of critical, fundamental discussions of the geological principles applicable to tunneling problems. Such data and written discussion as may apply are widely scattered and not easily accessible, but papers of the type presented by Mr. Wahlstrom represent an encouraging step toward the rectification of that deficiency, and deserve encouragement.

Engineers and geologists desiring a more extended and analytical treatment of some aspects of tunnel geology and related construction problems may refer profitably to a treatment prepared by Karl Terzaghi,[20] Hon. M. ASCE.

Ernest E. Wahlstrom,[21] **Esq.**—The carefully considered discussion by several well-qualified experts emphasizes the diversity of opinion as to the exact functions of the geologist on engineering projects. This is only natural because geologists serve in different capacities from one project to another and have been assigned differing degrees of responsibility by engineering firms and governmental agencies. Moreover, the discussion clearly demonstrates the difficulty of writing a paper that places emphasis on general principles rather than on specific examples. Generalizations are always subject to exceptions.

Geology is a very complex, fluid science, and a geological paper written in a condensed, more or less academic manner should not be construed by the reader to mean that geologists work by rule of thumb or make interpretations which are based on elementary considerations only. Actually, a successful engineering geologist is a scientist who interprets geologic and engineering data artfully in the light of knowledge gained from long years of rigorous academic training and diversified field and laboratory experience. The engineering geologist attempts to apply the complex science of geology to the equally complex problems of engineering. He should remain primarily a geologist and should not attempt to usurp the place of the engineer, and first and last should think and act as a geologist and not as an engineer with a smattering of geological training.

There is an urgent need for publications that clearly detail and discuss "case histories." The vast amount of data in files of engineering firms and governmental agencies should be collated and made available to the geological and engineering professions as expediently as possible. Free interchange of ideas and widespread dissemination of the published results of geologic investigations of engineering projects will enable the practicing professional man measurably to improve both the qualitative and quantitative aspects of his work.

VARIATION OF COEFFICIENTS OF SIMULTANEOUS LINEAR EQUATIONS

By Bernard L. Weiner,[1] M. ASCE

With Discussion by Messrs. T. F. Hickerson, A. Floris, Frederick S. Merritt, I. F. Morrison, Sigmund Roos, and Bernard L. Weiner.

Synopsis

Simultaneous equations are of great importance in modern structural engineering, and the purpose of going through a solution is, obviously, to obtain numerical results for a specific set of conditions. It is often of equal importance, however, to know the effect of a change in the geometric and elastic properties of the structure. Without such knowledge it is impossible to study the design with a view toward obtaining the most in economy and certain other desirable qualities. Such studies, except for the simplest structures, can be made only at the expense of re-solving the equations each time a change is made in the coefficients, and the labor involved is so great that studies cannot ordinarily be made except very roughly and sketchily. With the theory presented in this paper, the effect on the solution produced by a change in any number of the coefficients in any one equation, or in any number of coefficients of any one unknown, can be computed quickly and simply in one step.

Although the variation of coefficients is the primary purpose of the paper, other useful properties of the theory, such as the solution of equations and the rapid correction of errors, follow simply as corollaries. In the actual operation of the method, however, the procedure is the same whether coefficients are being varied in a set of equations that have already been solved, or whether the purpose is to solve the equations. It is, as a matter of fact, possible to vary the coefficients endlessly and any particular "solution" therefore becomes merely a stopping point in an endless series of variations—from which it follows that the method is very flexible.

Variation of coefficients as a method of solving simultaneous equations has several marked advantages over the classical methods and leads also to the derivation of several useful properties of such equations. The numerical

work required for a solution by the method presented in this paper is very much less than that required by standard methods; and, what is perhaps more important, fewer significant digits are necessary in the intermediate computations to obtain any desired degree of accuracy in the final solution. In fact, with a little care and by using a few fairly obvious arithmetical manipulations, results sufficiently accurate for design purposes often may be obtained by slide rule for the bulk of the computations. The method is an exact one, however, and computations may be carried out to any degree of accuracy but with much less labor than that required by the classic methods.

In addition, the method of solution has another very important property. As will be shown, the solution falls into distinct steps, or partial solutions, each and every one of which is complete in itself. As a result, the computation may be checked completely and absolutely at the conclusion of each step or variation, so that it is not necessary to wait for the end of the solution to check for an arithmetical error. Should the computer, however, either neglect to check his work at intermediate points, or discover an error in the original setup of the equations, the basic theory of the solution is such that it offers a quick method for the correction of an error without the necessity of changing the entire computation from the point at which the error was made to the end of the solution. Furthermore, the method is self-checking in many different ways, so if it is found that the intermediate computations at some particular point in the solution have not been carried out to a sufficient number of significant digits, the defect may be remedied by using one of the checks to recompute the defective quantity.

INTRODUCTION

Structural analysis and many other engineering problems occasionally require the solution of simultaneous equations. Since classical methods of solution involve small differences resulting from the subtraction of large numbers, computations must be carried to many significant digits, thus making the work very laborious. Study of the effect of varying the characteristics of a structure (which involves, among other things, changing the coefficients of the unknowns) by these same methods is so time consuming as to make such studies prohibitive except in the simplest cases. The value of a direct and simple method for finding the effect of varying coefficients of simultaneous equations is therefore obvious.

Since an error in coefficients can be interpreted to mean that, in effect, a structure has been analyzed whose characteristics are expressed by the incorrect coefficients, the correction of such errors becomes a problem in "variation of coefficients." It was to meet just such a problem that the methods outlined in this paper were developed and later extended to other applications. An obvious extension of the concept involved leads directly to a new method for solving this type of equations—for, as will be shown, a "solution" is merely a stopping point in an endless chain of variations.

The theory presented, as it applies to the solution of simultaneous equations, differs in one respect from the classical theories in that it is developed from a different point of view. The usual method of solution for this and other types of equations consists, essentially, of what might be termed a process of "breaking down"—that is, the complete equations are converted to such forms that the extraction of a root or the elimination of other unknowns will result in a simple equation with only one unknown or root. This method, on the contrary, consists of a process of "building up"—that is, the solution begins with simple, reduced equations that are easily solved or need no solution, and are then built up, step by step, to the required equations by converting the solutions to conform to the new equations at each step. In this process, it is necessary to vary the coefficients of the unknowns and to find the resulting effect on the values of the unknowns. This process is direct, and the theory for the variation of the coefficients makes the method of solution almost self-evident.

DERIVATION OF THEORY FOR VARIATION OF COEFFICIENTS

Each one of a set of simultaneous equations takes the form:

$$a_{1n} X_1 + a_{2n} X_2 + a_{3n} X_3 + \cdots = c_n \ldots\ldots\ldots\ldots\ldots (1)$$

in which the X_m's are unknowns; the a_{mn}'s are coefficients dependent only on the elastic and geometric properties of the structure; and the c_n's are constants determined by the position and magnitude of the loads in addition to the properties of the structure.

For any given structure the coefficients are, of course, constant, but c_n will have as many sets of values as there are loading conditions to be analyzed. It has often been erroneously stated that the equations must be solved for each one of these sets of constants—a statement that is only a half-truth. If the work is properly arranged and the equations are solved for one set of values of c_n, the solution for any other set requires comparatively little additional labor. In practice, the equations are solved in a routine manner for all sets of values of c_n at the same time and the computation of influence lines is therefore no great additional hardship. A simple illustration of such a procedure is presented in Table 1, which gives a solution for the simultaneous equations:

$$\left.\begin{array}{r} +\,4\,x + 6\,y = \\ +\,2\,x + 5\,y = \end{array} \begin{array}{|c||c|c|} 42 & a & 0 \\ 31 & 0 & b \end{array}\right|\Bigg\} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Attention is called to Col. 7, from which it is easily seen that if a set of equations is solved for one set of values of c_n a solution for another set can be obtained simply by using the factors and performing on the new constants only the operations indicated in this column. However, if the number of sets of values for c_n is large, it is often advantageous to solve for sets of constants such as are shown in Cols. 5 and 6. The numerical solution $y = 5$, for example may then be obtained by setting $a = 42$ and $b = 31$, from which (line 5) $y = -\frac{1}{4} \times 42 + \frac{1}{2} \times 31 = 5$. Similarly (line 8), $x = +0.625 \times 42 - 0.75 \times 31 = 3$.

Any number of solutions may therefore be found either by following the operations indicated in Col. 7 or by using the factors in Cols. 5 and 6. It should be noted that these latter factors are actually solutions of Eqs. 2 for $c_n = a,0$ and $0,b$. However, if the coefficients of x and y were changed, it would give rise to a new set of equations. By the classical methods, solutions for the new set of equations can be found only by actually re-solving the equations. The factors in Cols. 5 and 6 can be used to avoid this difficulty and therefore are termed "variation coefficients."

TABLE 1.—SOLUTION OF EQS. 2 BY THE PROCESS OF ELIMINATION

Line No.					VARIATION COEFFICIENTS		Remarks
(1)	(2)	(3)		(4)	(5)	(6)	(7)
1	$+4x$	$+6y$	=	42	a	0	
2	$+2x$	$+5y$	=	31	0	b	
3	$+2x$	$+3y$	=	21	$0.5a$	0	½ (line 1)
4		$+2y$	=	10	$-0.5a$	b	(line 2) − (line 3)
5		y	=	5	$-0.25a$	$0.5b$	½ (line 4)
6		$5y$	=	25	$-1.25a$	$2.5b$	5 (line 5)
7	$2x$		=	6	$+1.25a$	$-1.5b$	(line 2) − (line 6)
8	x		=	3	$+0.625a$	$-0.75b$	½ (line 7)

Let it be supposed that it is desired to change the coefficient of x in line 1, Table 1, from 4 to 7. The new set of equations then becomes:

$$\left.\begin{aligned} 7x' + 6y' &= 42 \\ 2x' + 5y' &= 31 \end{aligned}\right\} \qquad (3)$$

which may be rewritten as

$$\left.\begin{aligned} 4x' + 6y' &= (42 - 3x') \\ 2x' + 5y' &= 31 \end{aligned}\right\} \qquad (4)$$

Now let $(42 - 3x'),31$ be treated as new values of c_n—that is, as additional constants of Eqs. 2 for which solutions are to be found. Substitution of $a = 42 - 3x'$, and $b = 31$, in line 8, Table 1, gives $x' = 0.625(42 - 3x') - 0.75 \times 31 = 3 - 1.875x'$; which gives

$$x' = \frac{3}{1 + 1.875} = \frac{24}{23} \qquad (5)$$

From line 5, Table 1, $y' = -0.25(42 - 3x') + 0.5 \times 31 = 5 + 0.75x'$; from which

$$y' = 5 + 0.75 \times \frac{24}{23} = \frac{133}{23} \qquad (6)$$

These values of x' and y' obviously satisfy Eqs. 3 and are therefore solutions of these equations. Furthermore, since the variation coefficients are also solutions of Eqs. 2, they too can be revised to satisfy Eqs. 3 for $c_n = a',0$ and

$0,b'$. Thus, by setting $a = a' - 3\,x'$, and $b = 0$,

$$x'_a = 0.625\,(a' - 3\,x'_a); \qquad \text{or} \qquad x'_a = \frac{0.625\,a'}{2.875} = \frac{5}{23}\,a' \ldots\ldots (7)$$

and

$$y'_a = -\,0.25\,(a' - 3\,x'_a); \qquad \text{or} \qquad y'_a = -\,\frac{a'}{4} + \frac{3}{4} \times \frac{5}{23}\,a' = -\,\frac{2}{23}\,a' \ldots (8)$$

Likewise, by setting $a = -\,3\,x'$, and $b = b'$,

$$x'_b = 0.625\,(-\,3\,x') - 0.75\,b'; \qquad \text{or} \qquad x'_b = -\,\frac{0.75\,b'}{2.875} = -\,\frac{6}{23}\,b' \ldots (9)$$

and

$$y'_b = -\,0.25\,(-\,3\,x') + 0.5\,b'; \qquad \text{or} \qquad y'_b = -\,\frac{3}{4} \times \frac{6}{23}\,b' + \frac{1}{2}\,b' = \frac{7}{23}\,b' \ldots (10)$$

The complete solution of Eqs. 3 for all values of c_n, as obtained by revision of Eqs. 2, is given in Table 2.

Eqs. 3 can be changed back to Eqs. 2—or may be "varied" to any other equations—by using the new variation coefficients, since it obviously does not matter whether one set of equations was solved by revising another set or was solved directly.

For simplicity, only one coefficient was varied in the previous problem. It will now be shown that any number of coefficients of the same unknown can be varied at the same time.

GENERAL FORMULAS FOR VARIATION OF COEFFICIENTS

Let it be assumed that the equations—

$$\left.\begin{array}{l} A_1\,x + B_1\,y + C_1\,z = \\ A_2\,x + B_2\,y + C_2\,z = \\ A_3\,x + B_3\,y + C_3\,z = \end{array} \left|\begin{array}{c} K_1 \\ K_2 \\ K_3 \end{array}\right\|\begin{array}{c|c|c} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & c \end{array}\right|\right\} \ldots\ldots\ldots\ldots\ldots (11)$$

—have been solved by some method, no matter what, with results as shown in Table 3.

Also, suppose that the coefficients A_1, A_2, A_3 are increased by d_1, d_2, and d_3, respectively. Following the procedure used in varying Eqs. 2:

$$\left.\begin{array}{l} a = K_1 - d_1\,x' \\ b = K_2 - d_2\,x' \\ c = K_3 - d_3\,x' \end{array}\right\} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Substituting in line 4, Table 3,

$$x' = a_1\,(K_1 - d_1\,x') + a_2\,(K_2 - d_2\,x') + a_3\,(K_3 - d_3\,x') \ldots\ldots (13a)$$

from which

$$x' + a_1 d_1 x' + a_2 d_2 x' + a_3 d_3 x' = a_1 K_1 + a_2 K_2 + a_3 K_3 \ldots\ldots (13b)$$

and

$$x' = \frac{a_1 K_1 + a_2 K_2 + a_3 K_3}{1 + a_1 d_1 + a_2 d_2 + a_3 d_3} \ldots\ldots (14)$$

As previously shown (Table 1), a solution for any set of constants, such as K_1, K_2, and K_3, may be found by setting $a = K_1$, $b = K_2$, and $c = K_3$. Therefore,

$$a_1 K_1 + a_2 K_2 + a_3 K_3 = S_1 \ldots\ldots (15a)$$

Similarly, by substituting $a = d_1$, $b = d_2$, and $c = d_3$:

$$a_1 d_1 + a_2 d_2 + a_3 d_3 = x_d \ldots\ldots (15b)$$

in which x_d is the solution for x, for a set of values of $c_n = d_1$, d_2, and d_3.

Substituting Eqs. 15*a* and 15*b* in Eq. 14,

$$x' = \frac{S_1}{1 + x_d} \ldots\ldots (16)$$

However, since S_1 is any solution for x,

$$x' = \frac{x}{1 + x_d} \ldots\ldots (17)$$

In a similar manner, substituting Eq. 12 in line 5, Table 3,

$$y' = b_1 (K_1 - d_1 x') + b_2 (K_2 - d_2 x') + b_3 (K_3 - d_3 x') \ldots\ldots (18a)$$

$$y' = (b_1 K_1 + b_2 K_2 + b_3 K_3) - (b_1 d_1 + b_2 d_2 + b_3 d_3) x' \ldots\ldots (18b)$$

$$y' = S_2 - x' \sum b_n d_n \ldots\ldots (18c)$$

Since S_2 is any solution for y, and $\sum b_n d_n$ is a solution for y when $c_n = d_1$, d_2, and d_3,

$$y' = y - y_d x' \ldots\ldots (19)$$

Similarly,

$$z' = z - z_d x' \ldots\ldots (20)$$

TABLE 3.—SUMMARY OF SOLUTION OF EQS. 11

Line No.						VARIATION COEFFICIENTS		
(1)	(2)	(3)	(4)		(5)	(6)	(7)	(8)
1...	$+ A_1 x$	$+ B_1 y$	$+ C_1 z$	=	K_1	a	0	0
2...	$+ A_2 x$	$+ B_2 y$	$+ C_2 z$	=	K_2	0	b	0
3...	$+ A_3 x$	$+ B_3 y$	$+ C_3 z$	=	K_3	0	0	c
4...	x			=	S_1	$a_1 a$	$a_2 b$	$a_3 c$
5...		y		=	S_2	$b_1 a$	$b_2 b$	$b_3 c$
6...			z	=	S_3	$c_1 a$	$c_2 b$	$c_3 c$

Three equations with three unknowns were chosen for simplicity. The derivation would obviously be the same for any number of unknowns. Also, in this derivation the coefficients of x were varied; but this is evidently immaterial, as no restriction is involved. Revised solutions for the unknown whose coefficients are being varied are given by Eq. 17; revised values for the solutions of all other unknowns are given by Eqs. 19 and 20.

Generalizing:

$$u' = \frac{u}{1 + u_d} \qquad \text{(21}a\text{)}$$

and

$$v' = v - v_d u' \qquad \text{(21}b\text{)}$$

in which u and u' represent, in the original and revised equations, respectively, the unknown whose coefficients are being varied; v and v' represent any other unknown in the original and final equations, respectively; d_n is the amount by which A_n, any coefficient of u, is increased; and u_d and v_d are solutions for u and v, respectively, when $c_n = d_1, d_2, \cdots, d_n$.

Application of basic Eqs. 21 to the solution of the equations—

$$\left.\begin{array}{r} 4x + 3y + 2z = \\ x + 4y + 3z = \\ 5x + 2y + 6z = \end{array} \left| \begin{array}{c} 28 \\ 26 \\ 49 \end{array} \right\| \begin{array}{c|c|c} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & c \end{array} \right\| \right\} \qquad (22)$$

—is illustrated in Table 4.

EXPLANATION OF TABLE 4

In Table 4, it is assumed that the set of simultaneous equations on lines 1, 2, and 3 (Eqs. 22) has been solved by some method, no matter what. The solutions corresponding to the four sets of constants are given on the next three lines. Let it be supposed that it is desired to reduce the coefficients of these equations by the amounts shown in brackets on the first three lines of the table. For example, on line 1 the coefficient of x, which totals 4, is to be reduced by 3 to a net value of 1; the coefficient of z, on the same line, is to be reduced by 2—that is, it is to be eliminated entirely. The order of variation is immaterial; by arbitrary choice the coefficients of z will be varied first.

From Eq. 21a, $u = z$, $u' = z'$, and $u_d = z_d$. Also, from Col. 4, lines 1, 2, and 3, $d_1 = -2$; $d_2 = -3$; and $d_3 = -5$. By definition, $u_d = z_d$ is a solution of the original equations for z corresponding to a set of constants $c_n = d_n$—that is, $c_1 = d_1 = -2$; $c_2 = d_2 = -3$; and $c_3 = d_3 = -5$.

To obtain this solution, z_d, it is necessary only to substitute the set of constants in line 6, setting $a = -2$, $b = -3$, and $c = -5$, as indicated in Col. 15, lines 7 to 9. Making this substitution, $u_d = z_d = \left(-\frac{2}{7}\right)(-2) + \frac{1}{9}(-3) + \frac{13}{63}(-5)$, from which $z_d = \frac{4}{7} - \frac{1}{3} - \frac{65}{63} = -\frac{50}{63}$, as shown on line 9, Cols. 9 to 12. Also, $1 + z_d = 1 - \frac{50}{63} = \frac{13}{63}$, and $\frac{1}{1 + z_d} = \frac{63}{13}$ as shown on line 9, Cols. 13 and 14.

Having computed the reciprocal of the denominator in Eq. 21a, the next step is to find the revised values of z. Thus, for $z = 5$, $z' = 5 \times \frac{63}{13} = \frac{315}{13}$; for $z = -\frac{2}{7}a$, $z' = \left(-\frac{2}{7}a\right) \times \frac{63}{13} = -\frac{18}{13}a$; that is, the original values on line 6 are multiplied by $\frac{1}{1 + z_d} = +\frac{63}{13}$ to obtain the revised values, z', on

line 12. For reasons that will be obvious later, the values of z' are also shown on line 9, Cols. 5 to 8.

With z', the revised values of z determined, the revised values of the other unknowns can be computed. With $v = x$, and $v_d = x_d$, x_d is the only value on the right-hand side of Eq. 21*b* that has not already been computed. Again by definition, $v_d = x_d$ is a solution for x of the original equations corresponding to the same sets of constants $c_n = d_n$. Therefore, substituting in line 4 the values $a = -2$, $b = -3$, and $c = -5$, $v_d = x_d = +\frac{2}{7}(-2) + \left(-\frac{2}{9}\right)(-3) + \frac{1}{63}(-5)$ from which $x_d = -\frac{4}{7} + \frac{2}{3} - \frac{5}{63} = +\frac{1}{63}$, as shown on line 7, Cols. 9 to 12.

Having obtained $v_d = x_d$, the term $v_d\, u' = x_d\, z'$ may be computed. Thus, for $x = 3$ and $z' = +\frac{315}{13}$, $x_d\, z' = \frac{315}{13} \times \frac{1}{63} = +\frac{5}{13}$. Likewise, for $x = +\frac{2}{7}a$ and $z' = -\frac{18}{13}a$, $x_d\, z' = \left(-\frac{18}{13}a\right)\frac{1}{63} = -\frac{2}{91}a$; that is, the values of z' on line 9 are multiplied by $x_d = +\frac{1}{63}$ to obtain the term $x_d\, z'$ on line 7 corresponding to each value of x (in the original equations) on line 4. Since, by Eq. 21*b*, $x' = x - x_d\, z'$, values on line 7, Cols. 5 to 8, are subtracted algebraically from corresponding values on line 4 to give the revised values, x', on line 10. Thus, for $x = 3$, $x' = 3 - \frac{5}{13} = +\frac{34}{13}$. Likewise, for $x = \frac{2}{7}a$, $x' = +\frac{2}{7}a - \left(-\frac{2}{91}a\right) = +\frac{4}{13}a$.

Similarly, setting $v = y$, $v' = y'$, and $v_d = y_d$ in Eq. 21*b* and substituting $a = -2$, $b = -3$, and $c = -5$ in line 5, $y_d = +\frac{1}{7}(-2) + \frac{2}{9}(-3) + \left(-\frac{10}{63}\right)(-5)$, from which $y_d = -\frac{2}{7} - \frac{2}{3} + \frac{50}{63} = -\frac{10}{63}$, as shown on line 8, Cols. 9 to 12. Multiplying the values of z' on line 9 by $y_d = -\frac{10}{63}$, the values of the terms $y_d\, z'$ are obtained as shown on line 8, Cols. 5 to 8. Thus, for $y = 2$ and $z' = +\frac{315}{13}$, $y_d\, z' = +\frac{315}{13}\left(-\frac{10}{63}\right) = -\frac{50}{13}$. Also, for $y = \frac{1}{7}a$ and $z' = -\frac{18}{13}a$, $y_d\, z' = \left(-\frac{18}{13}a\right)\left(-\frac{10}{63}\right) = +\frac{20}{91}a$.

Since, by Eq. 21*b*, $y' = y - y_d\, z'$, values on line 8, Cols. 5 to 8, are subtracted algebraically from corresponding values on line 5 to give the revised values, y', on line 11. For example, for $y = 2$, $y' = 2 - \left(-\frac{50}{13}\right) = +\frac{76}{13}$; for $y = +\frac{1}{7}a$, $y' = \frac{1}{7}a - \frac{20}{91}a = -\frac{1}{13}a$.

The computation for the variation of the coefficients of z is now complete, and lines 10, 11, and 12 are the solutions for the revised set equations—

$$\left.\begin{array}{rc|c||c|c|c|}
4x' + 3y' & = & 28 & a & 0 & 0 \\
x' + 4y' & = & 26 & 0 & b & 0 \\
5x' + 2y' + z' & = & 49 & 0 & 0 & c
\end{array}\right\}\dots\dots\dots\dots\dots(23)$$

In the next step of Table 4, Eqs. 23 are further revised by varying the coefficients of y' from 3, 4, and 2 to 0, 1, and 0, respectively. For this step, referring again to Eqs. 21, $u = y'$, and $v = x'$ or z' as the case may be. The computations follow, step by step, the procedure described in detail for varying the coefficients of z. Since the new set of equations are now being varied—that is, Eqs. 23—their solutions on lines 10, 11, and 12 are used to compute x'', y'', and z'' on lines 16, 17, and 18.

These solutions correspond to another new set of equations—

$$\left.\begin{array}{rc|c||c|c|c|}
4x'' & = & 28 & a & 0 & 0 \\
x'' + y'' & = & 26 & 0 & b & 0 \\
5x'' + z'' & = & 49 & 0 & 0 & c
\end{array}\right\}\dots\dots\dots\dots\dots(24)$$

In the last step of Table 4, Eqs. 24 are revised further by varying the coefficients of x'' from 4, 1, and 5 to 1, 0, and 0, respectively. For this variation, $u = x''$, and $v = y''$ or z''. The new solutions are given on lines 22, 23, and 24, corresponding to the new equations:

$$\left.\begin{array}{rc|c||c|c|c|}
x''' & = & 28 & a & 0 & 0 \\
y''' & = & 26 & 0 & b & 0 \\
z''' & = & 49 & 0 & 0 & c
\end{array}\right\}\dots\dots\dots\dots\dots(25)$$

Attention is called to the fact that each step in Table 4 is entirely independent and complete. Once the solution to a set of equations is known, it is immaterial whether it was obtained independently or by varying the coefficients of some other set of equations.

Solution of Simultaneous Equations by Variation of Coefficients

In Table 4, the coefficients have been varied in a more or less arbitrary manner. This numerical example illustrates clearly that, once the variation coefficients are known for any set of simultaneous equations, the coefficients can be varied at will and the order of the operations is almost entirely arbitrary. Also, the process is obviously reversible—which leads directly to another method for solving such equations.

In Table 4, it was assumed that Eqs. 22 were solved in some way, no matter how—the solutions being given on lines 4, 5, and 6. By a series of variation operations, all the coefficients in brackets in this original set of equations were removed, resulting in the corresponding revised solutions given on lines 22, 23, and 24. However, this last result obviously can be obtained directly by inspection. Since the process is reversible, the results shown on these last three lines can be varied back to the original set of equations—or to any other set of equations, for that matter. This reverse process is illustrated in Table 5, and thus another method for solving simultaneous linear equations is obtained.

22.....	x			=	$+3$	$+\frac{2}{7}a$	$-\frac{2}{9}b$	$+\frac{1}{63}c$							
23.....		y		=	$+2$	$+\frac{1}{7}a$	$+\frac{2}{9}b$	$-\frac{10}{63}c$							
24.....			(z)	=	$+5$	$-\frac{2}{7}a$	$+\frac{1}{9}b$	$+\frac{13}{63}c$							

Furthermore, it is not necessary to begin with lines 22, 23, and 24 of Table 4, which are duplicated in lines 4, 5, and 6 of Table 5. If a solution of any set of equations is known—from some previous computation or in any other way—it can be varied to any other set of equations desired. "Knowing a solution" means that the "variation coefficients"—which result from solving the equations for a set of constants a, 0, 0; 0, b, 0; and 0, 0, c—are known. The process is the same for any number of unknowns.

Explanation of Table 5

Referring to Table 5, Eqs. 22 (lines 1, 2, and 3) are to be solved by a series of steps which is the reverse of that in Table 4. All the coefficients and parts of coefficients in brackets are considered removed, giving rise to the new set of equations:

$$\left.\begin{array}{lllr|c||c|c|c|} x & & & = & 28 & a & 0 & 0 \\ & y & & = & 26 & 0 & b & 0 \\ & & z & = & 49 & 0 & 0 & c \end{array}\right\}\ldots\ldots\ldots\ldots\ldots\ldots(26)$$

This new set of equations can obviously be solved by inspection; the solutions shown on lines 4, 5, and 6 are merely the repetition of Eqs. 26. To solve the original set of equations, it is necessary to vary the coefficients of this reduced set until all the coefficients and parts of coefficients which have been removed are replaced. By arbitrary choice and also to furnish a comparison between Table 5 and Table 4, the coefficients are varied in the order of x, y, and z.

To replace the coefficients of x, $d_1 = +3$, $d_2 = +1$, and $d_3 = +5$, since comparison of Eqs. 26 with lines 1, 2, and 3 in Col. 2 shows that these values are the coefficients and parts of coefficients which have been removed. Substitution in line 4 of $a = d_1 = +3$, $b = d_2 = +1$, and $c = d_3 = +5$ gives $x_d = +3$, since x has a value other than zero only when $c_n = a$.

From this point to the end of the computation the procedure is exactly similar to that used in Table 4 and needs no further explanation. The final solution is given on lines 22, 23, and 24.

Reciprocal Properties of Simultaneous Equations

For ready reference, and also to bring out certain relationships, the operations shown in Tables 4 and 5 have been summarized in Table 6. It is customary to consider x, y, and z as the unknowns and a, b, and c as the constants; that is, the equations would be set up on this basis in a practical problem. However, once the equations are solved—considering lines 1 to 6 of Table 6—it is equally correct, mathematically, to consider a, b, and c as the unknowns and x, y, and z as the constants.

From this point of view, considering a, b, and c as the unknowns, lines 1, 2, and 3 give the solutions for the equations on lines 4, 5, and 6. To illustrate: Substitution in line 4 of the values $a = 4x$, $b = x$, and $c = 5x$, for example, gives $\frac{2}{7}(4x) - \frac{2}{9}(x) + \frac{1}{63}(5x) = x$, which checks. Similarly, substitution at random (in line 5, for example) of $a = 28$, $b = 26$, and $c = 49$ gives $\frac{1}{7} \times 28 + \frac{2}{9} \times 26 - \frac{10}{63} \times 49 = 2$, which checks again.

It should be remembered that, after a variation operation is completed, the set of resulting equations with their solutions are complete in themselves. The equations may not be those that are finally desired, but they are nevertheless complete. It therefore follows that any set of equations is merely a stopping point in an endless series of variations. Lines 7, 8, and 9, for example, are the solutions for a set of equations in which the coefficient of z is zero in the first two and equals unity in the third, but which is otherwise the same as the original set on lines 1, 2, and 3 (Eqs. 23). Either x, y, and z or a, b, and c may be considered as the unknowns and if the corresponding solutions are substituted the results will check in the new equations.

The reciprocity of the equations plus the fact that at each step in a variation process the results are complete makes the operations self-checking. Furthermore, there are so many methods of checking that some of the checks may be used to reduce the numerical work and still leave a sufficient number for actual verification.

A consideration of the fundamental theory of equations will bring to light other ways of checking not mentioned. For example, the fact that rows and columns of determinants may be interchanged leads to the conclusion that other sets of equations exist which may be obtained by "rotating" the coefficients to positions consistent with the corresponding "rotated" determinants.

Furthermore, in a practical problem in structural analysis, most coefficients occur in pairs as a consequence of the Maxwell theorem of reciprocal deflections. The final "variation coefficients" also occur in pairs and in the same order as the coefficients of the unknowns—furnishing an automatic check, which may also have other uses besides checking.

An examination of Table 6(*c*) will show that, on any line, terms above the heavy line are merely repetitions of the terms on the line immediately above. It will also be noted that the values of the solution on line 24 are not needed until the last step, those on line 20 are not needed until the next to last step, and so on, if there are more than three equations. Furthermore, once a value appears in the computation, it must be revised at every subsequent step. Hence, if there were a method of obtaining these values at the time they are actually required for the next step, they could be omitted from all the previous computations, thus saving part of the work of revising them. This abbreviation can be achieved by using one of the checks to obtain the omitted values.

The revised variation operations illustrated in Table 7 show that there is a considerable saving in work even though it is partly offset by the necessity of making a substitution computation at every step in the process.

THEORY OF ABBREVIATED SOLUTION

The procedure followed in Table 5 for solving a set of simultaneous equations may be simplified by taking advantage of certain characteristics of this type of solution.

Reference to Eqs. 21*a* and 21*b* will show that u', the revised value of the unknown whose coefficients are being varied in the particular step or "variation" under consideration, is computed first and that it also enters in the formula for the revised values of the other unknowns. The term u' may thus be considered the critical one for its step. It will be shown that, in a sense, a solution reduces to the computation of critical values only—that is, values of the unknowns that have not been critical in previous steps, and that are also not critical in the step under consideration or in the one immediately following, need not be computed.

TABLE 6.—COMPARISON OF RESULTS OF TABLE 4 AND TABLE 5

Line No.	EQUATIONS IN x, y, AND z →				Constants		← EQUATIONS IN a, b, AND c

12.....	0	0	$[z]^b$	=	$+14$	=	$-\frac{5}{4}a$	0	c
13.....	(x)	0	0	=	$+28$	=	a	0	0
14.....	0	$[y]$	0	=	$+26$	=	0	b	0
15.....	0	0	$[z]$	=	$+49$	=	0	0	c

In Table 5, for example, the solutions on lines 16, 17, and 18 correspond to Eqs. 23, in which the values of x and y are obviously determined by the first two equations and are independent of the third. Mathematically, this fact becomes evident in the computation for x_a and y_a on lines 7 and 8, respectively, Table 5; that is, $c = d_3 = +5$ is substituted in lines 4 and 5, where it is multiplied by zero; d_3 is obviously the coefficient of x in the third of Eqs. 23. The corresponding result occurs in the computation for x_d and y_d in lines 13 and 14, wherein $c = d_3 = +2$ is multiplied by zero when substituted in lines 10 and 11; $d_3 = +2$ is obviously the coefficient of y in this same third equation.

27.....	0	0	(z)	=	$+5$	=	$-\frac{2}{7}a$	$+\frac{1}{9}b$	$+\frac{13}{63}c$

[a] (u) Unknown whose coefficients are being varied in step under consideration. [b] $[u]$ Unknown whose coefficients have been varied in previous steps.

Since the values of x and y are independent of the third of Eqs. 23, all the coefficients in this equation may be neglected in the computation up to this point. However, once x and y are known, the values of z can be computed from the third equation by direct substitution. It therefore follows that the values of z need not necessarily be computed in the previous steps. The values of z must be computed at this point, however, since the coefficients of z are varied in the next step of Table 5 and the critical value $u' = z'$ could not otherwise be computed.

Similarly, the solutions on lines 10, 11, and 12, Table 5, correspond to Eqs. 24, in which x is determined by the first equation and is independent of

the other two. Mathematically, this fact is again evident in the computation—the appropriate d_n-values are multiplied by zero in the computation for x_d. Hence, all the coefficients of the second and third equations may be neglected in the computation up to this point—that is, in the computation for $u' = x'$.

The values of both y' and z' may be computed by direct substitution, once x' is known. However, it is necessary to compute only the values of the unknown whose coefficients are to be varied in the next step—in this case y' is the next unknown to become critical. The revised values of z can be computed later, as already explained.

The abbreviated procedure may now be summarized. In Table 7, lines 1, 2, and 3, all the coefficients below the lower heavy line in each column may be neglected in each step or "variation." The values of u', which is critical, are computed by Eq. 21*a*; the values of v', corresponding to the unknowns whose coefficients have already been varied in previous steps, are computed by Eq. 21*b*; and the values of v', corresponding to the unknown whose coefficients are to be varied in the next step, are computed by direct substitution. The values of the remaining unknowns are neglected because they are not essential to the final solution, and are not computed until they are about to become critical in the step immediately following.

EXPLANATION OF TABLE 7

In Table 7, the order of variation of the coefficients is the same as in Table 5: x, y, and z.

In the first step, it is only necessary to use $d_1 = 3$, corresponding to $[3\,x]$ in line 1, Col. 2, as previously explained. With this exception, nothing new is presented by line 7, which gives the first revised value of x. The primes are omitted for simplicity—the x in line 7, for instance, is really x'. Since the solution in this step will correspond to Eqs. 24, the values of y, which is critical in the next step, may be computed from the second of these equations—$y = c_2 - x$.

Values of x on line 7, Cols. 5, 6, and 7 subtracted from the corresponding values on line 2 result in the revised values of y in line 8. As previously explained, it is not essential to compute the revised values of z at this point.

In the second step, variation of the coefficients of y, it is only necessary to use $d_1 = +3$ and $d_2 = +3$. With this exception, the computations on lines 9 and 10, and lines 14 and 15 present nothing new. Since the solution in this step will correspond to Eqs. 23, the values of z can be computed from the third of these equations—$z = c_3 - (+5\,x + 2\,y)$. The quantities in parentheses are computed on lines 11 and 12 and are summed up on line 13. Subtraction of the values on line 13 from the corresponding values on line 3, Cols. 5, 6, 7, and 8, gives the revised values of z on line 16.

The third and last step presents nothing new since d_1, d_2, and d_3 are used and there is no substitution to be made; the last variation in Table 7 is exactly the same as that in Table 5.

MULTIPLE VARIATION

If the number of unknowns is large, the solution still requires considerable work—there will be as many steps or variation operations as there are unknowns. A further simplification is possible in such a case. If the coefficients of two or more unknowns are varied at the same time, an auxiliary set of simultaneous equations must be solved. If the coefficients of all the unknowns were varied simultaneously, for instance, the auxiliary equations would simply be a repetition of the original equations. However, since it is fairly easy to solve a set of two or even three equations, it does save considerable work to vary two or three unknowns at a time. The result of such a procedure is, in effect, that one large set of equations is broken up into several smaller sets. It is well known that, when a similar situation occurs in an analysis as the result of symmetry, the resulting equations are much easier to solve.

Referring to Eqs. 11, let it be supposed that the coefficients A_1, A_2, and A_3 are to be increased by d_1, d_2, and d_3, respectively, as before. In addition, however, the coefficients B_1, B_2, and B_3 also are to be increased by amounts e_1, e_2, and e_3, respectively. Following the same procedure used for varying the coefficients of only one unknown:

$$\left.\begin{aligned} a &= K_1 - d_1 x' - e_1 y' \\ b &= K_2 - d_2 x' - e_2 y' \\ c &= K_3 - d_3 x' - e_3 y' \end{aligned}\right\} \qquad (27)$$

Substituting these values in line 4, Table 3, gives

$$\begin{aligned} x' = a_1(K_1 - d_1 x' - e_1 y') &+ a_2(K_2 - d_2 x' - e_2 y') \\ &+ a_3(K_3 - d_3 x' - e_3 y') \end{aligned} \qquad (28a)$$

or

$$\begin{aligned} (1 + a_1 d_1 + a_2 d_2 + a_3 d_3)x' &+ (a_1 e_1 + a_2 e_2 + a_3 e_3)y' \\ &= a_1 K_1 + a_2 K_2 + a_3 K_3 \end{aligned} \qquad (28b)$$

Therefore,

$$(1 + x_d)x' + x_e y' = x \qquad (29)$$

Similarly, substitution of the values for a, b, and c, in line 5, Table 3, gives

$$y_d x' + (1 + y_e)y' = y \qquad (30)$$

and substitution in line 6 gives

$$z' = z - z_d x' - z_e y' \qquad (31)$$

To obtain x' and y', Eqs. 29 and 30 must be solved simultaneously; the values of z' are then computed directly from Eq. 31.

If there were more than three unknowns, the equations for the remaining ones would take the same form as Eq. 31; for example:

$$r' = r - r_d x' - r_e y' \qquad (32)$$

Generalizing,

$$(1 + u_d)u' + u_e w' = u \qquad (33a)$$

$$w_d u' + (1 + w_e)w' = w \qquad (33b)$$

$$v' = v - v_d u' - v_e w' \qquad (34)$$

in which both u and w represent the unknowns whose coefficients are being varied, and e_n is the amount by which each of the coefficients of w is being varied. The notation is otherwise the same as that of Eqs. 21*a* and 21*b*, and the primes have the same meaning.

Revised values of the unknowns whose coefficients are being varied simultaneously are computed by solving an auxiliary set of simultaneous equations such as Eqs. 33. The remaining unknowns are then computed by Eq. 34. Eqs. 33*a*, 33*b*, and 34 can obviously be extended to include the simultaneous variation of any number of unknowns and the solution of a large set of simultaneous equations can thus be broken up into the solution of several smaller sets. The optimum number of simultaneous variations is more or less a matter of individual preference. The procedure is illustrated in Table 8 for a set of four equations split into pairs of two each.

Explanation of Table 8

The procedure for the variation of the coefficients of more than one unknown at one time is similar, in general, to that illustrated in the previous tables for variation of the coefficients of only one unknown.

In Table 8, the set of four equations—

$$\left.\begin{array}{r} +\,10\,w + 9\,x + 8\,y + 7\,z = \\ +\;\;9\,w + 6\,x + 5\,y + 4\,z = \\ +\;\;8\,w + 5\,x + 3\,y + 2\,z = \\ +\;\;7\,w + 4\,x + 2\,y + \;\;z = \end{array} \begin{array}{|r||c|c|c|c|} 114 & a & 0 & 0 & 0 \\ 76 & 0 & b & 0 & 0 \\ 53 & 0 & 0 & c & 0 \\ 39 & 0 & 0 & 0 & f \end{array}\right\}\cdots\cdots\cdots(35)$$

—is broken up into a pair of sets with two unknowns each, as indicated by the heavy lines in lines 1 to 4, Cols. 2 to 5. Since Table 8 illustrates a solution, the procedure and abbreviations of Table 7, suitably modified, are also used in Table 8.

Remembering that Eqs. 33*a*, 33*b*, and 34 are used instead of Eqs. 21*a* and 21*b*, reference to Table 7 will clarify the work in Table 8. Coefficients below the lower heavy line, for example, are omitted from the variation computations in both cases for reasons previously explained. However, since two sets of coefficients are being varied in the same step, the numerical equivalents of Eqs. 33 are shown in lines 9 and 10. These two auxiliary equations are solved simultaneously by inspection—as will be explained later—and the result is given in lines 11 and 12. Since the coefficients of both x and y are to be varied in the next step, their revised values are obtained at this point by direct substitution as shown in lines 13 to 16, and lines 19 and 20. It happens that there are no other unknowns, but if there were, their revised values would not have to be computed at this point; they can be computed later by direct substitution when needed. The complete solution for the first step is shown in lines 17 to 20.

The next step is similar: The auxiliary equations are shown in lines 21 and 22, their solution (by inspection) in lines 24 and 25, and part of the numerical equivalents of Eq. 34 in lines 30 and 31. The final solution for this step, which is the last of this computation, is shown in lines 32 to 35. Since this is the last step and there are no other unknowns, there is no direct substitution to be made.

An over-all check of the entire computation may be made by adding the four equations on lines 1 to 4, Table 8, and substituting, in the resulting equation, the sum of the solutions on lines 32 to 35, Table 8, setting $a = b = c = f = 1$. For example, $w = 2 - \frac{1}{2} + \frac{1}{2} + \frac{3}{2} - \frac{3}{2} = 2$, as shown in line 1, Col. 8, Table 9. The result of this substitution (line 5, Col. 7, Table 9) should equal the sum of the constants in lines 1 to 4, Table 8 (again setting $a = b = c = f = 1$), all as shown on lines 1 to 5, Table 9.

TABLE 9.—CHECK FOR SOLUTION OF EQS. 35 BY MULTIPLE VARIATION

Line No. (1)	(2)	(3)	(4)	(5)		(6)	(7)	Substitution factors (8)

3.......			$18y$		=	+90	+54	$y = 5$
4.......				$14z$	=	+56	+40	$z = 4$
5.......						+286	+286	$a = b = c = f = 1$
6.......			c		=	+71	+3	$c = +71$
7.......				$-f$	=	−53	+4	$f = +53$
8.......						+18	+5	$w = x = y = z = 1$
9.......							+6	
10......							+18	

The over-all check on lines 6 to 10, Table 9, is similarly made by considering a, b, c, and f as the unknowns and setting $w = x = y = z = 1$; that is, lines 32 to 35, Table 8, are considered as the simultaneous equations, with lines 1 to 4, Table 8, as the solutions.

As previously stated, the solutions of the auxiliary equations on lines 11 and 12, and on lines 24 and 25, Table 8, may be found practically by inspection. Considering a set of simultaneous equations such as is given in lines 1 to 4, Table 8, and its solutions on lines 32 to 35, it can be shown that the determinant formed from the coefficients of a, b, c, and f on lines 32 to 35 is the reciprocal of the determinant formed from the coefficients of w, x, y, and z on lines 1 to 4. Either determinant can be obtained from the other. An element a_{mn} of one determinant is equal to the cofactor of the element b_{nm} of the other determinant divided by the value of the latter determinant. The cofactors of a second order determinant are simply elements—in each case, simply the element not crossed out. It is also a simple matter to find the value of the determinant itself. The solution of the auxiliary equations can therefore be found practically by inspection.

As an illustrative example, reference is made to lines 9 and 10, Table 8, where the determinant formed by the coefficients of the auxiliary equations is: $\begin{vmatrix} 10 & 9 \\ 9 & 6 \end{vmatrix}$. The value of this determinant is $(10 \times 6) - (9 \times 9) = -21$.

The cofactor of the element 10 (which is a_{11}) is 6, and the element b_{11} of the reciprocal determinant is therefore $-\frac{6}{21} = -\frac{2}{7}$. The cofactor of a_{12}, or 9, is -9; the element b_{21} is $+\frac{3}{7}$; etc. The reciprocal determinant is, therefore, $\begin{vmatrix} -\frac{2}{7} & +\frac{3}{7} \\ +\frac{3}{7} & -\frac{10}{21} \end{vmatrix}$. The elements of this determinant are the variation coefficients on lines 11 and 12, Cols. 7 and 8.

The values shown in parentheses in lines 24 and 25, Cols. 9 and 10, are similarly obtained from the determinant formed from the coefficients on lines 21 and 22, Cols. 4 and 5.

In both cases, the other values are obtained by using the variation coefficients to obtain other solutions. For example, the set of constants from lines 21 and 22, Col. 8 (that is— $-22\,b$ and $-23\,b$), are substituted for c in line 24, Cols. 9 and 10. Thus, $y' = \left(-\frac{29}{42}\right)(-22\,b) + \frac{25}{42}(-23\,b) = +\frac{3}{2}\,b$, which is the value of y' in line 24, Col. 8. The primes are not indicated in Table 8 for simplicity.

Similarly, substitution of the constants -217 and -245 for c, line 25, gives $z' = +\frac{25}{42}(-217) + \left(-\frac{23}{42}\right)(-245) = +5$, which is the value of z' in line 25, Col. 6. The other values are computed in similar manner.

It will be noticed that the coefficients on lines 1 to 4, Table 8, occur in pairs, as they would in a practical design problem as a result of the Maxwell theorem of reciprocal deflections. The variation coefficients, lines 32 to 35, also occur in pairs and in the same order.

ACCURACY OF COMPUTATIONS

In practical design, the question of the number of significant digits to which the computations must be carried is a difficult one to determine. It is, however, a very important consideration from the point of view of time. The method of variation of coefficients makes the determination of the required accuracy a simple matter.

DISCUSSION

T. F. HICKERSON,[2] M. ASCE.—This interesting paper is presented elaborately and clearly, except in certain instances where the author generalizes rather abruptly while introducing a multiplicity of unfamiliar symbols.

Two sets of simultaneous equations will be solved independently with a twofold purpose—(1) to help elucidate inductively the application of the author's key formulas and (2) to make comparisons of the relative advantages claimed by the author. Of the so-called classical methods the writer would eliminate determinants and include only the method of successive elimination by addition or subtraction after the coefficients of each unknown, in turn, have been made equal by multiplication or division—as was done in Table 1.

The solution of the set of three equations (Eqs. 22) given in Table 10 is believed to be self-explanatory. Anticipating a later variation of the coefficients, the letters a, b, and c are used here in a manner similar to that in Table 4. It will be seen that the equations are not renumbered when multiplied, or divided by any quantity, because in effect they are unchanged. Thus,

$$4\,x + 3\,y + 2\,z = 28 = a \tag{36a}$$

is equivalent to

$$12\,x + 9\,y + 6\,z = 84 = 3\,a \tag{36b}$$

In Table 10, let the coefficients of z in (1), (2), and (3) (Eqs. 22) be reduced by 2, 3, and 5, respectively, as was done in Table 4. Then a, b, and c will be replaced by $(a - 2\,z')$, $(b - 3\,z')$, and $(c - 5\,z')$, respectively. Hence, z', the revised value of z, becomes

$$z' = -\frac{2}{7}(a + 2\,z') + \frac{1}{9}(b + 3\,z') + \frac{13}{63}(c + 5\,z') \tag{37a}$$

Rearranging terms,

$$z' + \left[\frac{2}{7}(2) - \frac{1}{9}(3) - \frac{13}{63}(5)\right] z' = -\frac{2}{7}a + \frac{1}{9}b + \frac{13}{63}c \tag{37b}$$

It must be seen that the right side of Eq. 37*b* represents z (= 5), the initial (unrevised) value of z; the expression in the brackets equals z'_d and is comparable to x_d in Eq. 15*b*, the numerical value of which is $-\frac{50}{63}$, as given in Col. 12, line 9, Table 4. By factoring Eq. 37*b*, and solving for z', $z' = \dfrac{5}{1 + \dfrac{50}{63}}$ (see Eq. 21*a*) $= \frac{315}{13}$, as recorded in Col. 5, line 12, Table 4.

---

[2] Prof. of Applied Mathematics, Univ. of North Carolina, Chapel Hill, N. C.

To determine the corresponding revised values of x (designated x') due to the variation in the three coefficients of z, $x' = \frac{2}{7}(a + 2z') - \frac{2}{9}(b + 3z') + \frac{1}{63}(c + 5z') = x - \left(-\frac{4}{7} + \frac{2}{3} - \frac{5}{63}\right)z' = 3 - \left(\frac{1}{63}\right)\left(\frac{315}{13}\right) = \frac{34}{13}$, as

TABLE 10.—WORK SHEET FOR SOLUTION OF EQS. 22

Equation	x	y	z	Constant term
(1)	4	3	2	$= 28 = a$
(2)	1	4	3	$= 26 = b$
(3)	5	2	6	$= 49 = c$
(1)	12	9	6	$= 84 = 3a$
(2)	2	8	6	$= 52 = 2b$
(4)	7	7	0	$= 35 = 3a - c$
(5)	10	1	0	$= 32 = 3a - 2b$
(4)	1	1		$= 5 = \frac{3}{7}a - \frac{1}{7}c$
(6)	9	0		$= 27 = \frac{18}{7}a - 2b + \frac{1}{7}c$
(6)	1 (x)			$= [3] = \frac{2}{7}a - \frac{2}{9}b + \frac{1}{63}c$
(4)		1 (y)		$= [2] = \frac{1}{7}a + \frac{2}{9}b - \frac{10}{63}c$
(1)			1 (z)	$= [5] = -\frac{2}{7}a + \frac{1}{9}b + \frac{13}{63}c$

Check: $x + y + z = 10 = \frac{1}{7}a + \frac{1}{9}b + \frac{4}{63}c = \frac{28}{7} + \frac{26}{9} + \frac{4 \times 49}{63} = 10$

TABLE 11.—WORK SHEET FOR SOLUTION OF EQS. 35

Equation	w	x	y	z	Constant term
(1)	10	9	8	7	$= 114 = a$
(2)	9	6	5	4	$= 76 = b$
(3)	8	5	3	2	$= 53 = c$
(4)	7	4	2	1	$= 39 = f$
(1)	10	9	8	7	$= 114 = a$
(2)	15.75	10.5	8.75	7	$= 133 = 1.75b$
(3)	28.0	17.5	10.5	7	$= 185.5 = 3.5c$

(5)	−5.75	−1.5	−0.75	0	$= -19.0 = a - 1.75b$
(6)	−12.25	−7.0	−1.75	0	$= -5.25 = 1.75b - 3.5c$
(7)	−21.0	−10.5	−3.5	0	$= -87.5 = 3.5c - 7.0f$
(5)	7.667	2.0			$= 25.333 = -1.333a + 2.333b$
(6)	7.0	4.0	1		$= 30.0 = -b + 2c$
(7)	6.0	3.0	1		$= 25.0 = -c + 2f$
(8)	0.667	−2.0	0		$= -4.667 = -1.333a + 3.333b - 2c$
(9)	1.0	1.0	0		$= 5.0 = -b + 3c - 2f$
(8)	0.333	−1.0			$= -2.333 = -0.667a + 1.667b - c$
(10)	1.333	0			$= 2.667 = -0.667a + 0.667b + 2c - 2f$
(10)	1 (w)				$= [2] = -0.5a + 0.5b + 1.5c - 1.5f$
(9)		1 (x)			$= [3] = 0.5a - 1.5b + 1.5c - 0.5f$
(7)			1 (y)		$= [4] = 1.5a + 1.5b - 14.5c + 12.5f$
(4)				1 (z)	$= [5] = -1.5a - 0.5b + 12.5c - 11.5f$

Check: $w + x + y + z = 14 = c - f = 53 - 39 = 14$

recorded in Col. 5, line 10, Table 4. Likewise, $y' = \frac{1}{7}(a + 2z') + \frac{2}{9}(b + 3z') - \frac{10}{63}(c + 5z') = y - \left(-\frac{2}{7} - \frac{2}{3} + \frac{50}{63}\right)z' = 2 - \left(-\frac{10}{63}\right)\left(\frac{315}{13}\right) = \frac{76}{13}$, as recorded in Col. 5, line 11, Table 4. The revision due to the variation of the coefficients of z alone is now complete, and the revised set of equations is given by Eqs. 23. The variation will not be continued as was done by the author in Table 4. Instead of breaking the four equations (Eqs. 35) into a pair of sets with two unknowns each, as is indicated in Table 8, the classical method is applied for purposes of comparison (Table 11).

TABLE 12.—WORK SHEET FOR SOLUTION OF EQS. 35 AND THE REVISION —WHEN THE COEFFICIENTS OF w ARE VARIED

Equation	w	x	y	z	Constant
(1)	10 (8)	9	8	7	= 114
(2)	9 (7)	6	5	4	= 76
(3)	8 (6)	5	3	2	= 53
(4)	7 (5)	4	2	1	= 39
(1)	10 (8)	9	8	7	= 114
(2)	15.75 (12.25)	10.5	8.75	7	= 133
(3)	28.0 (21.0)	17.5	10.5	7	= 185.5
(4)	49.0 (35.0)	28.0	14.0	7	= 273.0
(5)	−5.75 (−4.25)	−1.5	−0.75	0	= − 19.0
(6)	−12.25 (−8.75)	−7.0	−1.75	0	= − 5.25
(7)	−21.0 (−14.0)	−10.5	−3.5	0	= − 87.5
(5)	7.667 (5.667)	2.0	1		= 25.333
(6)	7.0 (5.0)	4.0	1		= 30.0
(7)	6.0 (4.0)	3.0	1		= 25.0
(8)	0.667 (0.667)	−2.0	0		= − 4.667
(9)	1.0 (1.0)	1.0	0		= 5.0
(8)	0.333 (0.333)	−1.0			= − 2.333
(10)	1.333 (1.333)	0			= 2.667
(10)	1 (w)				= 2.0 [2.0]
(9)		1 (x)			= 3.0 [3.0]
(7)			1 (y)		= 4.0 [8.0]
(4)				1 (z)	= 5.0 [1.0]

Check: $26w + 24x + 18y + 14z = 282$ and $52 + 72 + 144 + 14 = 282$

Omitting a, b, c, and f would shorten the work 50% or more, hence at least one of the coefficients may be varied and the corresponding equations resolved before starting the computation of the conversion factors proposed by the author. This point is illustrated in Table 12, in which varied coefficients of w and values of the constants are shown in parentheses. If, however, the constants are to be varied while the coefficients remain fixed—that is, if the loading conditions are varied while the framework remains unchanged—it is advantageous to exprdss the values of w, x, y, and z in terms of a, b, c, and f.

A. FLORIS,[3] ESQ.—The proposed method of solving simultaneous equations is a modification of the process of successive elimination of unknowns. This is clearly seen from the "Remarks" in Col. 7, Table 1. From a practical point of view the author's method is of value only if a numerical error has been made in the statical analysis, necessitating the change of one or several coefficients of the unknowns. Hence, it is of restricted usefulness in the design of structures, since a change in the shape will require changing all the coefficients of the unknowns, including the terms that depend on the loading.

---

[3] Los Angeles, Calif.

The method presented is not readily adapted to the solution of ill-conditioned equations; that is, equations in which different values for the unknowns can be obtained that will satisfy the equations.

The following equations, given by T. S. Wilson,[4] are cited as examples:

$$5x + 7y + 6z + 5u = 23 \tag{38a}$$

$$7x + 10y + 8z + 7u = 32 \tag{38b}$$

$$6x + 8y + 10z + 9u = 33 \tag{38c}$$

and

$$5x + 7y + 9z + 10u = 31 \tag{38d}$$

The exact values of the unknowns in Eqs. 38 are

$$x = y = z = u = 1 \tag{39}$$

There are other solutions besides Eq. 39, however, as may be demonstrated by substituting the following three sets of values, successively, in Eqs. 38:

x	y	z	u
14.6	−7.2	−2.5	3.1
2.36	0.18	0.65	1.21
1.136	0.918	0.965	1.021

The result is three additional values for the right-hand side of Eq. 39, as follows:

Eq. 38a	Eq. 38b	Eq. 38c	Eq. 38d
23.1	31.9	32.9	31.1
23.01	31.99	32.99	31.01
23.001	31.999	32.999	31.001

Similar cases of ill-conditioned equations also can be found among those amenable to iteration.

FREDERICK S. MERRITT,[5] ASSOC. M. ASCE.—The writer has used the method of variation of coefficients on several occasions for solving the simultaneous linear equations arising in engineering practice. As a result of this experience, he has reached the conclusion that the method is especially well adapted for the purpose.

In the linear equations encountered in structural engineering, for example, the coefficients of the unknowns on the left side of the equation are generally functions of the dimensions of the structure and the constant terms on the right side are usually functions of the magnitude and position of the load. Classical methods of solution may readily be applied when the coefficients and the constants are unchanged, or even when the constants have several sets of values. However, when any of the coefficients are changed, say, because of change in the dimensions of a part of the structure, classical methods leave no recourse other than to re-solve the equations. On the other hand, the method of variation of coefficients makes it possible to eyaluate, directly, the effect of a change in the coefficients.

[4] "The Escalator Method in Engineering Vibration Problems," by Joseph Morris, John Wiley & Sons, Inc., New York, N. Y., 1947, p. 42.

[5] Associate Editor, *Engineering News-Record*, New York, N. Y.

I. F. MORRISON,[6] ESQ.—In this interesting paper the author has developed a systematic method for the solution of simultaneous linear equations which offers "several marked advantages over the classical methods" without specifying which of the several classical methods. The method developed in the paper somewhat resembles the Doolittle method, which is a modification of the method developed by C. F. Gauss. The writer has always found this to be a most satisfactory method for the solution of such equations. It is certainly classical. In so far as he is aware, no difficulty concerning the small difference of quantities arises, as it so often does in the classical Cramer method. The introduction of the idea of a change in some of the coefficients is novel and of merit. The method developed in the paper possesses the advantages inherent in all well-planned computation procedure.

In the analysis of any structure, indeterminate to the nth degree, a set of simultaneous linear equations eventually must be solved in one way or another. Even the modern relaxation methods are simply a way of doing this. These equations may be written in condensed form as

$$a\,x = C \dots\dots\dots\dots (40)$$

in which a is a square matrix of order n, based solely on the size, shape, and elastic properties of the structure; in fact, it may be said to represent the structure in mathematical form. The elements of this matrix, a_{ij}, are most conveniently computed numerically from assumed self-stressed conditions. The elements of x, which is a column matrix, are the redundants—that is, the unknown thrusts, moments, shears, etc., which are sought.

The elements of C, also a column matrix, are the loading terms. They depend on the loads and the structure but, nevertheless, are independent of a. They may be changed to meet any number of local requirements.

The solution of Eq. 40 is

$$x = a^{-1}\,C \dots\dots\dots\dots (41)$$

and since a^{-1} is not dependent on C, it will be constant for all loadings provided there be no change in a.

The paper presents the following mathematical problem: Given a set of simultaneous equations in the form of Eq. 40, in which the symbols represent matrices, which have been solved for x, it is required to find from that solution what new values of x (say, x') will result from a change of the matrix a into $[a + b]$. The assumed solution of Eq. 40 is given by Eq. 41, which presupposes that a^{-1} is known. According to the conditions of the problem,

$$[a + b]\,x' = C = a\,x \dots\dots\dots\dots (42a)$$

which, multiplied through by a^{-1}, becomes

$$a^{-1}\,[a + b]\,x' = [I + a^{-1}\,b]\,x' = x \dots\dots\dots\dots (42b)$$

In Eq. 42b, I is the unit matrix. To solve Eq. 42b, multiply through by $[I + a^{-1}\,b]^{-1}$, so that,

$$x' = [I + a^{-1}\,b]^{-1}\,x \dots\dots\dots\dots (43)$$

In this solution, all the factors on the right-hand side are known so that x' is determined from the original x.

---

[6] Prof. of Applied Mechanics, Dept. of Civ. and Municipal Eng., Univ. of Alberta, Edmonton, Alberta, Canada.

By way of further explanation, it should be mentioned that the reciprocal matrix is best determined by finding the adjoint of the matrix and dividing by the determinant of the matrix. Thus, Eq. 43 may be written

$$x' = \frac{\text{adjoint}\ [I + a^{-1}\, b]}{|I + a^{-1}\, b|}\, x \ldots\ldots\ldots\ldots\ldots\ldots (44)$$

The adjoint A of a matrix a is another matrix of the same order in which the element a_{ij} is the cofactor of the element a_{ji}. The cofactor of a_{ji} is $(-1)^{i+j}$ times the $(n - 1)$-row determinant obtained by striking out row j and column i of $|a|$. It is not necessary to work out the value of the determinant because, if one multiplies the first row of the matrix by the first column of the adjoint, the result is the numerical value of the determinant. It is advisable to avoid large determinants.

In the first example (which, of course, has been chosen for simplicity), $a = \begin{bmatrix} 4 & 6 \\ 2 & 5 \end{bmatrix}$; $b = \begin{bmatrix} 3 & 0 \\ 0 & 0 \end{bmatrix}$; $a^{-1} = \frac{1}{8}\begin{bmatrix} 5 & -6 \\ -2 & 4 \end{bmatrix}$; and $x = \begin{bmatrix} 3 \\ 5 \end{bmatrix}$. According to the foregoing theory,

$$a^{-1}\, b = \frac{1}{8}\begin{bmatrix} 5 & -6 \\ -2 & 4 \end{bmatrix}\begin{bmatrix} 3 & 0 \\ 0 & 0 \end{bmatrix} = \frac{1}{8}\begin{bmatrix} 15 & 0 \\ -6 & 0 \end{bmatrix}$$

$$I + a^{-1}\, b = \frac{1}{8}\begin{bmatrix} 23 & 0 \\ -6 & 8 \end{bmatrix}$$

and

$$[I + a^{-1}\, b]^{-1} = \begin{bmatrix} \frac{8}{23} & 0 \\ \frac{6}{23} & 1 \end{bmatrix}$$

Thus,

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \frac{8}{23} & 0 \\ \frac{6}{23} & 1 \end{bmatrix}\begin{bmatrix} 3 \\ 5 \end{bmatrix} = \begin{bmatrix} \frac{24}{23} \\ \frac{133}{23} \end{bmatrix}$$

These results check those given in the paper. The first row of a-values multiplied by the first column of the cofactor of a^{-1} is 8, which is the value of the determinant $\begin{vmatrix} 4 & 6 \\ 2 & 5 \end{vmatrix}$.

The foregoing theory is quite general, however. Suppose, for example, all the elements of the original matrix are changed so that $b = \begin{bmatrix} 1 & -1 \\ -3 & 2 \end{bmatrix}$; and let the other data remain the same. Then,

$$a^{-1}\, b = \frac{1}{8}\begin{bmatrix} 5 & -6 \\ -2 & 4 \end{bmatrix}\begin{bmatrix} 1 & -1 \\ -3 & 2 \end{bmatrix} = \frac{1}{8}\begin{bmatrix} 23 & -17 \\ -14 & 10 \end{bmatrix}$$

$$I + a^{-1}\, b = \frac{1}{8}\begin{bmatrix} 32 & -17 \\ -14 & 18 \end{bmatrix}$$

$$[I + a^{-1}\, b]^{-1} = \frac{1}{40}\begin{bmatrix} 18 & 17 \\ 14 & 31 \end{bmatrix}$$

and

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \frac{1}{40}\begin{bmatrix} 18 & 17 \\ 14 & 31 \end{bmatrix}\begin{bmatrix} 3 \\ 5 \end{bmatrix} = \begin{bmatrix} \frac{139}{40} \\ \frac{197}{40} \end{bmatrix}$$

Referring to Eqs. 22 of the paper,

$$\text{Adjoint}\begin{bmatrix} 4 & 3 & 2 \\ 1 & 4 & 3 \\ 5 & 2 & 6 \end{bmatrix} = \begin{bmatrix} 18 & -14 & 1 \\ 9 & 14 & -10 \\ -18 & 7 & 13 \end{bmatrix}$$

from which the reciprocal matrix and solution of the equations can be written immediately.

Whether this general method offers any advantage over a direct solution starting fresh with the revised, or new, matrix is open to doubt. The author has developed a step-by-step process, in work sheet form, which provides periodic checks. It is likely that this method will possess a definite advantage, especially for those not familiar with matrix calculations. For large sets of equations the method of submatrices[7] will be found very useful.

The author has correctly stated that in structural analysis certain coefficients occur in pairs. For any structure, the analysis of which is based on the assumption of Hooke's law, the matrix a, as a consequence, will always be symmetrical. This fact affords a check on computations because the reciprocal matrix a^{-1} will also be symmetrical. Moreover, the product of row 1 of a by column 1 of a^{-1}, row 2 by column 2, etc., will always be one; and row 1 by column 2, etc., will be zero. This affords a check on the computation of the reciprocal matrix.

SIGMUND ROOS,[8] M. ASCE.—The need for an efficient method of solving simultaneous linear equations is of primary importance in all fields of engineering. The method of variation of coefficients presented in this paper was developed for use in solving the equations encountered in structural engineering work, but it can be used for other equations to great advantage. The method is applied easily and gives exact answers rapidly.

The author is to be commended highly for his work, as he has employed the principles of advanced mathematics to formulate procedures which may be used without knowledge of the underlying mathematics. In this connection, it is suggested that the author add to his closing remarks a rigorous mathematical proof of the method. More engineers would be inclined to use the method if they knew its scientific basis.

It is difficult to make comparisons between the present paper and others that go so far toward satisfying a universal need among all engineers. In the field of structural engineering, however, it will be found that Mr. Weiner's paper has certain distinct advantages. It can be checked at each step and it can be adjusted easily to changes in design.

---

[7] "Some Devices for the Solution of Large Sets of Simultaneous Linear Equations," by W. J. Duncan, *Philosophical Magazine*, Vol. 35, 1944, p. 660.

[8] Structural Engr., Clarke, Rapuano and Holleran, Cons. Engrs., New York, N. Y.

It is the last mentioned feature of the method of variation of coefficients which makes this method particularly attractive. A system of equations which represents the geometric and elastic properties of a statically indeterminate structure may undergo considerable variation as the problems of design and detail are more completely studied. Minor changes of any one member or group of members of a continuous framework usually have an insignificant effect on the entire structure. An experienced designer knows the limits within which the length and cross section of a member can be varied without changing the elastic properties of the structure as a whole. Nevertheless, these limits are often exceeded, and the present method provides a quick procedure of accurately determining the resultant effects without resolving the entire system of equations. The writer has found the method of variation of coefficients to be a remarkably efficient tool for this purpose. In one case, it was found that, when the foundations for a rigid frame bridge were excavated, the elevation of rock was considerably lower than indicated on the boring record. The necessary adjustments in design were easily performed by using the method presented in this paper.

The method also presents a possibility not mentioned by the author, in that it is possible to use this method for the direct design of statically indeterminate structures. If one frame of a group of similar frames is designed, the other frames may be designed directly by merely varying the coefficients of the system of equations for the first frame.

In addition, the method of variation of coefficients possesses a very dynamic quality. Any system of equations can be extended far beyond the original conditions, thus giving the user great freedom of action. For these reasons, many new and important applications will undoubtedly be found as the method is used.

Bernard L. Weiner,[9] M. ASCE.—It is unfortunate that most of the discussers have stressed only one feature of the paper—the application of the theory to the solution of simultaneous equations—and have compared the method of solution by the variation of coefficients with other methods. The writer has never felt this application to be the salient feature of the theory. In fact, the theory was developed by the writer when it was necessary to find some way of correcting several errors in coefficients in a rather complicated analysis when there was insufficient time to re-solve the equations with the corrected coefficients. Application of the theory to the solution of equations came later as a rather obvious corollary.

As far as the solution of equations is concerned, comparisons may be made between the method of varying coefficients and other methods—both new and old. However, as far as the writer knows, there is no other method for finding the effect on the values of the unknowns resulting from a change in the coefficients—excepting, of course, the obvious one of re-solving the equations. It is well known that the analysis of statically indeterminate structures consists of the process of assuming the sizes of the various members—either from previous experience or from preliminary approximate designs—and then analyzing the structure to check the adequacy of the assumed sizes. If the designer is either sufficiently experienced, or lucky, his first assumption may be close enough for design purposes. However, should he find that his "guesses" are too far off, he must run another complete check analysis to test the revised sections.

---

[9] Associate Engr., D. B. Steinman, Cons. Engr., New York, N. Y.

With the method presented in this paper, the effect of the changes can be determined without going through an entirely new analysis. For frames and other structures in which the moments are large in comparison to the thrust—that is, in which the thrust has a large eccentricity—rather drastic changes may be made in the sections without seriously affecting the value of the redundants. However, in arches and other structures in which the thrust has a small eccentricity, the stresses are sensitive to changes in section and a check analysis becomes imperative. Variation of coefficients is a valuable tool in such cases.

However, in most instances, even if the designer finds that his first assumption of member sizes is sufficiently close, he cannot be sure that he has achieved the maximum in economy unless he tries to change sizes to achieve a net reduction in material. This, of course, involves changing the coefficients. Such studies, in which the number of redundants is large, are too time consuming to permit anything more than a very rough and inadequate investigation if the equations are re-solved for every change.

The writer believes that this application of the paper is its most important feature. Although it is believed that the theory offers many advantages in its application to the solution of equations, there are other methods. The fact remains, however, that variation of coefficients is the only known quick method for making the investigations previously described.

It is to be noted that, for the variation of any number of the coefficients of one unknown, only two simple formulas are necessary for the application of the theory. The factors such as u_d and v_d are actually solutions of the equations for a set of constants $c_n = d_1, d_2, d_3, \cdots, d_n$. Hence, no cumbersome formulas are necessary for their evaluations. This fact makes the theory easy to apply and the procedure also lends itself readily to work sheet form.

The writer disagrees with Mr. Floris' comment that Col. 7, Table 1, headed "Remarks," proves that the method of variation of coefficients is a modification of the process of successive elimination of coefficients. Table 1 is merely introductory and its heading states that it gives the solution of Eqs. 2 by the process of elimination. The purpose of this table is to obtain a solution by any method whatever, in order to illustrate the properties of certain solutions—namely, solutions for the values of $c_n = a$, 0, 0; 0, b, 0; and 0, 0, c. Later in the paper, it is shown that these solutions can be used to obtain the necessary conversion factors for varying the coefficients and are therefore designated "variation coefficients."

Mr. Floris states that the theory is not readily adaptable to the solution of certain types of equations and gives Eqs. 38 as an example. These equations are rather "tricky" and their solution would be difficult by any method unless special devices were used. This situation occurs fairly often in computations when the equations under consideration approach certain limits. Under such conditions, if certain special methods are used, the solution becomes very simple—more simple, very often, than in more "normal" cases; if they are not used, the solution becomes very difficult. A common example is the problem of finding middle ordinates or tangent offsets to a circular arc with very large radius. The usual method of the difference of the squares becomes very cumbersome; successive approximations however make the solution very simple—so simple in fact that slide rule computations are often sufficiently accurate. If the radius is very large, even the first correction is small enough to be neglected.

Mr. Floris shows that Eqs. 38 have the solution $x = y = z = u = 1$, but states that they also have other solutions. He then gives a series of solutions and shows that substitution of these values in Eqs. 38 results in a series of constants on the right-hand side of the equations which differ only slightly from the original constants.

The writer must disagree with Mr. Floris' statement that Eqs. 38 are satisfied by more than one value for each unknown. The determinant formed from the coefficients of Eqs. 38 is equal to 1. Since this determinant does not equal zero, it follows from the theory of equations that there exists only one solution for each unknown for any given set of constants. In spite of the fact that the values of the constants given in the second set of numbers differ only slightly from the original values (23.1, 23.01, and 23.001 instead of the original 23, for example), these constants are not the same, as would be the case if it were merely a question of accuracy of computations. The values given are absolutely exact and are different sets of constants. The difficulty lies in the fact that the equations are nearly "parallel" to each other and are therefore sensitive to slight changes—in this region, at least.

If similar equations with only two unknowns were solved, the solution would represent the coordinates of the intersection of two straight lines. If these lines were nearly parallel, their intersection point would be very sensitive to the constants on the right-hand side of the equations. Properly transformed —as shown in analytical geometry—these constants could be made to represent the distance from the origin of the points where the lines intersect the x-axis. If the two lines were made more and more nearly parallel, a slight change in this distance for one of the lines would make a tremendous difference in the point of the intersection. A change of, say, one unit in this distance could be made to result in a change of a million units—or any other large number in the location of the point of intersection by making the lines sufficiently parallel to each other. If they were absolutely parallel, the change, of course, would be infinity.

This conclusion can readily be proved. If Eqs. 38 are solved for a set of constants,

$$c_n = 1, -1, -1, 1 \ldots\ldots\ldots\ldots\ldots\ldots (45)$$

the results are

$$x = 136, \quad y = -82, \quad z = -35, \quad \text{and} \quad u = 21 \ldots\ldots\ldots (46)$$

Mr. Floris' results for the new constants of Eqs. 38 can be obtained by superposition by combining the original constants with multiples of Eq. 45. Combining Eq. 39 with the same multiples of Eqs. 46, the corresponding new values for x, y, z, and u given by Mr. Floris can be obtained; for example, taking

0.1 of Eq. 45 and adding to the constants of Eqs. 38 gives: $23 + 0.1 = 23.1$; $32 - 0.1 = 31.9$; $33 - 0.1 = 32.9$; and $31 + 0.1 = 31.1$.

Taking 0.1 of Eqs. 46 and combining them with Eq. 39 gives: $x = 1 + 0.1 \times 136 = 14.6$; $y = 1 - 0.1 \times (-86) = -7.6$; $z = 1 + 0.1 \times (-35) = -2.5$; and $1 + 0.1 \times 21 = 3.1$.

The remaining values on the second and third lines of the two sets of numbers given by Mr. Floris may be similarly obtained by using factors 0.01 and 0.001, respectively, instead of the factor 0.1 used in this computation.

This computation clearly illustrates that Eqs. 38 can be solved for any set of constants and the solution will have only one value for each unknown. The method of variation of coefficients may be used as well as any other method. This example of "ill-conditioned equations," as Mr. Floris calls them, is susceptible to easy solution with the aid of special devices (as are other equations) when they approach certain limits which make them difficult to handle by "routine" computations.

The contention of Mr. Floris that variation of coefficients is of limited usefulness is contradicted by some of the other discussers, especially by Mr. Roos who tells of some applications of the theory to problems he has solved.

Professor Hickerson varies the coefficients of the writer's Eqs. 22 as illustrated in Table 4 by re-solving the equations by successive elimination of the unknowns. The work is illustrated in Table 10; and, by using a, b, and c for the constants in addition to the numerical values 28, 26, and 48, it is shown how the basic formulas (Eqs. 21) come into the computation. The letter constants, a, b, and c, give rise, of course, to the solutions designated by the writer as "variation coefficients." After completing the solution, this method leaves the computer no advantage whatever. He has to re-solve the equations once more for another variation—unless he takes advantage of the variation coefficients as explained in the paper.

Professor Hickerson also solves Eqs. 35, by successive elimination of the unknowns. The advantage of breaking up a large set of equations into smaller sets as was done by the writer is not apparent in this example for two reasons. Throughout the paper, simple numerical examples were chosen in order to illustrate principles, thus eliminating the distractions produced by the mechanical difficulty of handling large numbers. Secondly, four equations with four unknowns only begin to make the solution of such equations cumbersome. However, as the number of terms in a set of simultaneous equations is equal to the square of the number of unknowns, this number increases very rapidly. In larger sets of equations (equations with twelve and eighteen unknowns) the simplifications become very marked.

The writer notices that Professor Hickerson has omitted the "Remarks" column from his work sheets. The writer on numerous occasions has found this column invaluable and has been grateful to the unknown person who suggested its use. The writer agrees wholeheartedly with one of the other discussers (Professor Morrison) that systematic arrangement is the very essence of any computation. It not only helps eliminate errors, but also reduces the labor involved in any computation more than practically any other one single feature. The writer has made a statement (under the heading, "Introduction") to this effect in which it is also stated that the computation for multiple loading constants (such as influence lines) is no great hardship if the work is systematically arranged. The writer fails to see how anything but numerous loading conditions can be used in the design of modern structures.

Since the computation of variation coefficients is a simple matter if the work is systematically arranged, the device suggested by Professor Hickerson for varying the coefficients of at least one unknown by re-solving becomes unnecessary. In fact, the writer sees no need at all for re-solving the equations. That 50% or more of the work would be saved by omitting the constants *a*, *b*, and *c* is greatly to be doubted in view of the arguments previously given. The question whether or not to use *a*, *b*, *c*, $\cdots$, *n*, therefore becomes academic, and their use amounts to computing "variation coefficients." In any case, if the constants are "varied" (in Professor Hickerson's words) there is no problem—the procedure for accomplishing this is well known. If this were the only question involved, this paper would never have been written. If the coefficients are varied, there is a problem which this paper has attempted to solve. From either point of view, therefore, it is desirable to compute the variation coefficients.

Professor Morrison's discussion is very interesting from several points of view. Most important, in the writer's judgment, is the point which this discusser makes as to the value of a well-planned computation procedure.

It cannot be reiterated too often that, just as it is necessary to plan a construction job in the field, it is also necessary to plan the work in the office. It has been the writer's sad experience to have to wade through computations spread over innumerable pages, without page numbers, dates, or titles. The usual result is that such computations are worthless a week or even a day after they are made. They are unintelligible even to the computer—if he has not neglected to add his initials and can be identified. More often than not, such haphazard computations contain serious errors. Wherever possible, computations should be tabulated, thus saving much repetition of explanatory matter. Tabulated computations are concise, are easy to follow, save much labor, and reduce errors. If a series of results is in tabular form, an error can very often be detected simply by the fact that it looks erratic—out of proportion—when compared with similar results adjacent to it.

The writer notes that Professor Morrison considers the idea of a change in some of the coefficients as novel and of merit. To writer's knowledge, this idea is unique in the theory of this type of equations. Professor Morrison develops the fundamental mathematical basis of the paper by the use of matrix algebra and gives the final result in general terms in Eq. 44. It is well worth the effort to follow through this discussion in detail, but, as matrix algebra is not too familiar a subject, a simple explanation of the high lights—sufficient to enable one to follow Professor Morrison's mathematics—is readily available in a paper by Stanley U. Benscoter, Assoc. M. ASCE.[10]

Professor Morrison then proceeds to apply Eq. 44 to some of the problems worked out in the paper; in one case, he solves a problem in which he varies the coefficients of two unknowns. He admits, however, that it is open to doubt whether this general method has any advantage over the direct solution offered by the writer, and again calls attention to the fact that the method presented in the paper lends itself to a step-by-step process in work sheet form, always a distinct advantage in itself.

---

[10] "Matrix Analysis of Continuous Beams," by Stanley U. Benscoter, *Transactions*, ASCE, Vol. 112, 1947, p. 1109.

The writer, too, doubts that this general method based on matrix algebra has any advantages for numerical solutions. For research purposes, however, the method is invaluable. Every time a familiar analysis is studied from a new point of view or by another method of attack, the results will often appear in a new form, hitherto unknown. By making the proper algebraic or other mathematical transformations, the new form can always be converted to the more familiar forms, but a gain has nevertheless been made. Such studies are usually worth the effort.

For this reason, and also to anticipate a point raised by Mr. Roos, the writer has extended Professor Morrison's analysis (Eq. 44) to derive Eqs. 17, 19, and 20, which, when generalized, give Eqs. 21, the basic equations of the paper. Extending the analysis further, the writer has also derived the equations used in multiple variations (Eqs. 33 and 34).

A system of n equations with n unknowns takes the form:

$$\left.\begin{array}{l} a_{11}\,x + a_{12}\,y + a_{13}\,z + + + = c_1 \\ a_{21}\,x + a_{22}\,y + a_{23}\,z + + + = c_2 \\ a_{31}\,x + a_{32}\,y + a_{33}\,z + + + = c_3 \\ \cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot\;\cdot \\ a_{n1}\,x + a_{n2}\,y + a_{n3}\,z + + + = c_n \end{array}\right\} \dotfill (47)$$

It is desired to increase the coefficients of x by $d_1, d_2, d_3, \cdots, d_n$, respectively, and to find the resulting effect on all the unknowns.

For the present purpose, it will be sufficient to take three equations with three unknowns; the derivation will be exactly the same for any number of unknowns.

Referring to Eq. 44,

$$a = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} \dotfill (48)$$

$$a^{-1} = \frac{\text{adjoint } a}{a} = \frac{1}{a}\begin{vmatrix} A_{11} & A_{21} & A_{31} \\ A_{12} & A_{22} & A_{32} \\ A_{13} & A_{23} & A_{33} \end{vmatrix} \dotfill (49)$$

and

$$b = \begin{vmatrix} d_1 & 0 & 0 \\ d_2 & 0 & 0 \\ d_3 & 0 & 0 \end{vmatrix} \dotfill (50)$$

Therefore,

$$a^{-1}\,b = \frac{1}{a}\begin{vmatrix} A_{11} & A_{21} & A_{31} \\ A_{12} & A_{22} & A_{32} \\ A_{13} & A_{23} & A_{33} \end{vmatrix} \; \begin{vmatrix} d_1 & 0 & 0 \\ d_2 & 0 & 0 \\ d_3 & 0 & 0 \end{vmatrix} \dotfill (51)$$

and

$$a^{-1}\,b = \frac{1}{a}\begin{vmatrix} (d_1\,A_{11} + d_2\,A_{21} + d_3\,A_{31}) & 0 & 0 \\ (d_1\,A_{12} + d_2\,A_{22} + d_3\,A_{32}) & 0 & 0 \\ (d_1\,A_{13} + d_2\,A_{23} + d_3\,A_{33}) & 0 & 0 \end{vmatrix} \dotfill (52)$$

However,

$$\left.\begin{aligned} \frac{d_1 A_{11} + d_2 A_{21} + d_3 A_{31}}{a} &= x_d \\ \frac{d_1 A_{12} + d_2 A_{22} + d_3 A_{32}}{a} &= y_d \\ \frac{d_1 A_{13} + d_2 A_{23} + d_3 A_{33}}{a} &= z_d \end{aligned}\right\} \ldots\ldots (53)$$

Substituting Eqs. 53 in Eq. 52,

$$a^{-1} b = \begin{vmatrix} x_d & 0 & 0 \\ y_d & 0 & 0 \\ z_d & 0 & 0 \end{vmatrix} \ldots\ldots (54)$$

and

$$I + a^{-1} b = \begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{vmatrix} + \begin{vmatrix} x_d & 0 & 0 \\ y_d & 0 & 0 \\ z_d & 0 & 0 \end{vmatrix} \ldots\ldots (55a)$$

from which

$$I + a^{-1} b = \begin{vmatrix} 1 + x_d & 0 & 0 \\ y_d & 1 & 0 \\ z_d & 0 & 1 \end{vmatrix} \ldots\ldots (55b)$$

and

$$[I + a^{-1} b]^{-1} = \frac{\text{adjoint } [I + a^{-1} b]}{I + a^{-1} b} = \frac{\text{adjoint } [I + a^{-1} b]}{1 + x_d} \ldots (56a)$$

Therefore,

$$[I + a^{-1} b]^{-1} = \frac{1}{1 + x_d} \begin{vmatrix} 1 & 0 & 0 \\ - y_d & 1 + x_d & 0 \\ - z_d & 0 & 1 + x_d \end{vmatrix} \ldots\ldots (56b)$$

and

$$\begin{vmatrix} x' \\ y' \\ z' \end{vmatrix} = \frac{1}{I + x_d} \begin{vmatrix} 1 & 0 & 0 \\ - y_d & 1 + x_d & 0 \\ - z_d & 0 & 1 + x_d \end{vmatrix} \begin{vmatrix} x \\ y \\ z \end{vmatrix} \ldots\ldots (57)$$

from which

$$\left.\begin{aligned} x' &= \frac{x}{1 + x_d} \\ y' &= y - \frac{y_d x}{1 + x_d} \\ z' &= z - \frac{z_d x}{1 + x_d} \end{aligned}\right\} \ldots\ldots (58)$$

Eqs. 58 will be recognized as being the same as Eqs. 17, 19, and 20, respectively.

To derive Eqs. 33 and 34, the value of b in Eq. 50 becomes

$$b = \begin{vmatrix} d_1 & e_1 & 0 \\ d_2 & e_2 & 0 \\ d_3 & e_3 & 0 \end{vmatrix} \ldots\ldots (59)$$

and

$$a^{-1} b = \frac{1}{a} \begin{vmatrix} A_{11} & A_{21} & A_{31} \\ A_{12} & A_{22} & A_{32} \\ A_{13} & A_{23} & A_{33} \end{vmatrix} \begin{vmatrix} d_1 & e_1 & 0 \\ d_2 & e_2 & 0 \\ d_3 & e_3 & 0 \end{vmatrix} \ldots\ldots (60)$$

Therefore,

$$I + a^{-1}\,b = \begin{vmatrix} 1 + x_d & x_e & 0 \\ y_d & 1 + y_e & 0 \\ z_d & z_e & 1 \end{vmatrix} \quad \text{.................(61)}$$

$$[I + a^{-1}\,b]^{-1} = \frac{\begin{vmatrix} (1+y_e) & -x_e & 0 \\ -y_d & (1+x_d) & 0 \\ y_d\,z_e - (1+y_e)\,z_d & x_e\,z_d - (1+x_d)\,z_e & (1+x_d)\,(1+y_e) - x_e\,y_d \end{vmatrix}}{(1+x_d)\,(1+y_e) - x_e\,y_d} \quad \text{..(62)}$$

and

$$\begin{vmatrix} x' \\ y' \\ z' \end{vmatrix} = \frac{1}{D} \begin{vmatrix} (1+y_e) & -x_e & 0 \\ -y_d & (1+x_d) & 0 \\ y_d\,z_e - (1+y_e)\,z_d & x_e\,z_d - (1+x_d)\,z_e & (1+x_d)\,(1+y_e) - x_e\,y_d \end{vmatrix} \begin{vmatrix} x \\ y \\ z \end{vmatrix} \quad \text{..(63)}$$

in which $D = (1 + x_d)\,(1 + y_e) - x_e\,y_d$. Therefore,

$$\left.\begin{aligned} x' &= \frac{(1 + y_e)\,x - x_e\,y}{(1 + x_d)\,(1 + y_e) - x_e\,y_d} \\ y' &= \frac{(1 + x_d)\,y - y_d\,x}{(1 + x_d)\,(1 + y_e) - x_e\,y_d} \end{aligned}\right\} \quad \text{...............(64)}$$

$$z' = z - z_d\,x' - z_e\,y' \quad \text{....................(65)}$$

Eqs. 64 are the solutions of Eqs. 29 and 30, and Eq. 65 is the same as Eq. 31.

If all the coefficients were varied at once, Eqs. 50 would become

$$b = \begin{vmatrix} d_1 & e_1 & f_1 \\ d_2 & e_2 & f_2 \\ d_3 & e_3 & f_3 \end{vmatrix} \quad \text{.........................(66)}$$

and

$$I + a^{-1}\,b = \begin{vmatrix} 1 + x_d & x_e & x_f \\ y_d & 1 + y_e & y_f \\ z_d & z_e & 1 + z_f \end{vmatrix} \quad \text{.............(67)}$$

The matrix of Eq. 67 is a full one; that is, it contains no zeros and is equivalent to the matrix involved in re-solving the equations.

It is again shown that, if the coefficients of all the unknowns are varied at one time, this procedure simply results in the complete solution of the equations by one of the classic methods—in this case, by determinants. In fact, this is exactly the result of Professor Morrison's numerical example illustrating the general solution. The simplicity of this numerical general solution is deceiving; the examples used both by the discusser and by the writer were chosen deliberately for the purpose of illustrating principles with the least amount of distraction from the mechanical details of manipulating difficult numbers.

For this reason the writer agrees with Professor Morrison that it is doubtful whether the general method based on matrix algebra offers any advantage since it is really a solution by determinants. The writer is grateful to Professor Morrison for submitting his very interesting and enlightening discussion.

Mr. Roos' comments relating how he has used the theory presented in this paper indicate that variation of coefficients is not a mere mathematical curiosity, but a useful engineering tool. When the millennium comes, there may be a paradise in which designers will have the foresight to anticipate all contingencies and the final design will be exactly the same as the preliminary design. Adjustments will then not be necessary. The fact remains, however, that normally changes are made and adjustments are necessary.

If the structure under consideration is indeterminate to a large degree, an accurate determination of the exact effect of the changes is too time consuming to permit anything more elaborate than a "guesstimate" to be made. Mr. Roos corroborates the writer's experience that variation of coefficients is an efficient tool for this purpose and for the other purposes he mentions.

Mr. Roos states that, with the method, he has been able to adapt one basic design to several other structures. The writer has stated (under the heading, "Solution of Simultaneous Equations by Variation of Coefficients") that if a solution of any set of equations is known—from some previous computation or in any other way—it can be varied to any other set of equations desired. Thus, the writer, from his own experience, has anticipated Mr. Roos' findings.

Mr. Roos requests the mathematical basis for the method. It is supposed that what is desired is a more rigorous proof, but the writer feels that the proof given under the heading, "General Formulas for Variation of Coefficients," leading to the derivation of Eqs. 21, is sufficiently rigorous. Nevertheless, he has complied with Mr. Roos' request by extending Professor Morrison's Eq. 44 to the derivation of Eqs. 21, 33, and 34. Matrix algebra deals of course with determinants, hence this latter proof in terms of determinants constitutes a rigorous mathematical proof.

The writer is grateful to Mr. Roos for presenting evidence that the paper is a useful engineering tool and not a mere problem in abstract mathematics.

Mr. Merritt has also used the theory of the paper and calls attention to the fact that, when any of the properties of the structure are changed, resulting in a change in coefficients, classical methods permit no other alternative than re-solving the equations. If the loading conditions are changed, no particular problem is involved—provided the work is arranged according to a well-laid plan. The writer is grateful also to Mr. Merritt for his brief discussion presenting additional evidence of the practical value of the method as an engineering tool.

The writer feels that there are simplifications still possible in the evaluation of simultaneous equations and that further studies will reveal them. One difficulty encountered in the study of these equations is the fact that, when expanded, the algebraic forms rapidly become very cumbersome. On the other hand, if the solutions are expressed symbolically, it is very difficult to see relationships not already known. Matrix algebra and similar devices have been developed to overcome the first difficulty and the writer feels that further study of the theory of variation of coefficients with the aid of such methods should reveal other simplifications. Although modern procedures are most helpful in practical design of structures having a high degree of indeterminancy, the general methods necessitating sets of linear simultaneous equations are still the primary ones for research. It is to be hoped that such studies will be undertaken by the members of the profession and that further simplifications will be discovered and reported.

Paper No. 2359

THE SOCIETY'S FUTURE AND ITS ECONOMIC LIMITATIONS

ANNUAL PRESIDENTIAL ADDRESS

BY R. E. DOUGHERTY,[1] PRESIDENT, ASCE

In accordance with the provisions of the Constitution, it is the privilege of the President to address the Society on important phases of its affairs at the Annual Convention. Although I would very much prefer to discuss ethereal or perhaps technical questions with you, nevertheless, the most important problem before us is financial, prosaic though it may be.

The dues of the Society were fixed in accordance with the present constitutional provisions in 1921. There is no need to expatiate on the changing world that has since evolved, with its expansion of problems and the decrease in the value of the dollar.

In recent years, your various Boards of Direction, in order to meet the increasing obligations and requirements of the Society, passed deficit budgets and based their judgment primarily on the cash position. This procedure could not be followed indefinitely, and the 1947 Board endeavored to persuade the Society to secure additional revenue by amendments authorizing an increase in dues, and—failing in that effort— wisely decided to balance its budget in any event. This caused serious curtailment in many activities, including the Technical Divisions and Committees, the Local Sections and their ramifications, the Juniors and Student Chapters, and the publications, already reduced beyond the satisfaction of many members preparing papers—in fact, a general, all-around reduction in the efficiency of our functioning.

I would like to pause for a moment to seize upon this opportunity—and I am sure every member of the Board will concur—to pay tribute to the careful and efficient work of the Budget Committee consisting of George W. Burpee as Chairman, Roy W. Crum, and Irving V. A. Huie.

The present problem has received the careful attention, not only of the Board but likewise of the Sections, and two petitions have been submitted offering amendments permitting the dues to be increased. These amendments will be very shortly submitted to you and may be briefly summarized as follows:

---

[1] Vice-Pres.-Asst. to Pres., New York Central System, New York, N. Y.

Amendment Based on Petition No. 1:

> "(1) An increase of five dollars ($5.00) a year in the dues of Members, Associate Members and Affiliates.
>
> "(2) An increase of two dollars and fifty cents ($2.50) a year in the dues of Juniors."

This amendment, if passed, would still retain the existing differential between the dues paid by the members in District No. 1 and the rest of the Society.

Petition No. 1 was signed by 148 members in Zone I, 348 members in Zone II, 485 members in Zone III, and 379 members in Zone IV, a total of 1,360.

Amendment Based on Petition No. 2:

> "The annual dues payable by Members, Associate Members, Affiliates and Junior Members within District No. 1, shall be the same as those payable by corresponding members residing outside District No. 1."

This amendment would accord to the membership in District No. 1 the same treatment as that enjoyed by the rest of the Society. Please note most carefully that the second amendment is to be made effective only if the first passes.

Petition No. 2 was signed by 138 members in Zone I, 203 members in Zone II, 338 members in Zone III, and 237 members is Zone IV, a total of 916. It did not originate in Zone I.

An increase of $85,000 of revenue would be made available under the first amendment. If both amendments became effective, the additional amount realized would be reduced to $67,000.

In either event the immediate financial problem would be solved and the functioning of the Society restored substantially to the status prior to the reductions of the budget adopted in 1947.

The question has been raised as to what would happen if these amendments were not passed. I, for one, dislike to think of any further loss of efficiency in our functioning, but that is just exactly what it would mean. The Board has reached no conclusion as to just what form this further curtailment might take, but the Budget Committee thinks that it might mean an additional cut of $25,000. Various suggestions have been considered as to the form of further reductions, but I am sufficiently optimistic and confident to believe that that unfortunate contingency will not prevail. Let me call your attention to the very pertinent views expressed by Director Samuel A. Greeley of Chicago, Ill., in *Civil Engineering*[2] for July, 1948, very well stating the case in greater detail.

I shall endeavor to present a factual analysis of Petition No. 2 and the accompanying amendment.

Many members residing outside of District No. 1 may have the idea that the differential now existing should continue, although others consider it to be an inheritance of past thinking, when the activities of the Society primarily centered in the old building at Fifty-seventh Street and before the days of Local Sections. In those days there was an advantage, although now largely dissipated as a sequel to the transfer of activity from Fifty-seventh Street to the Engineering Societies Building and the initiation of Local Sections. The Metropolitan Section pays for the use of its rooms in the Engineering Societies Building.

---

[2] *Civil Engineering*, July, 1948, p. 55.

None of the other founder societies makes any distinction as to dues charged to members in the Metropolitan area as against dues charged to the rest of the membership.

Geographical expediency necessitates calling upon the membership in District No. 1 for the brunt of such work as membership on United Engineering Trustees, Engineering Foundation, Engineering Societies Library, consideration of questions involving securities and investments, the recurring responsibility for the Annual Meetings, and other duties of a similar character.

On the other hand, I have heard it stated that this is one of the distinct advantages for service to the profession which is enjoyed by members in District No. 1, and is less available to members living at greater distances. It has also been stated that it is an advantage to the membership of District No. 1 to have the Annual Meetings in New York.

It is sometimes claimed that there is a distinct advantage in close contact with the Engineering Societies Library. Analysis indicates that a large proportion of the service, possibly 60%, at least, is furnished to the membership outside of New York State, let alone District No. 1. Furthermore, the service rendered by the Library is primarily of advantage to employing organizations rather than to individual members.

I have endeavored in the foregoing to present impartially the various arguments "for" and "against," and will leave it for you to strike the proper equation.

The question has also been raised as to certain functions of the Society being outside the limits of technical activities and beyond the scope of the Constitution and its original purpose. I disagree emphatically with that idea, and let me quote the following from Article I of the Constitution:

> "3. The objects of the Society shall be the advancement of the sciencel of engineering and architecture in their several branches, the professionas improvement of its members, the encouragement of intercourse between men of practical science, and the establishment of a central point of reference and union for its members."

The Society is facing a different world from that of the founding fathers. The great problems of the world today are in economics and in public and human relations, and the Society should take its proper place in these considerations. What better example can we have of this theory of service than that offered by the unselfish response of our Past-President E. M. Hastings to an invitation to go to China as a member of a special survey mission to China appointed by Economic Cooperation Administrator Paul Hoffman. It is a great tribute not only to our Past-President but likewise to the Society. The day has long since passed when any organization or individual can face these basic problems with complacency and with the thought that others will assume the burden. It must be remembered that inertia at various times through the years has prompted the formation of other organizations which it now seems might well have been avoided. It is easy enough to second guess the past, but it is unpardonable if we do not use such experience as guidance for the future.

In considering the problems of the Society, let me emphasize the importance of the work of the Student Chapters, now numbering 125, with a total membership of approximately 8,600, which originated in 1920, only one year before the dues were last raised. Similarly, an increased interest in the Juniors is another distinct manifestation of progress as compared with the older days, certainly applying to the period when I first became a Junior in 1903. In 1921 there were 500 Juniors out of a total membership of 10,000. In 1948 there are 7,250 out of a total membership of 23,600. The importance of these particular activities cannot be overestimated. Let me commend to the attention of the Local Sections careful consideration of the advisability of placing a Junior on their Boards.

The question has arisen as to whether we should eliminate the field offices, particularly the two in Chicago and Los Angeles, Calif. A careful review of this question by the Board and discussion with many Presidents of Local Sections, including the coordination of these considerations by the Vice-Presidents and Directors of Zones III and IV, leads to the inescapable conclusion that the Regional Representatives, Walter E. Jessup and George S. Salter, are serving a most useful purpose, particularly in dealing with the Local Sections, Juniors, and Student Chapters. It must be remembered that we are a far-flung organization and although the initiation of the idea originally, largely but not entirely, had to do with collective bargaining, nevertheless, that is now very much of a minor consideration in so far as time is concerned and the only functioning of Messrs. Jessup and Salter in that respect has to do with keeping headquarters "posted" as to what is going on in their respective territories. I have never heard anyone raise the slightest question as to the necessity for the Regional Office in Washington, D. C. The service of E. L. Chandler in keeping the Board and the Executive Secretary informed as to legislation and other federal activities, as well as his other work in connection with the Local Sections, Juniors, etc., has justified that position in the eyes of everyone familiar with this work. One has only to discuss that particular subject with members of the District of Columbia Section to realize the appreciation that we should extend to Mr. Chandler.

There was a great deal of confusion for several years in connection with collective bargaining, and the 1943 Board came in for considerable criticism when it took cognizance of that very controversial issue, which was particularly acute as it involved the membership of the Society in the western, central, and southern states and, to a more limited extent, in the east. Any pioneer movement in an uncharted field is bound to be accompanied by certain actions which subsequently have to be modified and this instance is no exception. Like most of you, I was not too familiar with its ramifications when I came back to the Board as a Vice-President in 1944. Although the original procedure had to be changed radically, the 1943 Board was faced with a very serious situation and I am convinced that, controversial though the subject and procedure may have been, the Society owes a debt of gratitude to that Board for its courage in endeavoring to meet a critical problem. By the very differences of opinion that arose out of it, the action of that Board of Direction focused active attention on the subject in a way that could hardly have been accomplished. Fortunately, the Taft-Hartley Act has eliminated some of that worry, but there are even presently problems in that same connection that must be watched carefully. Is there anyone who will argue that careful attention to national legislation and policy should not be given the direct and continuing consideration of our Society in cooperation with others involved?

The question has been raised with me on several occasions that we should more clearly state the aims and intent of our organization. In casting about to develop that suggestion, I find that some of the Sections, following the leadership of the Kentucky and Illinois Sections, are using a statement of reasons for membership that I would be willing to adopt as a platform. You will find this effort more fully outlined on the editorial page of the July, 1948, issue of *Civil Engineering.*[3]

> "To encourage and perfect discoveries in basic and applied science and to bring these discoveries to all members of the profession, it has published technical papers and discussions.
>
> "To stimulate professional activity at the local level, it has created and supported local sections.
>
> "To afford the beginnings of professional associations in universities and colleges, it has established and encouraged student chapters.
>
> "To advance the economic standing of the profession, it has formulated and adopted classification and compensation schedules for civil engineering positions.
>
> "To encourage the payment of higher salaries by employers, it has recommended adequate fees for consulting engineering services.
>
> "To foster the professional standing of its members, it has promoted national registration laws.
>
> "To improve engineering education standards, it has cooperated with other national engineering societies in the accrediting of engineering curricula.
>
> "To free its members from enforced collectivism, it has taken effective action on national labor legislation affecting the profession.
>
> "To the older engineer, membership in the Society provides the professional associations and contacts by which success in his profession usually has been attained.
>
> "To the Junior engineer, membership is the medium for providing wider sources of technical information, more varied personal relations, and less formal contacts with his superiors than he usually finds in his daily work.
>
> "And to all engineers, membership in the Society carries a recognition of professional standing in a degree second to no other organization."

I have endeavored to analyze the economies that might be effected if we were to be confined entirely to technical activities, which certainly should be considered as including the functioning of the Society with its Local Sections, Juniors, and Student Chapters, and have reached the conclusion that a large proportion of that which many call professional activity involves functioning on the executive level for both the Board and the staff. It is difficult to place a finger on any material saving that could be accomplished by even a literal compliance with that suggestion. In addition, and on the minus side, it certainly would entail a tremendous loss of prestige.

---

[3] *Civil Engineering*, July, 1948, p. 54.

In order better to meet the many problems before us, it was wisely concluded about four years ago to cooperate actively with the other Founder Societies and with the American Chemical Society in the formation of what is now known as Engineers Joint Council, which presently consists of the president, immediate past-president, and secretary of each organization. This combination is actively watching over the general affairs of the profession from a national and international standpoint and in company with other organizations. The general provisions of its Constitution were approved at a meeting of the Council on July 8 and at the Seattle (Wash.) Meeting of your Board of Direction, and may be stated as follows:

The objectives of the Council shall be:

> "(*a*) To advance the general welfare of mankind through the available resources and creative ability of the engineering profession.
>
> "(*b*) To promote cooperation among the various branches of the engineering profession.
>
> "(*c*) To develop sound public policies respecting national and international affairs wherein the engineering profession can be helpful through the services of the members of the engineering profession."

A Committee of the Engineers Joint Council has been created consisting of one member appointed by each Constituent Society to prepare a plan for the increased unity of the engineering profession.

Let me emphasize the advisability of a more intensive cooperation with other organizations than those now included in Engineers Joint Council. The Executive Secretary and I have conferred with the president and executive director of the Associated General Contractors, and our Board has just authorized the designation of a joint committee to work with the Associated General Contractors with the objective of close cooperation. I certainly hope the day will come when there will be complete understanding among the various engineering organizations that should have the same eventual purpose in mind.

I have heard the statement made that the Society "is at the crossroads." I am not inclined toward such a comparison. I am more given to an analogy with travel on a highway as it may have existed in 1921, probably not more than two lanes wide and lucky if it were even of gravel or macadam, but which now has four or six lanes. I cannot help but compare the "brass-nosed flivvers" and similar automobiles of those days with the equipment that we now enjoy. I sincerely hope that the membership will permit its Board to operate with what corresponds to a modern automobile on an improved through thoroughfare, and not require it to attempt to keep its proper place among the professions with out-of-date equipment or outmoded concepts. The days of the 1921 roads and motor vehicles have gone. Crossroads? No! The same road of the engineering profession modernized and a road upon which I hope we may travel with up-to-date equipment.

MEMOIRS OF DECEASED MEMBERS

Honorary Members

FRANCIS TRENHOLM CROWE, Hon. M. ASCE[1]

Died February 26, 1946

Francis Trenholm Crowe, the son of John and Emma (Wilkinson) Crowe, was born on October 12, 1882, at Trenholmville, Que., Canada. John Crowe, born in Huddisfield, England, came to the United States in 1869 and was married to Emma Wilkinson in Brooklyn, N. Y., in 1880. They resided in Sherbrook, Que., Canada, for two years, and then moved to Trenholmville where Francis was born.

John Crowe had established a woolen mill in Trenholmville in 1882, and in 1888 he sold his interests and moved his family to Fairfield, Iowa, where he invested in another mill. This venture was unsuccessful, so, in 1890, the family moved back to Kezar Falls, Me., where the father worked as superintendent in a large woolen mill. In 1892 still following his interests in woolen mills the family again moved—this time to Picton, N. J., where they stayed for seven years. In 1899 they settled at Byfield, Mass.

At Byfield, Francis completed his elementary studies and started high school. The town did not have a high school, but sent its students to Dummer Academy (the oldest school of its type in the United States, founded by Governor Dummer, who was appointed by the English throne in prerevolutionary times). He was graduated from Dummer Academy in June, 1901, and that fall he entered the University of Maine at Orono.

Mr. Crowe often mentioned that his father had wanted him to follow the ministry or practice medicine, but the young man's mind had long been made up to be an engineer, so it was that he studied civil engineering at the University of Maine. At the university he excelled in mathematics and engineering and took an active part in military work; in his junior year he was also selected as artist for the year book, "The Prism."

During Mr. Crowe's junior year at college, in January, 1904, Frank E. Weymouth,[2] M. ASCE (Class of 1896), had returned from the west where he was employed by the United States Reclamation Service, and he gave a series of lectures on the plans for reclaiming vast regions of land. Mr. Crowe's enthusiasm was immediately aroused, so much so that, after the course of lectures, he approached Mr. Weymouth and asked, "If I show up on your project this spring, will you give me a job?" Mr. Weymouth assured him of work and so in the spring of 1904 Mr. Crowe borrowed enough money to make the trip. He worked the summer of that year on a survey party for the Reclamation Service on the Lower Yellowstone River near Glendive, Mont.

---

[1] Memoir prepared by S. O. Harper, Walker R. Young, and W. V. Greeley, Members, ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 107, 1942, p. 1712.

He returned to the university in November, 1904, a most enthusiastic booster of the west and of the great work the Reclamation Service was doing in reclaiming vast, arid regions. He had fallen in love with that country and had learned much about its rugged life in the few short months he spent there; he could make camp, ride a bronco, and spin and throw a lariat (Will Rogers' style). He earned his trip back to Chicago (Ill.) as a drover of several carloads of horses; his drover's ticket enabled him to cover partly the cost of a ticket from Chicago to Bangor, Me. Mr. Crowe brought back with him a large buffalo skull that adorned the fireplace in the Sigma Alpha Epsilon house for many years. It was a common sight to see him showing the students how easy it was to throw the rope and to catch the boys as they ran by. His interest in what he had seen showed in his every thought and action and he was extremely impatient to return to the west.

In January, 1905, he took and passed the civil service examinations at Bangor. Mr. Weymouth offered him a job, but it was necessary for him to start work about the middle of May, a month before graduation. He immediately arranged with Harold Boardman, M. ASCE, dean of the civil engineering department, for special examinations, which he passed with high marks. So, not waiting for commencement exercises or his diploma, he started west again—this time to stay and to begin a career which was to bring him fame as a great construction engineer and dam builder. This enthusiasm showed during his last year at Maine; it spread throughout the senior and junior classes, and many students followed him west, the most notable being Frank A. Banks, Assoc. M. ASCE (Class of 1906).

His first work with the Reclamation Service, after leaving the university, was as engineering aid and instrumentman on construction of the headworks for the Lower Yellowstone irrigation system. He was assigned to this project during 1905 and 1906. In 1906, having met James Munn, M. ASCE, a general contractor, he left the Reclamation Service to join Mr. Munn as superintendent of construction, in charge of several large reinforced concrete siphons, sluiceways, and spillways.

He left Mr. Munn in 1908 and went back to work for the Reclamation Service as engineer and superintendent of construction on the second lift pumping station on the Minidoka project in Idaho. In 1910 and 1911 he was engineer and, later, superintendent of construction on the Snake River storage project, involving investigation of the storage possibilities at Jackson Lake in Wyoming, the location and construction of 35 miles of wagon road through the Teton Range of the Rocky Mountains, and construction of Jackson Lake Dam. It was at this time that Mr. Crowe was married to Marie Sass, who passed away in 1911.

In December, 1911, Mr. Crowe was appointed assistant superintendent of construction on the Arrowrock Dam in Idaho under Mr. Munn, who had given up his contracting firm and joined the Reclamation Service. This dam, then 349 feet high, was the highest concrete dam in the world at the time. While at Arrowrock Mr. Crowe showed his inherent skill in the mechanical field by designing a comprehensive concrete conveying and distributing system, as well as a unique pipe system for transporting cement pneumatically. It was during this period that he saw the great possibilities for the use of cableways in the construction of concrete dams, and he spent considerable time in studying them and developing their efficiency. He later became a strong advocate of the cableway system and recommended its use wherever possible.

From 1913 to 1915 Mr. Crowe was superintendent of construction on the Boise project in Idaho in charge of the building of 50 miles of large open drains, returning in 1915 to superintend the Jackson Lake Dam enlargement. In 1916 he was appointed project manager of the Flathead project in Montana, remaining there until 1920. The same year he left the Reclamation Service and formed a partnership (under the name of Rich, Marcus, and Crowe) in Missoula, Mont., with Messrs. Rich and Marcus. This partnership was dissolved after a year's operation and Mr. Crowe returned to the Reclamation Service in 1921 as construction engineer at Tieton Dam (235 feet high) on the Yakima project in Washington.

On the completion of Tieton Dam in 1924, he was appointed general superintendent of construction in the office of the chief engineer of the Bureau of Reclamation (formerly Reclamation Service) in Denver, Colo. In this position he had general supervision of all construction activities of the bureau in seventeen western states, and as principal assistant to the chief engineer, he was in charge of the Denver office in the latter's absence. Thus it was that he became one of the top-ranking men of the bureau, having acquired an enviable reputation for organizing ability and ingenious and rapid prosecution of construction work.

In 1925 the policy of handling the construction of its major projects by government forces, which the bureau had followed for many years, was changed, and this type of construction was abandoned in favor of construction by contract as current jobs were brought to completion. This change in construction methods resulted in a radical change in Mr. Crowe's duties. He was always happiest in the open spaces on the front line of a tough construction job, and the limitations of an executive office were most irksome to him. On one occasion he remarked, "Do you know what I feel like sitting at this desk shuffling papers? I feel like a bull in a china shop."

So it was that Mr. Crowe came to an important turning point in his career. He was only beginning to realize his greatest ambition to build bigger and bigger dams. During the years past his close association with such engineers as F. H. Newell,[3] M. ASCE, A. P. Davis,[4] Past-President, ASCE, A. J.

---

[3] For memoir, see *Transactions*, ASCE, Vol. 98, 1933, p. 1597.

[4] *Ibid.*, Vol. 100, 1935, p. 1582.

Wiley,[5] M. ASCE, D. C. Henny,[6] M. ASCE, C. H. Paul,[7] M. ASCE, F. E. Weymouth,[2] and others had fired his imagination with dams of unprecedented size, and he was determined he could build them. He loved his work and associations in the Bureau of Reclamation, but he had a conviction that he could best develop his own abilities and perform a more useful service by directing the building of dams on the ground rather than by long-range supervision of construction. Therefore, when the opportunity came to enter the construction field he made his decision without reservation to cast his lot with contractors.

Mr. Crowe resigned in 1925 from the bureau and accepted the position of superintendent in charge of construction of Guernsey Dam on the North Platte River in Wyoming for the Morrison-Knudsen Company of Boise. This was a young and aggressive organization, which was just starting out in the heavy construction field, and which was later to become one of the largest construction companies in the world. Mr. Crowe soon hit his stride in successfully bidding and building dams throughout the west. After completing Guernsey Dam in 1927, he built Van Giesen (Coombe) Dam on the Bear River in California in 1927–1928, and Deadwood Dam in Central Idaho in 1929–1930.

Hoover Dam (formerly Boulder Dam), 726 feet high, was open for bids by the Bureau of Reclamation in 1931. This dam, located in the rugged Black Canyon of the Colorado River, was of such magnitude and presented such unusual hazards and seemingly unsurmountable problems that most contractors hesitated to tackle it. Mr. Crowe, however, was determined to build it—this was his life's ambition. He had waited for this job ever since its conception by the bureau engineers years before. With his enthusiasm, confidence, and prodding, he inspired H. W. Morrison of the Morrison-Knudsen Company to promote the organization of Six Companies, Incorporated, a syndicate of six large construction companies, to bid on the job. In preparing the bid for the dam each member of the combine made its individual estimate. Mr. Crowe made the cost estimate for the Morrison-Knudsen Company. With a slight adjustment of approximately one per cent, his figures were accepted as the official cost estimate of Six Companies, Incorporated, and proved to be the low bid for the job. So great was the confidence of the syndicate in Mr. Crowe that he was appointed immediately as general superintendent in charge of building the dam. His genius at organizing, designing the construction plant, and moving materials in the most efficient manner was demonstrated by the fact that Hoover Dam was completed twenty-five months ahead of schedule. This record started Mr. Crowe and Six Companies, Incorporated, well on the way to fame.

In 1935 he took enough time off to make a trip back to his alma mater, the University of Maine, where he was awarded the honorary degree of Doctor of Engineering in recognition of his outstanding contributions to the profession.

---

[5] For memoir, see *Transactions*, ASCE, Vol. 96, 1932, p. 1577.

[6] *Ibid.*, Vol. 101, 1936, p. 1577.

[7] *Ibid.*, Vol. 107, 1942, p. 1809.

In 1936 Mr. Crowe and Six Companies, Incorporated, bid and were awarded the construction of Parker Dam on the Colorado River. The group "left over a million dollars on the table" in bidding the job, which made most of the members uneasy. Mr. Crowe, however, was still so confident of his bid that he went into partnership with Charles Shea of the J. F. Shea Company (one of the Six Companies group) and subcontracted the job. From the outset it was very difficult because of the unprecedented depth of foundation excavation, and the subcontractor was constantly threatened with heavy loss. The dam, although 320 feet high from the foundation, required excavation to a depth of 235 feet below the original river bed in sand and gravel heavily saturated with water. The treacherous Colorado and Bill Williams rivers threatened disaster on several occasions, but Mr. Crowe stayed with the job day and night, fighting all the threats of nature and a very difficult foundation problem. His determination and his efforts were rewarded by completing the job well ahead of schedule, with a profit for the contractors. He also constructed the Copper Basin and Gene Wash dams in near-by California for the Metropolitan Water District of Southern California in 1937 and 1938.

The next dam to be undertaken by Mr. Crowe was Shasta Dam on the Sacramento River in California, the key structure in the immense Central Valley project of the Bureau of Reclamation. Although the group he was associated with in bidding for this job was unsuccessful by a small margin, the low bidders, Pacific Constructors, Incorporated, had such confidence in his ability that they employed him as general superintendent. Shasta Dam, 602 feet high, the second highest and second largest dam in the world, presented many difficult problems. It was here that Mr. Crowe, an advocate of the cableway system, devised a system of handling concrete that was unique in construction practice. He designed a 460-foot central tower from which radiated seven 25-ton cableways, delivering concrete and materials to all parts of the job. The cableway system was so well planned and so well built that full coverage on the entire dam was possible from the first to the last bucket of concrete placed. In 1944 Shasta Dam was completed—another monument, and a final one, to a great construction engineer.

He received the crowning distinction of honorary membership in the Society in 1944. In recognition of his great work the "Moles," a New York (N. Y.) organization of tunnel and heavy construction men, gave him an honorary award in 1945 for outstanding contributions to the engineering and construction profession.

Mr. Crowe was pre-eminent as a builder of dams. Associated with some of the largest construction firms in the west, he had never been submerged in any company. He and his men were an institution within themselves; all were picked and trained over a period of years for the difficult tasks involved in dam building. They followed him about, from job to job, some as far back as Arrowrock Dam thirty years before and some even into the second generation, with father and son working together in crews. He directed his work through personal contact with his men. He knew them by name, and was known to all as "The Old Man." By his friends and associates in the construction industry he was invariably called "Frank," and he carried the name "Frank Crowe" on his personal letterhead in preference to his given name, "Francis."

He was a man of few words and a master of terse and forceful language which construction men understand so well. He disliked long letters and reports, and his own letters seldom consisted of more than two or three sentences. A typical example was a letter to the Bureau of Reclamation when he felt that the progress at Shasta Dam was being unnecessarily delayed —it read: "Herewith a picture of the Hay-Wire Dam," and the following caption was on the picture: "A view from Point Despair where Time Marches On and the dam stands still."

Mr. Crowe probably knew more about dam construction than any other man of his generation. He designed, built, and used much of the equipment which has become standard for construction men today. He was the outstanding authority on the cableway method of building dams. The system he designed for Shasta Dam, using a central tower as a hub with cables radiating out to cover the entire structure, was a radical departure from prevailing practice and involved previously unknown stresses and strains. Although many authorities questioned the feasibility of the system, Mr. Crowe never doubted that it was fundamentally sound and this was proved by its efficient operation over a period of four years.

As construction methods progressed from the days of the horse drawn scrapers through the era of the steam shovel on into the modern period of robot operation of electrical equipment, he was a leader in devising new and better methods of obtaining faster operation and more efficiency. As specifications for building became more rigid he pioneered many new schemes in order to keep up production and at the same time meet all the stringent requirements set forth by the designers.

Hoover Dam may well be considered Mr. Crowe's crowning achievement, as well stated in a magazine article: [8]

> "To the extent it can be said to belong to any single man, Boulder was Frank Crowe's triumph. For five long years the heat, the mud, the remorseless current, the swift floods, the jangling telephones were his responsibility. 'We had 5,000 men jammed in a 4,000-foot canyon,' Crowe says. 'The problem, which was a problem in materials flow, was to set up the right sequence of jobs so they wouldn't kill each other off.' "

In 1945 he was asked by the War Department to take complete charge of all rehabilitation work in the American occupation zone in Germany. He was ready to tackle this tough assignment, but the forty years he spent in pioneering the construction of the west and in becoming the world's outstanding dam builder were slowly exacting their toll, and he was forced to refuse this assignment on doctor's orders.

---

[8] "The Earth Movers," *Fortune*, August, 1943.

During the construction of Shasta Dam Mr. Crowe acquired extensive cattle ranches in northern California and at his death he was engaged in managing the property, as well as acting as a construction consultant for the Morrison-Knudsen Company. He died suddenly on February 26, 1946, at Redding, Calif., near one of his greatest achievements—Shasta Dam.

He is survived by his widow, the former Linnie Kortz of Boise, now residing in Redding, and two daughters, Patricia (Mrs. Stanley Lee) of San Francisco, Calif., and Bettee (Mrs. Robert Parry) of Palo Alto, Calif.

Mr. Crowe belonged to Sigma Alpha Epsilon fraternity, the engineering honor society of Tau Beta Pi, and the Episcopal Church. In addition, he was a Thirty-Second Degree Mason, a Shriner, an Elk, and a Rotarian.

His projects will stand forever as monuments to his great ability as a constructor, but he will be best remembered by his many friends and close associates for his ever-present human understanding, his extreme fair-mindedness, his wonderful sense of humor, and his absolute integrity—once his word was given it was carried out, no matter what his personal sacrifice might be.

Mr. Crowe was elected an Associate Member of the American Society of Civil Engineers on May 3, 1910; a Member on October 11, 1915; and an Honorary Member on October 11, 1943.

GEORGE WATSON KITTREDGE, Hon. M. ASCE[1]

DIED AUGUST 22, 1947

George Watson Kittredge was born on December 11, 1856, at North Andover, Mass. His parents were of English ancestry, resident in New England since 1660.

His father, Joseph Kittredge, M.D., was born in North Andover and his mother, Henrietta Frances Watson, was born in Belfast, Me. Dr. Kittredge was the seventh generation of an unbroken line of physicians, dating back to John Kittredge, a sea captain, who was born in Lowestoft, England, and settled in Billerica, Mass., in 1660. The fifth generation physician was Thomas Kittredge who was a surgeon in Col. James Frye's regiment at the battle of Bunker Hill and who built the North Andover home in 1784. The ninth in this unbroken line is Edwina Kittredge, M.D., of Yonkers, N. Y., a niece of George Watson Kittredge.

The boyhood of George Kittredge was spent on the family's fifty-eight-acre farm and home in North Andover where he attended the public schools. He was graduated from the Massachusetts Institute of Technology at Boston in 1877 with the degree of Bachelor of Science in Civil Engineering. After graduation he engaged in private engineering practice and was associated with the South Boston Flats Improvement in 1878 and 1879.

---

[1] Memoir prepared by Boynton S. Voorhees and George A. Noren, Members, ASCE.

He began his railroad career in 1880, at the age of twenty four, as rodman on the lines of the Pennsylvania Railroad Company west of Pittsburgh, Pa. He rose, successively, to division engineer on the Peoria Division, between Peoria, Ill., and Terre Haute, Ind.; the Louisville Division, between Indianapolis, Ind., and Louisville, Ky., and the Panhandle Division, between Pittsburgh and St. Louis, Mo. It was while working on the division last mentioned that the Johnstown (Pa.) flood occurred in 1889. Mr. Kittredge and his bridge, building, and track men were called upon for assistance and were the first reconstruction forces on the scene.

In June, 1890, the Cleveland, Cincinnati, Chicago and St. Louis Railway Company (the Big Four) offered him the job of assistant chief engineer at $2,000 a year. He accepted the offer and ended ten years of service with the Pennsylvania Railroad. During this period, and for several years subsequently, he acted as consultant chief engineer for the Louisville and Jeffersonville Bridge Company.

Mr. Kittredge became engineer, maintenance of way, of the Big Four on December 1, 1890. As this road later, like Mr. Kittredge, joined the New York Central System, it might be said that the last thirty-seven years of his professional life were dedicated to that single employer. At the age of thirty four (on July 1, 1891), he was promoted to the position of chief engineer of the Big Four with headquarters at Cincinnati, Ohio. During the succeeding fifteen years in which he held this position, extensive rebuilding was under way all over the Big Four system under his direction and supervision. A large part was double tracked; wooden bridges were replaced by structures of masonry and steel; alinement was straightened; curvature and gradients were reduced; and several lines of new railroad were built to shorten distance. One of these last projects was the construction of 44 miles of double track into St. Louis to handle the traffic for the World's Fair. In 1904 and 1905 the line from Cincinnati to Indianapolis was rebuilt between Lawrenceburg and Sunman in Indiana, reducing grades and rectifying alinement.

On April 9, 1906, at the age of forty nine, Mr. Kittredge was made chief engineer of the New York Central and Hudson River Railroad (later the New York Central, Buffalo (N. Y.) and East). The construction of the Grand Central Terminal was just starting; the electrification out of New York, N. Y., had been ordered; the freight situation on the west side of New York City was acute; at Albany, N. Y., and Buffalo, congestion of traffic was developing; at Rochester, Utica, and Rome in New York, improved facilities were needed; projects for four-tracking between New York and Albany were under study. These and other varied improvements (engine terminal, passenger station, grade revision, freight yard, etc.) were consummated under his direction and supervision, including the Hudson River Connecting Railroad (Castleton Cutoff) which eliminated the Albany bottleneck. Before his retirement on January 1, 1927, plans for the Buffalo Station, the Syracuse Improvement, and the West Side Improvement in New York City were well advanced. Among his other activities during this busy period, he was valuation engineer for the New York Central Railroad (Buffalo and East) and a member of the

Engineering Committee of the New York Central System. From 1911 to 1927 he was vice-president of the Eastern Railroad Association and a member of its executive committee.

Mr. Kittredge was a charter member of the American Railway Engineering Association, serving as president for two years (1901–1902 and 1902–1903), and was made an honorary member in 1933. He was also active on its committees and was chairman of Committee No. 18—Electricity, from 1909 to 1913. Prominent in Society affairs, he served as Director from 1908 to 1910 and as Vice-President in 1917 and 1918. He was active in committee work and on the Library Board of United Engineering Trustees. In 1931 Mr. Kittredge was a member of a committee to assemble authentic information relative to engineering opportunities in Russia. Always keenly interested in engineering society activities, he encouraged younger men to join, to participate in discussions, and to state their opinions and experiences. He well knew that such interest and activity were the surest way to produce valuable members and to increase engineering knowledge.

In addition to the foregoing societies, he was a member of the New York Society of the Order of Founders and Patriots of America, the Society of the Mayflower Descendants, the American Association for the Advancement of Science, and the Fortnightly Club for the Study of Anthropology. He attended church consistently and served as trustee for the Unitarian Church of Yonkers.

Mr. Kittredge interested himself deeply in the advancement of education and was active especially in the Halsted School of Yonkers, serving as president and finally president emeritus. He was coauthor of the early editions and author of the 1923 and 1926 editions of "The Metal Workers Pattern Book." After his retirement he was a consulting engineer for railroads in the United States and Canada.

He was an opera lover and enjoyed social functions. He played golf and for a number of years was a member of the Ardsley-on-Hudson (N. Y.) Club. His great hobby was the breeding and racing of homing pigeons. His love for animals, and pigeons especially, dated back to his boyhood days spent on a New England farm. His pigeon "Old Dearborn" held the one thousand-mile record; "Old Chatty" was released at Chattanooga, Tenn., at 6 a.m. and was in Yonkers at 9 a.m. the second morning; a pure white cock made 150 miles in 132 minutes. His pigeons were in both world wars and in World War I his pigeon carried the first carrier message from the front line trenches.

On October 17, 1888, Mr. Kittredge was married to Georgia Davis of Louisville. Mrs. Kittredge died on December 29, 1921. He is survived by a daughter, Mary Henrietta (Mrs. Denman McNear) of Petaluma, Calif.; and a son, George Davis Kittredge, a civilian employee with the Army Engineers in Puerto Rico. Also surviving are a grandson, Denman Kittredge McNear, a student at the Massachusetts Institute of Technology; and two granddaughters, Mary McNear (Mrs. James McNab) of San Francisco, Calif., and Georgia Kittredge (Mrs. Kenneth Schick) of Buffalo.

Mr. Kittredge was elected a Member of the American Society of Civil Engineers on January 6, 1886, and an Honorary Member on October 5, 1931.

LUIGI LUIGGI, Hon. M. ASCE[1]

DIED FEBRUARY 1, 1931

Massauwa, Tobruk, Derna, Bengasi, Homs, Palermo, Messina, Leghorn, Spezia, Genoa—ports bombed by Americans and Britons in World War II—were the life work of one of the world's outstanding harbor engineers, Luigi Luiggi.

With the practical nature, thrift, and conservatism characteristic of the Genoese, he abhorred waste—especially the waste of war. For forty years he had endeavored to build and to strengthen cordial relations between Italy and the two countries he admired deeply—England and the United States. Those who loved him—that is to say those who knew him—are glad he died before Italy was enchained to her enemy of two thousand years. Invariably when the name Germany came up in private conversation he had repeated, "It is a nation not to be trusted."

Luigi Luiggi was born on August 3, 1856, at Genoa. His grandfather, Pasquale Luiggi, was a captain of artillery in the port of Spezia. His father, Settimio Luiggi, had a stationery shop in Genoa which is still in the family. His mother, Francesca Bruzza, died when he was a young child. His father then married Paola Rossi; her stepson never forgot her angelic patience and serenity while bringing up the two families each of four children.

His preliminary education was received in Genoa, including two years at the University of Genoa. In 1875 he entered the Royal Civil Engineering College in Turin and was graduated in 1878 with the degree of Civil Engineer.

In 1880 he was appointed junior engineer in the Royal Corps of Italian Engineers and was sent to England to study harbors and lighthouses for two years under the late Sir James Douglas. Part of the basis for his appointment was the high rating he received in the English language courses. He recalled with amusement in later years that to his chagrin on landing at Dover the speech of Englishmen bore so little resemblance to that taught in Turin, he could make himself understood only in writing.

While in England he met Annie East of Lincoln, to whom he was married in 1887. The relationship was a happy one and her death on February 28, 1911, left for twenty years a void in his life that intensive work or travel could never fill. The home they planned together on Via Nomentana in Rome, in which many engineers from all over the world found welcome, bears their combined names in Spanish "Villa Luis-y-Ana." They had a daughter, Luise, and a son, M. L. Luiggi, an engineer, who has lived in the United States since 1920.

When he returned to Italy in 1882, he was sent to build a harbor in steaming Massaua. In connection with this project he spent some time at

---

[1] Memoir prepared by Mrs. M. L. Luiggi, New York, N. Y.

Famagusta on the island of Cyprus, where he was associated with the silent and pious young engineer who later became Lord Kitchener.

On again returning to Italy he was appointed a member of a staff of engineers to modernize the port of Genoa. His special work was constructing two dry docks behind the old mole and two great breakwaters, one a mile long, extending from 80 to 100 feet into the water. Fifty years later when the port was again enlarged, part of one of his breakwaters had to be removed. To his secret satisfaction, this was done with greatest difficulty.

Plans for enlarging the port, he found, called for the destruction of the beautiful Bank of St. George, built in the thirteenth century and believed to be the first building designed especially for banking purposes. In accordance with his lifetime motto, "Do not tear down the old; build new," he worked out a scheme to save the building. Original arrangements had called for a narrow road and a railroad running parallel to the harbor's edge, through the bank site. He relocated the railroad on the seaward side of the bank, below road level, on land made by building the harbor toward the sea and filling in. On the city side he tore down old tenements and laid out a wide road which he foresaw Genoa would eventually need along the sea. This great road was slowly extended so that, thanks to his forethought in the 1880's, Genoa has the most outstanding water-front highway of any Riviera city.

Similarly, by use of imagination, he preserved for his wife's home city of Lincoln, an irreplaceable antiquity, the "Stonebow," an arched gateway, remaining from the Roman city wall. To widen its main street the city planned to demolish this arch. Mr. Luiggi prepared a plan to route traffic one way and to build a cutoff road. The Stonebow remains one of Lincoln's attractions.

To obtain fill for the harbor of Genoa, heretofore brought by sea, Mr. Luiggi opened a quarry in a hill in the middle of the city. The citizenry, indignant at first, were delighted when a wide boulevard finally emerged through the hill to relieve congestion on narrow streets and connect Genoa with neighboring towns to the west.

In 1892–1893 he served as technical secretary to the ministry of public works in Rome. To study the working of railway ferryboats he went to Denmark and to New York (N. Y.)—the first of innumerable trips to the United States. On his return he directed the installation of railway ferries from the mainland across the Straits of Messina to Sicily.

During 1894–1895, as chief engineer of the ports of Tuscany, he overhauled and enlarged the harbors of Leghorn and Spezia. On the island of Tino, near Spezia, he installed the first electrically operated lighthouse in Italy. Power came from Ericsson hot air engines.

In 1896 Mr. Luiggi was chosen by the government of Argentina to select a site, prepare plans, and supervise construction of a military harbor for the upkeep of its nascent navy. After a detailed survey of the entire coast he chose a zone in an uninhabited sandy waste along the estuary of Bahia Blanca.

Within ten years this had been transformed into the most important harbor in the southern hemisphere. Among projects completed were a 1,000-

foot graving dock with a very low sill to allow entry of warships in sinking condition; wharves; a breakwater; lighthouses; buoys in the dredged channel; defense batteries at the harbor entrance and a railway connecting them with the main line 30 miles away; roads, sewers, a power station, and a water supply from sand dunes 5 miles away. To provide labor, he brought several thousand picked workmen from Italy, for whom hospitals and barracks were built. During these ten years he preferred to stay at Puerto Militar, close to his job, rather than to live at ease in Buenos Aires and supervise the work through resident engineers.

On concluding this work he was made an honorary citizen of Bahia Blanca and a principal street was named for him. Although a school in Bahia Blanca bears the name of Umberto I, Mr. Luiggi always thought of it as a memorial to the charm and determination of his British wife. When the king of Italy was assassinated in 1900, Italian workmen contributed a considerable sum of money to buy a bronze wreath for his tomb. Hearing of this during the absence of her husband, Mrs. Luiggi went before the final meeting and, in halting but obviously effective Italian, persuaded the donors to build a school for their children with the money.

At this school, Mr. Luiggi introduced Arbor Day in Argentina and presented trees for the pupils to plant on their school grounds. Always an ardent advocate of reforestation, he planted 100,000 eucalyptus trees around Puerto Militar (later called Puerto Belgrano) to prevent shifting of sand dunes. He set up extensive nurseries of eucalyptus and tamarisk from which the government made massive plantings along the dunes far down the coast.

In connection with Puerto Militar, he erected a chain of lighthouses and semaphores from Buenos Aires to the southernmost tip of Patagonia, some 800 miles distant. All were connected by a telegraph line. With only primitive means of transportation then available, it was a formidable undertaking. These, as well as the tower on the administration building overlooking Puerto Belgrano, bear the triple motif from the papal crown which only Genoese engineers may rightfully use. Pope Innocent III permitted its use by Genoese builders when, during a crusade, a Genoese engineer, Guglielmo Embriacus, devised the tenth century version of a tank. Armored scaffolds were pushed against the walls of Jerusalem and the walls were scaled and breached from inside the scaffolds. As a loyal son of Genoa, Mr. Luiggi always worked the motif somewhere into his constructions.

During his years in Argentina, he acted as consultant for new harbor works of Buenos Aires, Mar del Plata, Rosario de Santa Fe, Montevideo, and Rio Grande do Sul. He also reported on several proposed canals for inland navigation and for irrigation of the pampas.

He always referred to his years in Argentina as the happiest of his life. It was with great pleasure that he returned in 1910 as representative of the Italian government to the centenary celebration of Argentine independence. At this time he prepared plans for expanding the harbor of Buenos Aires, following his customary method—building out into the sea, then dredging sand from the approach channel and using it as fill. Thus, land area was increased and deep cuttings and heavy earth movements were avoided. In his honor, a railhead town in the Pampa Central was named "Ing. Luiggi." A library to his memory has been built in this flourishing community by his son.

Again, in September, 1928, he returned, amid warm welcomes, to unveil a monument of General Belgrano by the Italian sculptor, Arnaldo Zocchi, the gift of citizens of Genoa to the city of Rosario de Santa Fe. On this last visit to the country for which he had so strong an attachment, he was asked by the government to complete the expansion project of his plan of 1896 for Puerto Militar.

To symbolize the close relationship between the people of Argentina and Italy, a graceful white marble lighthouse which he designed stands on the Janiculum hill behind the Vatican. It was built in 1911 by popular subscription from Italians in Argentina. Nightly it flashes the red, white, and green of the Italian flag onto the dark perennial oaks in the Pincio gardens across the Tiber.

It gave him much pleasure to install a similar light in 1912 when planning improvements in navigation of Lake Garda. Before World War I the north half of the lake belonged to Austria, and although the population was chiefly Italian, the Italian flag could not be displayed. From a new lighthouse he built at Sermione, the forbidden red, white, and green swept over the facade of the city hall in Austrian Riva di Garda.

On returning to Italy in 1906, Mr. Luiggi became inspector general of the Royal Corps of Civil Engineers and was appointed to the seven-member board of directors of the Italian State Railways. In 1906 when the contracts leasing the railways to private operating companies expired, the government decided to appoint a board of directors responsible to parliament for their rehabilitation and operation. Rolling stock was insufficient, rights of way had long been poorly maintained, and marshalling yards were inadequate. Until 1911 he was in charge of personnel, equipment, and electrification.

Especially important was the line through the Alps between Turin and Modane. This link with France had vital strategic importance since the only other connection was the highly vulnerable one through Ventimiglia, along the Mediterranean coast. The French government had decided to double-track the steam access railway on its side to the 8-mile-long tunnel at the summit of Montcenis.

Mr. Luiggi, on the other hand, decided to electrify the single-track section from Turin to the Italian portal. The expense of building a double track on this winding, mountainous line with heavy gradients would have been prohibitive. He decided on a synchronous, three-phase system to give constant speed both in upgrade and downgrade so that trains would meet exactly on time at crossings. The wisdom of his choice was shown during World War I, when heavy military traffic was handled much more easily on the Italian than on the French side. Among the many marshalling yards which he built, the large ones at Genoa and at Mestre near Venice were particularly important in World War I.

To effect quick and economical improvement of rolling stock, he bought second-hand locomotives and immediately began expanding locomotive and car building works in Italy. Jointly he and Sen. Riccardo Bianchi developed a series of locomotives ranging from light tank engines for lines where traffic was sparse to heavy decapods for hauling freight on the Porretta line between Bologna and Florence. A new electrified line was begun at a much lower level, but World War I halted construction. When finished in 1932, it included the 11.5-mile "tunnel of the Apennines" at the summit, the longest double-track tunnel in the world.

Early, Mr. Luiggi foresaw the importance of electrical development and was active in building new hydroelectric plants and tying all schemes into one network. At first, plants had to be built to furnish current solely for railways. As soon as possible, he arranged for them to supply power to industry also. Likewise he insisted that all new railway bridges of a certain importance should be built to carry public roads as well. Also, he installed on all trains in Italy, except international expresses, at least one third-class coach.

In 1912 when Italy occupied Tripolitania, he took over projects and works there for the harbors of Tripoli, Bengasi, Derna, and Homs. These, including the building of a system of lighthouses along the Lybian coast, he carried out with exceptional rapidity. At various times he inspected and prepared plans for improving the harbors of Massaua and Assab on the Red Sea, Ras Filuk in Somaliland, and Brava and Benadir on the African east coast.

After this, he was in charge of all Italian harbors, among the more important of which were Genoa, Naples, Palermo, Leghorn, Spezia, and Imperia. An especially interesting project, never carried out, was for a new harbor at Ostia, the port of Rome 25 miles away. He planned it to be built like an atoll in the Mediterranean, connected with the mainland by a causeway. Since Roman days various harbors had been built at Ostia, but had eventually been buried by silt from the Tiber. He estimated that it would be at least 1,000 years before the delta of the Tiber could reach this atoll harbor.

From 1913 until his death he was a member of the International Advisory Board for the Suez Canal and for the harbor of Alsa in Egypt, and he belonged to the European board for navigation of the Danube River. In 1912 he acted as consultant to the Russian government for improving navigation of the Volga River. Collaborating with Sir Cyril Kirkpatrick, he acted for the Egyptian government in the decade before his death, and was responsible for port and harbor undertakings at Alexandria, Damietta, Kossier, and Mersa Matru. In 1925 he visited Rhodes and Durazzo to confer on improving harbors and roads.

Although Mr. Luiggi was one of the outstanding authorities of the past generation on port and harbor works, his interests embraced all types of civil engineering. He carried out important work on navigable and irrigation canals and built or acted as consultant on aqueducts at Bahia Blanca and Puerto Militar in Argentina, as well as those in Leghorn, Lucca, Pontedera, Chiavari, and Apulia, and the Val Noci and Entella aqueducts of Genoa.

In his native commune of Genoa he was honorary consultant for the Genoa-Milan-Stelvio and Genoa-Piacenza railways, for the Lavagna-Cavi road, and for the hospitals of Pammantone and Albera. He gave his services to the commune of Chiavari for defense against inroads of the sea.

An illustration of his ingeniousness in solving problems is found in the borax works at Lardarello in central Italy, where he harnessed several small volcanoes to produce electric power. During World War I, with coal scarce, he exerted every effort toward maximum utilization of Italy's electrical resources. Since Roman times, borax has been extracted from these volcanoes by injecting water into the ground. It is returned as superheated steam, rich in boric acid. Mr. Luiggi, to preserve the heat in this steam, passed it through an aluminum heat exchanger so that as the boric acid deposited, the superheat was utilized to produce low pressure steam for operating turbines. As much as 10,000 kilowatts were produced.

Another increase in Italy's resources which he aided on every possible occasion was the replanting of denuded hills. Particularly in southern Italy he encouraged tree planting as a control to violent flash-floods that swept away railway bridges year after year. He presented trees for planting by school children of many localities (accompanying the trees with a treat for each child). He reiterated:

> "Whoever plants new trees or protects those already planted, contributes to the prosperity of the country. He helps regulate water, produces building material, beautifies the landscape, and renders life more healthful and pleasanter. Whoever plants new trees serves his country."

He was author of monographs on the ports of Antwerp, Southampton, Hull, Genoa, and Tripoli; on Argentine lighthouses and the electric lighthouse in the harbor of Spezia; and on the advantages of electric traction. One report described the great construction difficulties in building the Apulian aqueduct in Southern Italy, the longest in the world when it was completed in 1913. He published various articles on dams, both of concrete—principally the multiple-arch type—and of earth. These latter types he considered the most suitable for Italian needs and did much to develop their use.

A series of sunken dams which he built in riverbeds in the Tessenei region of Italian Somaliland were successful in storing up water to raise the subsurface level so that cotton could be successfully grown in the area. During summer months, water coming from the mountains had lost itself in the wide, sandy river bottoms. He built clay cutoffs in trenches across the river beds to impound the water. Heavy loss from evaporation was averted by keeping the level below the surface.

Perhaps his most important publications are those on his research as to the force of sea waves and their effects on breakwaters. Others were on concrete, reinforced concrete, pozzuolanic cement, and other materials best adapted to resist corrosive action of sea water. He also published the results of experiments on adhesion of concrete to iron, both clean and rusted, and on the type of reinforced concrete best adapted for piers, caissons, and other maritime constructions. His reports are valued because he was an authority on the subject of pozzolana and pozzolana mortars and cement for making concrete blocks that are cheaper and more durable in sea water than those made with ordinary Portland cement.

Endowed with an expansive and sympathetic personality as well as a keen mind, Mr. Luiggi made himself more than an accomplished linguist. "When I speak French with a Frenchman, I think as a Frenchman—I really am a Frenchman," he often said. He felt equally able to think in English or Spanish. Within six months of landing in Argentina he had acquired fluent Spanish. He spoke German less easily.

Because he was a real citizen of the world, his country relied upon him for four decades to represent it with dignity and charm in international congresses. He served as delegate to such gatherings in Frankfurt, Manchester, Paris, Chicago, London, Petrograd, Stockholm, Buenos Aires, Philadelphia, San Francisco, Geneva, Lausanne, and Tokyo, among others.

He was particularly happy in his relations with English-speaking countries. In July, 1914, he visited Australia as honorary guest of the British Association for the Advancement of Science and delivered several lectures on Italian irrigation at the universities of Melbourne, Adelaide, and Sydney. From Melbourne he received the honorary degree of Doctor of Science. At the request of the Australian government he made recommendations for unification of railway gages. The University of London in 1922 invited him to give a course of lectures on characteristic Italian hydroelectric works.

He headed the Italian section of the International Trade Congress on its visit to various cities in the United States in 1919, and remembered Denver (Colo.) and Kansas City (Mo.) with special pleasure. He was vice-president of the International Chamber of Commerce soon after it was organized. At the meeting in Rome in 1922 he was unofficial host, a role which he enjoyed and in which he was unsurpassed. Many who came from various parts of the world will recall luncheons in the sunny room overlooking the Roman campagna toward Tivoli and Castel Gandolfo, where often several languages were being spoken at the long table. When especially well-known guests were expected, he invariably included some obscure acquaintance. "It will give her pleasure the rest of her life to remember that she sat next to a Cardinal," he answered when a relative remonstrated with him for placing an elderly filing clerk beside His Eminence.

In 1930 he was given by the Hon. Herbert Hoover, Hon. M. ASCE, then president of the United States, one of sixteen gold medals struck off at the fiftieth anniversary of the American Society of Mechanical Engineers. From Rensselaer Polytechnic Institute in Troy (N. Y.), he received the honorary degree of Doctor of Engineering in 1925.

He was a member of the institutes of Civil Engineers and Structural Engineers of London, the College of Engineers of Genoa, and the Centro Nacional de Ingenieros of Buenos Aires. He was honorary correspondent member of the Sociedad Cientifica Argentina. For three terms of three years each he served as president of the Italian Society of Civil Engineers in Rome.

From the king of Italy he received three high honors: Grand Commander of Saints Maurice and Lazzarus, Grand Commander of the Star of Italy, and Grand Commander of the Crown of Italy. He also received a medal for engineering services during the Abyssinian campaign of 1882–1884 and that of Lybia in 1911–1912. A gold medal was given him for his work as member of the munition board of World War I, in which his title was honorary colonel of engineers. The Italian Red Cross also gave him a gold medal for his aid in organizing transportation.

The crimson rosette of the Legion d'Honneur was awarded him by the Republic of France for arbitrating disputes between French and Italian industries. For acting as consultant on the ports of Candia, Piraeus, and Salonika, the Greek government gave him the cross of Saint Salvatore. The title that he prized most, however, was the one on his hospitable doorway—Ing. Luiggi—Engineer Luiggi.

In 1921 he undertook the thankless job of acting as member of parliament from Genoa, hoping to help restore order after postwar political disturbances. He resigned with relief on being appointed to the Italian Senate in 1924. Members of this supreme advisory body are chosen for life from leaders in various fields.

Although he retired from active public life in 1923 as honorary president of the superior council of the corps of engineers, some of his most useful advisory work was done in his last eight years. Whenever Italy needed a representative at international congresses and conferences—where few faces were more familiar than his—he would continue to go, although his health became increasingly less robust.

At the time of his retirement he was president of the royal commission of irrigation; member of the council of administration of state railways; member of the higher council of public instruction; and professor of hydraulics and maritime construction at the University of Rome.

He continued to give a course of lectures each year at the university because he had always taken keen pleasure in associating with young engineers and in passing on his accumulated knowledge to them. His library of some twenty thousand engineering books, pamphlets, maps, and plans was presented by his son to that engineering school. It is housed in a bright, frescoed room and a bronze bust of him, created by his friend, the sculptor Arnaldo Zocchi, keeps paternal watch over the students.

He last saw his many American friends in September, 1930, when he headed the Italian delegation to the International Roads Congress in New York. In 1926 he had served as president of the congress at its first meeting in Milan.

Senator Luiggi had looked forward with eagerness to going to Hull (England) in April, 1931, to consult with his colleague of many years, Sir Cyril Kirkpatrick, on the widening of the Humber River, but death came on February 1.

He had been on a leisurely drive with an old friend from Argentina on a January morning when spring flowers were already in bloom in his garden.

"The day is too perfect to go indoors—" he said, and was suddenly silent. Cerebral thrombosis had struck and he died five days later.

To muted dirges from a military band he was carried across the street to the eighth century church of Saint Agnes. Vatican singers chanted softly during the simple rites. Then he was laid in the chapel tomb he had designed twenty years before, on which were entwined details from the cathedrals of Lincoln and Genoa.

Mr. Luiggi was elected a Member of the American Society of Civil Engineers on February 7, 1906, and an Honorary Member on October 10, 1921.

Members

FRANK HOOKER ALFRED, M. ASCE[1]

Died October 6, 1947

Frank Hooker Alfred was born on December 24, 1866, at Logan, Ohio. His parents were George Washington Alfred, a native of Burlington, Vt., and Mary Loraine Hooker, who was born near Baltimore, Md.

Later the family moved to a farm on the outskirts of Lancaster, Ohio, in which city the father established a law practice. Frank Alfred attended the public schools of Lancaster and was graduated from the local high school. At that time, a sewerage system was being installed in Lancaster. Young Frank, much intrigued by the doings of the engineers, decided that he would like such work and shortly obtained a position as chainman and rodman on the corps. However, when he enrolled at the University of Michigan at Ann Arbor in 1886, he planned to study law, his father's profession.

When the college year ended, Mr. Alfred obtained a job as rodman on the construction of the Columbus, Lima and Milwaukee Railroad. He found himself in his element, and it was not long before he became resident engineer. The idea of leaving active and responsible work to return to college made no appeal whatever to him, so he continued with the railroad until its completion in 1889, going then to the Norfolk and Western Railway as assistant engineer. In 1892 and 1893 he had charge of field work and construction on the Columbus (Ohio) terminal, and during that time contrived to study engineering for a year at Ohio State University at Columbus.

In May, 1894, an event occurred which Mr. Alfred always considered the most fortunate of his career. He met Maud Bush, a native of Mansfield, Ohio, whose family was then living in Daytona, Fla. They were married in Daytona on October 17, 1894. It was a union that endured in happiness for fifty-three years. To it Mrs. Alfred brought qualities of sagacity, poise, and thoughtful devotion that made their home a haven of peace that was no small factor in his success.

---

[1] Memoir prepared by Paul Chipman, M. ASCE.

After a brief period with the Denver and Rio Grande Western Railroad Company, Mr. Alfred become engineer, maintenance of way, of the Cleveland, Akron and Columbus Railway Company, remaining in that position until November, 1899, when he joined the Wheeling and Lake Erie Railway Company as engineer, maintenance of way.

In the latter part of the year 1900, the State of Michigan began an appraisal of the railroad property within its borders with a view toward uniform taxation. This was the first railroad valuation to be based on inspection and, to a large extent, it set the pattern for the federal valuation begun in 1913. This appraisal was made under the direction of Mortimer E. Cooley,[2] Hon. M. ASCE, with Henry Earle Riggs, Past-President and Hon. M. ASCE, in charge of the roadway division. Time was limited and a force of about one hundred and fifty men was hastily recruited—for the most part, engineers from the middle west. Mr. Alfred was offered a position on this work and was assigned the important task of determining unit prices and supervising the computing office. As the project drew to a close in 1901, Mr. Riggs was asked by the president of the newly formed Pere Marquette Railroad Company to select some young man from his force who would make a competent chief engineer and would qualify for promotion. He named Mr. Alfred, who in 1902, after a brief trial period as district engineer, became the chief engineer of the railroad that was eventually to become the field of his most constructive efforts.

The Pere Marquette was then making some extensive grade revisions and in 1903, by acquiring its Canadian lines, extended its operations to the Niagara frontier; at the same time a short extension to the southwest made possible a great improvement in its Chicago (Ill.) terminal arrangements. Numerous surveys were made to determine the feasibility of line and grade changes and new routes. All this work, as well as maintenance of way, was under the supervision of the new chief engineer. At about this time the seemingly bright prospects of the rapidly expanding Pere Marquette made it the object of financial manipulation which saddled it with heavy fixed charges. Mr. Alfred saw the consequences of this situation and later was to have an active hand in correcting it.

In 1905 Canada was entering a period of rapid development. J. G. White and Company, engineers and contractors of New York, N. Y., formed a subsidiary known as Canadian White Company, Limited, with headquarters at Montreal, Que. Mr. Alfred was chosen general manager of this company, and filled the position until the depression of 1907–1908 caused the company's discontinuance. During this period he directed the construction of a number of important projects; among them were a large hydroelectric plant on the Soulanges Canal near Montreal, a section of the Grand Trunk Pacific Railway in Saskatchewan, and a sewer system at Calgary, Alberta.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 110, 1945, p. 1619.

Mr. Alfred returned to his primary interest of railroading by becoming assistant to the president of the Cincinnati, Hamilton and Dayton Railway Company in 1908 and two years later was made general superintendent. In April, 1912, he returned to the Pere Marquette as assistant general manager and in December of that year he was made general manager for the receivers, who leaned heavily upon him in shaping their policy. On the reorganization of the Pere Marquette in April, 1917, he was chosen president and general manager.

His talents were admirably suited to the task before him—the rehabilitation of a property, the resources of which had been drained by excessive fixed charges, in order to meet the demands of a territory that was rapidly developing industrially. Abhorring waste, he kept a tight rein on expenditures, but welcomed every justifiable improvement. The track structure was improved, new yards were constructed and old ones extended, signal facilities were installed and improved, and new cars and locomotives were bought. This work was delayed at its start by the entry of the United States into World War I and the consequent taking over of the railroads by the federal government. During this period, Mr. Alfred was a regional director for the railroad administration, having in his charge the Pere Marquette, the Grand Trunk Western Railway, the Ann Arbor Railroad, and the Detroit and Mackinac Railway.

As the result of the improvement program and of the growth and prosperity of the industries in the territory, the net earnings of the Pere Marquette soon became very satisfactory. Mr. Alfred had attractive offers to enter broader fields, but he did not like to quit an unfinished job nor did he like to break his associations in Detroit, Mich. Wistful glances were now being cast toward the Pere Marquette from various quarters. The Van Sweringen interests failed to secure approval of a merger of the Chesapeake and Ohio, the Nickel Plate, the Erie, and the Pere Marquette roads; but the Interstate Commerce Commission, recognizing the mutual advantage of affiliation, authorized the purchase by the Chesapeake and Ohio of a controlling interest in the Pere Marquette. This was soon accomplished and the affiliation continued in this form until 1947, when the Pere Marquette was merged with the Chesapeake and Ohio by an exchange of securities.

Mr. Alfred retired from active duties on the Pere Marquette in August, 1929, but continued for a time as consultant on special assignments. Undoubtedly, the rehabilitation of the Pere Marquette was his greatest achievement. Making all due allowance for better business conditions, it was the policies he advocated and his leadership in putting them into effect that made it possible within a few years to transform a bankrupt railroad into a highly profitable one.

Mr. Alfred was more widely known in Detroit as a civic leader than as a railroad administrator. He was a director and one of the founders of the Governmental Research Bureau (later the Citizens' League), the function of which was to supply voters with information regarding candidates and public issues. Starting in 1917 he served for many years on the Detroit Board of

Education, a part of the time as its president, and was for several years a member of the Detroit Library Commission. A trustee of the Young Men's Christian Association, he headed a campaign in 1920 to provide adequate facilities for that organization in rapidly growing Detroit. He was a trustee of the First Baptist Church of Detroit, of Kalamazoo College (Kalamazoo, Mich.), and of the Salvation Army.

In business, he was a director of the Mid-West Casualty Company, the Selected Securities Corporation, and the Commonwealth-Federal Bank, one of two Detroit commercial banks that weathered the storm of 1933 without reorganization. Like many a man brought up on a farm, he had a liking for country life which led him in 1920 to purchase a six hundred-acre estate near Milford, Mich. His family spent part of the year there for a number of seasons, and he would join them for such limited periods as his duties permitted.

In 1933 he was appointed by Franklin D. Roosevelt, President of the United States, as chairman of the three-man Michigan Advisory Board of the Public Works Administration and served until the duties of that board were completed in the following year. This was the only political appointment that he ever held, and it was accepted with the understanding that politics would have no part in the activities of the board. This stipulation was strictly observed, in contrast with the functioning of similar boards in many other states.

After his retirement from active work, he declined opportunities in broad administrative fields in both railroad and public service. This was fortunate, for in a short time he was warned that the state of his health would not permit any considerable activity. Thereafter, he disposed of his country estate and he and Mrs. Alfred divided their time between their summer cottage at Walloon Lake, near Charlevoix, Mich., and Orlando, Fla., where they purchased a home which eventually became their yearlong residence. He now had ample opportunity to indulge his fondness for good reading and made many additions to his already extensive library.

Perhaps his outstanding attribute was courage, moral and physical—"Courage, the footstool of the virtues, upon which they all stand." Once a conviction was formed, he did not hesitate to give it voice on due occasion. Aggressive but cautious, he planned his course with care, after due counsel, and held it with determination, with little regard for personal consequence. A more apparent trait was intense concentration on the task in hand. A job was something to be done, and done well, but without delay. Of great mental and physical vigor, he never acquired an easy pace in his work. The tension was often relieved by flashes of humor, however, for his ingrained jocularity was another marked characteristic. He kept it under reasonable control during serious discussion, but in his home and among friends it had free rein. In work or play, he relished a contest, preferably as a participant rather than as a spectator. As a young man he was fond of baseball, and in the rather infrequent hours of relaxation in his later active life he played a good game of golf and an excellent game of billiards.

A keen judge of men and motives, his discernment and sincerity commanded the respect of all. He inspired loyalty by his fairness, his enthusiasm, and his consideration for those about him. He prized originality and initiative, but valued the patience and persistence of the routine worker, and had high praise for good craftsmanship in any field. Interested in any practical plan for social betterment, he was generous in promoting self-help and self-reliance, but did not approve of indiscriminate charity. Underlying all his deeds and decisions, hidden from public view and revealed to but few associates, was an enduring faith in the great Engineer of the Universe, whose guidance he sought throughout his life. The confinement of his last years was borne with the same courage and cheerfulness that distinguished his entire career.

When living in Detroit, Mr. Alfred was a member of the Detroit Club, the Detroit Golf Club, the Oakland Hills Country Club, and the Ingleside Club. He was a life member of the American Railway Engineering Association.

He is survived by his widow; a daughter, Dorothy (Mrs. Wilton W. Minto), of Detroit; and three grandchildren, Wilton, Maud, and Alfred Minto.

Mr. Alfred was elected a Member of the American Society of Civil Engineers on June 3, 1903.

EDWARD ANDERBERG, M. ASCE[1]

DIED JANUARY 18, 1947

No one could have been associated with Edward Anderberg for long without recognizing his essential goodness, uprightness, and integrity. Associated with these elements of character was a keen, analytical mind, and a store of technical knowledge gained from many years of work on projects of magnitude in various parts of the United States.

Edward Anderberg was born into a well-to-do family at Mount Vernon, N. Y., on September 23, 1881. His parents were Erland and Mary (Drews) Anderberg. Mr. Anderberg was graduated from the Mount Vernon High School in 1899, and in September of that year, he entered New York University in New York, N. Y., where he received the degree of Bachelor of Science in Civil Engineering in 1904, and the degree of Civil Engineer in 1909. He was a member of Delta Upsilon fraternity.

Due to ill health, he spent the year 1902–1903 in the west, and for a period of nine months, he worked with a survey party of the Atchison, Topeka and Sante Fe Railroad Company in New Mexico, Texas, Oklahoma, and Kansas. In 1904 and 1905 he was employed in Basking Ridge, N. J., on surveying work.

---

[1] Memoir prepared by Leslie G. Holleran, Stanley H. Wright, and Samuel Rosenberg, Members, ASCE.

From 1905 to 1925, Mr. Anderberg worked for the State of New York on surveys and designs for the Barge Canal, and on the supervision of Barge Canal construction contracts of considerable magnitude. His design work included locks and other structures, as well as the Barge Canal terminals in New York City, and elsewhere. He supervised construction of the Barge Canal through difficult terrain in upstate New York, as well as the Lockport (N. Y.) locks and bridges. As senior assistant engineer, he was in charge of the New York City residency of the state engineers' office from 1917 to 1925, and directed the construction of eight Barge Canal terminals and a grain elevator there.

In 1925 Mr. Anderberg entered the employ of the Westchester County Park Commission as right-of-way engineer, but was soon promoted to division engineer, in charge of the commission's construction work in the easterly half of the county, during the development of its extensive park and parkway program. The projects on which he supervised construction were: The Hutchinson River Parkway, the Cross-County Parkway, and part of the Saw Mill River Parkway; also the Glen Island bathing beach and bathhouse, together with the approach road and the bascule bridge; and the Saxons Woods Golf Course, parts of Playland at Rye Beach; and numerous smaller projects.

The parkway project included numerous stone-faced reinforced concrete bridges, several of which were of rigid-frame design as adapted to bridge construction shortly before by the engineering department of the Westchester County Park Commission. At that time, the design and construction of parkways was a new development, and Mr. Anderberg took part in the pioneer work of the commission in planning them.

In 1933, due to the depression, construction work of the park commission was suspended and Mr. Anderberg was appointed engineer examiner in the Office of Director of the Public Works Administration (P. W. A.) for New York State. Later, he was promoted to assistant chief engineer for the state. In these positions, Mr. Anderberg reviewed or supervised the review of numerous and varied municipal projects for which funds had been requested from the P. W. A.

On completion of this assignment in 1937, he became assistant manager, and afterwards, manager of the planning division for the Works Progress Administration in New York City. From 1938 to 1940, he was responsible for the review and administration of the federal supervision of important municipal projects in New York State for the P. W. A.

In February, 1941, Mr. Anderberg was recalled from retirement by Col. H. M. Waite, who was organizing the Defense Projects Unit, which was later called the War Projects Unit of the Bureau of the Budget. Mr. Anderberg's former experience in governmental service with the P. W. A. had especially equipped him for war service with a group of engineers who were to prepare "confidential" and "secret" reports on war activities. His construction engineering experience was used during 1941, 1942, and 1943, in connection with critical surveys of contracts, covering a wide range of facilities—from airfields and aircraft plants to various types of ammunition and ammunition component manufacturing plants, hospitals, and shipbuilding and industrial plants of all kinds—constructed with governmental funds to meet the war emergencies. When these facilities were completed and placed in operation, progress and production reports were prepared in the War Projects Unit for various purposes. Mr. Anderberg had prepared himself to take over field reporting on the production of airplanes, aviation gasoline, synthetic rubber, ammunition components, and other articles of war. With the passing of Colonel Waite, his associate, Col. E. W. Clark, assumed the direction of the War Projects Unit. Colonel Clark had only the highest praise for Mr. Anderberg's work, and he continued with the War Projects Unit until it was terminated on December 31, 1945.

Following the retirement of Colonel Clark, this group of engineers was reorganized into the inspection group, Division of Estimates, in the Bureau of the Budget. The change from wartime to peacetime activities necessarily changed the scope of the work of the engineers in the inspection group, but without lessening the need for men with technical experience and training. Mr. Anderberg continued his activities with this group until his death, which occurred shortly after his return from a meeting with the United States Army Engineers in Columbus, Ohio. The nature of this confidential work required the utmost tact, diplomacy, analytical ability, technical skill, and a consideration for others. Mr. Anderberg was noted for all these traits.

While engaged on the construction of the Barge Canal at Lockport, Mr. Anderberg met and was married to Winifred Huntley in 1911. His widow and four children, Mary Ralston, Jannet Elizabeth, Elinor Drews, and Edward, Jr., survive, as well as two sisters—Clara G. and Augusta H. Anderberg.

For many years prior to his death, Mr. Anderberg lived with his family at 26 Oakwood Avenue, White Plains, N. Y. He was a vestryman at Christ Protestant Episcopal Church, in Lynbrook, N. Y., for two years prior to moving to White Plains in 1925. He was also a life member of the Red Jacket Lodge of the F. and A. M. in Lockport.

Mr. Anderberg had great respect for the right of other people to choose their own way of life, either individually or as nations. This was evident from the wide latitude he gave his children in their selection of subjects at college, and in the life work they wished to follow. He was concerned about his former associates, some of whom he felt could not readily adjust themselves to new associations during the depression and after World War II, and he made it his business to interest people in their behalf. He was friendly, but somewhat reserved in his association with others, and not many were privileged to know him intimately. Those who knew him will feel keenly the loss of this kindly, considerate, and understanding friend.

Mr. Anderberg was elected a Junior of the American Society of Civil Engineers on March 5, 1907; an Associate Member on March 1, 1910; and a Member on April 4, 1922. He became a Life Member in January, 1945.

RUPERT ANDREW ANDEREGG, M. ASCE[1]

Died July 18, 1947

Rupert Andrew Anderegg, the eldest son of James Albert and Lily May (Turrittin) Anderegg, was born in Kasota, Minn., on February 8, 1894. The family consisted of one daughter and six sons.

Rupert received his early education in the public schools of Le Sueur, Minn. In September, 1913, he entered the University of Cincinnati (Cincinnati, Ohio) as a cooperative student in civil engineering. While a cooperative student, he performed surveying work, in the various capacities of chainman, rodman, and instrumentman, which was followed in succession by railroad trackwork, concrete viaduct construction, simplex pile construction, and inspection work on concrete building erection. In addition to his academic studies and cooperative employment Mr. Anderegg participated in college athletics and was a member of the football squad.

On August 13, 1917, young Mr. Anderegg was commissioned a Second Lieutenant in the Corps of Engineers, United States Army. He served as a Second Lieutenant with the First Engineers until November, 1918. From November, 1918, to February, 1919, he was a First Lieutenant in the Chemical Warfare Service and Assistant Division Gas Officer of the Ninety-Second Division; one year of this service was in Europe.

Following the termination of this military duty, Mr. Anderegg accepted a commission in the Officers' Reserve Corps. He was active in the reserve until ill health made it mandatory for him to go on an inactive status in 1941. He held successive reserve commissions as Second Lieutenant, First Lieutenant, and Captain in the Corps of Engineers, and those of Captain, Major, and Lieutenant Colonel in the Coast Artillery Corps (antiaircraft division). In 1941 he was ordered to active duty with the Second Army Headquarters as a Lieutenant Colonel in the Coast Artillery Corps. Ill health prevented him from assuming this duty.

On conclusion of his active military service in World War I, Mr. Anderegg returned to the University of Cincinnati and was awarded the degree of Civil Engineer in June, 1919. From June, 1919, to July, 1921, he was superintendent of construction for the Texas Company at Port Arthur, Tex. He laid out and supervised $7,000,000 worth of new work, which included twenty-four units of pressure stills, eight units of crude stills, a steam powerhouse, a pump house, tanks, and an office building.

In September, 1921, Mr. Anderegg accepted an appointment as instructor in the Civil Engineering Department at the University of Cincinnati. He received promotions to assistant professor in September, 1929, associate professor in June, 1930, and a full professorship in 1941.

From January to September, 1929, Professor Anderegg was on leave of absence from the university in order to perform special work with the Cin-

---

[1] Memoir prepared by R. W. Renn, M. ASCE.

cinnati District of the United States Engineer Office. He was placed in charge of the Flood Control Section and made power, flood, navigation, and irrigation investigations and reports on the Miami, Licking, and Kentucky rivers. From January to April, 1934, in conjunction with his academic duties, Professor Anderegg served as engineering supervisor with the United States Coast and Geodetic Survey for the Southwest Ohio Civil Works Administration project.

Professor Anderegg was granted a leave of absence in July, 1944, from the University of Cincinnati to serve on the staff of the Price Adjustment Section, Cincinnati Ordnance District. Ill health forced his retirement from this work in the spring of 1945, and he resumed his academic duties at the University of Cincinnati in the summer term of that year.

During his university career Professor Anderegg participated in many activities both in the academic field and in the professional field of civil engineering. He served as faculty adviser to the band from 1924 to 1946, to the orchestra from 1929 to 1946, and to the Varsity Vanities from 1936 to 1946. He was President of the Cincinnati Section of the Society in 1939, and was an active member of the Society for the Promotion of Engineering Education (later, the American Society for Engineering Education), the American Association of University Professors, and the Reserve Officers' Association.

On November 29, 1917, Professor Anderegg was married to Mabelle L. Davis. They had four sons, James Albert and Rupert Andrew, Jr., Juniors, ASCE, Richard Davis, and David Louis, who survive him. He was a member of the Knox Presbyterian Church of Cincinnati, serving as an Elder of that church.

Throughout his years at the University of Cincinnati, Professor Anderegg was a staunch supporter of the cooperative system of education, and a firm believer in his chosen field of civil engineering. The two eldest sons followed in their father's footsteps and were graduated from the cooperative course in civil engineering at the University of Cincinnati. At his death, the two youngest sons were attending Withrow High School in Cincinnati. The faculty of the university has lost one of its hardest workers, the students have lost a true friend and adviser, and the civil engineers of the community have suffered a real loss in the passing of Professor Anderegg.

Professor Anderegg was elected a Member of the American Society of Civil Engineers on February 23, 1932.

FRANK ALEXANDER BARBOUR, M. ASCE[1]

DIED MAY 24, 1947

Frank Alexander Barbour was born at St. John, N. B., Canada, in 1870. His parents were George Ludlow and Elizabeth Augusta Barbour. He was graduated from the University of New Brunswick at Fredericton in 1888, and received his first training in engineering in the Dominion of Canada. Early in his career he joined the engineering staff of the water department of the City of Boston (Mass.), where he was associated with Desmond FitzGerald,[2] Past-President and Hon. M. ASCE, and Frank McInnis,[3] Assoc. M. ASCE (the latter, a graduate of New Brunswick University).

---

[1] Memoir prepared by Arthur D. Weston, M. ASCE.

In 1892 Mr. Barbour was employed by the City of Brockton (Mass.) in the design, construction, and operation of a sewage disposal works for that city, working under the direction of F. H. Snow,[4] M. ASCE, city engineer. In 1900 Mr. Barbour and Mr. Snow opened a consulting office in Boston which the former conducted until his death. Frank Barbour was a specialist in matters of water supply and water purification, sewerage, and sewage disposal practice, and appraisal of water works property. This work he loved, and, although president of the New England Pressed Steel Company, most of his time was devoted to the practice of sanitary engineering.

Other works of interest include appraisals of property of the Passaic (N. J.) Consolidated Water Company, the Long Island (N. Y.) Water Corporation, and the New Rochelle (N. Y.) Water Company. With W. E. Fuller,[5] M. ASCE, he was responsible for reconditioning the Passaic consolidated system. He collaborated with John Gregory,[6] M. ASCE, to prepare a report on the subject of a water supply for the Northern Metropolitan District of New Jersey for the Water Policy Commission. In the interstate case of Connecticut versus Massachusetts he made investigations and appraisals of water power and process water damages, resulting from the diversion of the Ware and Swift rivers by the Metropolitan District Water Supply Commission of Massachusetts.

Mr. Barbour served as president of the American Water Works Association, the Boston Society of Civil Engineers, and the New England Water Works Association, being an honorary member of both water works associations. He was a member of the Board of Direction of the Society from 1934 to 1936, during which time he served on the Committee on Publications, including one year as chairman. Mr. Barbour was a member of the Engineering Institute of Canada, and he served on the executive committee of the American Society for Testing Materials. In addition he was on the editorial advisory board of *Water Works Engineering* and was the author of numerous technical articles.

He was an engineer of rare ability and sound judgment; and those working with him could not but profit from the association. His death has resulted in a great loss to the engineering profession, to all the engineering societies with which he was associated, and especially to the field of sanitary engineering.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 92, 1928, p. 1656.

[3] *Ibid.*, Vol. 102, 1937, p. 1879.

[4] *Ibid.*, Vol. 108, 1943, p. 1634.

[5] *Ibid.*, Vol. 101, 1936, p. 1556.

[6] *Ibid.*, Vol. 102, 1937, p. 1552.

In April, 1916, he was married to Dorothy Boswell in Philadelphia, Pa. He is survived by his widow.

Mr. Barbour was elected a Member of the American Society of Civil Engineers on September 5, 1900. He became a Life Member in January, 1935.

WALTER LACY BOYD, M. ASCE[1]

Died June 11, 1947

Walter Lacy Boyd was born in Owingsville, Bath County, Ky., on November 9, 1874. Mr. Boyd, whose parents were James William and Anna Elizabeth (Robinson) Boyd, was the eldest of five children.

Most of his life, including much of his engineering experience, was spent in Florida—particularly in Polk County, at Bartow, the county seat. There, he was graduated from high school, completing the courses of Summerlin Institute. Following one year at the Florida Agricultural College in Lake City, he spent two years at the South Florida Military College in Bartow, receiving the degree of Bachelor of Science in 1896—an award which was later confirmed by the University of Florida at Gainesville. During these years of study, he was, at the same time, serving as deputy tax collector of Polk County. Upon graduation Mr. Boyd continued this work for the following five years, until 1901, as a regularly appointed deputy.

His first actual engineering work began during the latter part of 1901, with the position of rodman for the Atlantic Coast Line Railroad Company in southeast Georgia. Wishing to obtain the contractor's point of view, he left this work in November, 1901, to become foreman of railroad construction on a grading contract for the Atlanta, Birmingham and Atlantic Railway Company between Waycross and Cordele in Georgia. At the request of the chief engineer of the railroad he was released after a few months to become assistant engineer. This work comprised the location of some 200 miles of road from Cordele to Birmingham, Ala., and it was completed about a year later, in April, 1903. At this time Mr. Boyd accepted a similar assignment with the Illinois Central Railway Company at Jackson, Tenn. After considerable survey and drafting work, he was transferred to Memphis, Tenn., where he became engineer on construction of a large freight yard.

After about a year with the railroad, Mr. Boyd had a longing to return to Florida. For a few months in the spring of 1904 he was assistant superintendent on construction of an extensive plant for the International Phosphate Company at Jane Jay, Fla., and, for several months during the remainder of 1904, Mr. Boyd set up an office as a real estate broker at Bartow. This, however, did not appeal to him and in January, 1905, he established his own office at Bartow as a professional engineer. With a number of short interruptions this professional practice continued for almost forty years until his death.

---

[1] Memoir prepared by Harry Cornell, Florida State Board of Engr. Examiners, Bartow, Fla.

Among the interruptions to this general practice were a number of engagements. For most of 1909 he was secretary to the Byrom Corporation in Byromville, Ga., and was employed on farming, industrial, and banking work. Similarly, most of 1912 was devoted to business for himself as an electrical contractor in Miami, Fla. During 1929 and 1930 Mr. Boyd was engaged in making mineral surveys in North Carolina and Georgia including engineering work for a marble quarry at Andrews, N. C. For the first half of 1934 he was chief of party for the United States Bureau of Soils, making base map soil surveys in Madison County, Florida, as well as a road survey of Washington County, Florida, under the Federal Emergency Administration. The remainder of 1934 was spent with the Florida State Road Department in making general and detailed surveys of roads in Hillsboro and Polk counties.

In his private consulting work Mr. Boyd was engaged in making land surveys and in general civil engineering, much of it in the vicinity of Bartow. This private work included: Phosphate mine railroad location and construction; highway design, location, and construction; various kinds of engineering surveys, including the re-establishment of public land surveys; drainage, dams, water supply and irrigation work; subdivision design and development; concrete and steel bridge and culvert construction; and municipal work.

Among his more important mining clients were the Phosphate Mining Company at Nichols, Pierce Phosphate Company at Pierce, Armour and Company at Agricola, the Charleston Mining Company at Fort Meade, and Swift and Company whose mine is located near Bartow—all in the State of Florida. Dams, railways, terminal facilities, and heavy mine buildings were included in his work, as well as a considerable amount of surveying.

With the increase in highway transportation, Mr. Boyd devoted considerable time to highway engineering. In 1924 the Board of County Commissioners of Polk County retained him as county engineer. He made surveys, drew up plans and specifications, and supervised some of the construction, including the solving of many drainage problems. The work amounted to about $10,500,000. His standards were high and, in fact, when ordered to construct work which he felt was of an unsatisfactory quality and, indeed, a public hazard, he promptly resigned from office.

For various Works Progress Administration projects in and around Bartow, Mr. Boyd served as nonrelief supervisor. Considerable paving, as well as design and construction of storm sewers, were included in this work. There was also work on the plan of the Summerlin Institute, at which Mr. Boyd had studied as a youth. Under the same auspices he completed the Civic Center at Bartow.

The bulk of his work as consultant was devoted to surveying projects. While individually these were not extensive—each, nevertheless, involved its own problem. Principally, this phase of his practice consisted in untangling property lines which had become so snarled that the abstractors, the lawyers, and the owners were all in confusion. Re-establishing "obliterated" corners was an important feature of this work. Mr. Boyd was particularly satisfied with his success on such problems, especially when they involved dispute and his work could avoid litigation.

In May, 1900, Mr. Boyd was married in Montezuma, Ga., to Julia Dupree. Of their two sons, only James William Boyd survives him. Mrs. Boyd died in August, 1923. In February, 1945, he was married, a second time, to Mrs. Grace Pemberton in Tampa, Fla. His widow survives him.

Mr. Boyd had a certificate as a professional civil engineer in Florida, and also, one as a professional land surveyor. He became a member of the Tuscan Lodge No. 6 of the F. and A. M. at Bartow on March 16, 1916. At his death he held the position of county surveyor of Polk County.

He died in Tampa on June 11, 1947, and was buried in Bartow on June 13, 1947.

Mr. Boyd was elected an Associate Member of the American Society of Civil Engineers on December 31, 1913, and a Member on October 15, 1923. He became a Life Member in January, 1945.

PAUL LEMON BROCKWAY, M. ASCE[1]

DIED JULY 20, 1945

Paul Lemon Brockway was born in Riverton, Nebr., on May 4, 1879. He was the son of Charles L. and E. S. (Leech) Brockway.

He went from the public schools of his home town to the University of Nebraska in Lincoln, from which he received the degree of Bachelor of Science in Civil Engineering in 1905. In 1927 he received the degree of Civil Engineer from the same school.

In 1905 Mr. Brockway entered the engineering department of the Chicago, Rock Island and Pacific Railway Company as assistant engineer in charge of masonry construction. Two years later, in 1907, he was called to the position of assistant city engineer of Wichita, Kans., and remained in this department until his death. He was made city engineer in 1917.

His success in remaining in an unusually turbulent city government for thirty-eight years demonstrated the sufficiency of the lifelong principle he held as to public service. On entering the city employ, he was familiar with the common belief that such employment was, of necessity, temporary, and that each year added new enemies to one in public service because of the requests one felt compelled to refuse, until a sufficient number of enemies necessitated removal. Mr. Brockway reasoned, "Why not make a friend of each potential enemy?" With expenditure of time and painstaking tact he followed this policy for thirty-eight years and at his death, he was secure in his office with the respect and confidence of all.

During his service Wichita passed from the council to the city manager form of government. Also, the city went through two depressions, an oil boom, and, finally, the war boom which doubled the population in two years. Councilmen, commissioners, and city managers came and went, but after each upheaval the city rallied around this one engineer whose judgment was dependable and whose honesty was unimpeachable.

---

[1] **Memoir prepared by Lloyd B. Smith, M. ASCE.**

To the customary duties of a city engineer—supervising the construction and maintenance of pavements, sewers, and public improvements of a community passing from a country county seat to a city with a population of a quarter of a million—were added the difficult problems of flood protection, which, at times, became very serious. In the unusual flood of 1945 he abandoned his car, waded through a quarter of a mile of floodwater, rode to his office on a high wheel blade grader, and continued to supervise rescue work without changing his clothes. This incident typically demonstrates his faithfulness to duty and his serious attitude toward his responsibilities, and, in this case, tragically so—as he never rallied from its effects.

Exhibiting unusual tact and ability in forming and developing the thoughts of his political employers and the general public on new ideas in government, such as city planning, a city manager, and revisions of outmoded methods, he even changed the point of view of officials who were elected to office on the platform of ousting him from office.

Mr. Brockway engaged in many activities outside the strictly technical functions of his engineering duties. He was secretary of the city planning commission from its inception until his death, in addition to holding membership on the board of directors of the American Society of City Planning Officials, and the City Planning Committee of the Society. A past-president of the American Society for Municipal Improvements, he was also past-president of the Kansas Section of the Society, the Kansas Engineering Society, and the Wichita Engineering Club. Mr. Brockway was secretary of the Kansas Registration Board for Professional Engineers, and took an active part in the American Association for the Advancement of Science.

For thirteen years he was one of the three members of the local membership committee of the Society. His judgment on the qualifications of prospective members was invaluable in helping maintain a high and uniform standard of membership for the Kansas Section. He was the author of numerous articles in technical publications, such as *Engineering News-Record, Public Works, Concrete,* and *American City.*

Mr. Brockway never forgot that he was a professional man and, as such, service was always the predominant motive of his life. He had an unusual combination of the scientific and artistic in one personality. Although his musical talent was only partly developed due to his professional duties, he took part in the musical activities of the city. Much of his leisure was spent in the cultivation of flowers, and he was especially active in Kiwanis and the Boy Scout movement.

During his later years he had six operations in succession. When confined in the hospital, he wrote and later published a small book of poems on hospital life[2] with such captions as "The Surgeon's Saw," "The Closed Door," and "The Transfer Wagon."

In 1904 Mr. Brockway was married to Kate Weed of Bailey, Nebr. Besides his widow, Mr. Brockway is survived by five children: Stella (Mrs. S. E. Omopundro) of Leadville, Colo.; Lawrence Olin Brockway, professor of chemistry at the University of Michigan, in Ann Arbor; Esther Brockway of Independence, Mo.; Lois (Mrs. C. M. Jamison) of De Land, Fla.; and Charles Edward Brockway of Akron, Ohio.

Mr. Brockway was elected a Member of the American Society of Civil Engineers on May 28, 1923.

ORA BUNDY, M. ASCE[1]

Died June 12, 1946

Ora Bundy, the son of Amasa D. and Mary Ann (Hemby) Bundy, was born in Carthage, Ind., on October 14, 1882. After graduation from high school, he obtained employment in Indianapolis, Ind., to earn funds to start college. Three years later he entered Purdue University in Lafayette, Ind., and was graduated in 1908 with the degree of Bachelor of Science in Civil Engineering. While attending the university Mr. Bundy was active in athletics and was a member of the football and track teams.

In June, 1908, he was employed by the Memphis (Tenn.) Bridge Company, and continued in its service until 1912. During this period he was advanced, successively, from draftsman to detailer, designer, and foreman, and spent a year and a half as erection foreman throughout the southern states. From 1913 to December, 1917, Mr. Bundy was associated with the Vincennes (Ind.) Bridge Company; during 1916 and 1917 he was general superintendent of construction operating in eleven states.

In December, 1917, he was commissioned a Captain in the Corps of Engineers, United States Army, and served as constructing quartermaster, Construction Division, in charge of wartime projects in Alabama, Arizona, Maryland, New Jersey, Texas, and Utah until January 1, 1922, when he resigned from the Army with the rank of Major to enter the engineering and contracting business at Ogden, Utah, with Joseph S. Kroft as a partner. At this time he accepted a commission as Major, Corps of Engineers—Reserve, U. S. Army, and was called to active service many times. His last tour of duty was as commanding officer at the Fort Douglas Reserve Officers' Camp, Salt Lake City, Utah, in 1938.

Among the contracts completed by Kroft and Bundy was the forty-two mile Wendover highway across the mud flats and salt beds of western Utah—famous throughout the world for its difficult construction. After Mr. Kroft's withdrawal from the firm in 1925, Major Bundy carried on the business under the name of Ora Bundy, Engineer and Contractor, in Utah, Idaho, Nevada, and Wyoming in the construction of concrete and bituminous paved highways, bridges, and other projects.

---

[2] "Temple of Healing," by Paul Brockway, Wichita, Kans., 1938.

[1] Memoir prepared by R. K. Brown, O. C. Lockhart, and R. R. Mitchell, Members, ASCE.

Major Bundy served as mayor of the City of Ogden from 1930 to 1934, and was appointed a member of the Utah Public Works Advisory Board in 1933. In 1941 he achieved membership on the Utah State Department of Publicity and Industrial Development Commission, becoming its chairman in 1944, and also was president of the National Reclamation Association and the Ogden River Water Users' Association. Major Bundy was a member of the Society of American Military Engineers; the Ogden Chapter, American Association of Engineers (past-president); the Ogden Engineers' Club (past-president); and the Utah Section, later the Intermountain Section of the Society (past-president). In addition, he was a past-president of the Utah Chapter of the Associated General Contractors of America and a past-commander of the Utah department of the American Legion and of the Baker-Merrill Post No. 9 of Ogden. A Thirty-Second Degree Mason, he was a member of George Washington Lodge No. 24 in Ogden; El Monte Commandery No. 2, Knights Templars; Ogden Chapter No. 2, Royal Arch Masons; Ogden Council No. 3, Royal and Select Masters; El Kalah Temple, Nobles of the Mystic Shrine; the Ogden Shrine Club; and the National Sojourners. He was also on the advisers' council, Order of DeMolay, and belonged to the Ogden Lodge No. 719, Benevolent and Protective Order of the Elks; the Weber Club; the Ogden Golf and Country Club; the Chamber of Commerce; the Forty and Eight of the American Legion; and the Pine View Yacht Club.

Possessed with a yearning for leadership in order to carry out his ideas and vigorous opinions, Major Bundy also had the driving force to attain that leadership. In the professional, business, and fraternal associations with which he was affiliated, he took an active part and left his stamp as a positive character. Essentially a man of action, he vigorously prosecuted whatever work he had in hand.

During his term on the Utah State Department of Publicity and Industrial Development Commission, of which he was chairman until his death, he was appointed director of postwar planning by the Hon. Herbert B. Maw, Governor of Utah, and made an extensive survey with the cooperation of others. As a result his department published a comprehensive volume.[2]

Major Bundy wrote:

> "To the Reader:
>
> "The transition to a wartime footing brought great changes to Utah and especially to the narrow strip designated as the Wasatch Front, where approximately two-thirds of the population of the State reside. Another transition, to a peacetime basis, lies ahead.
>
> "The 'After Victory' Report for Utah and the Wasatch Front, enclosed herewith, is the result of a cooperative attempt, under the auspices of the State of Utah, to assemble and make readily available pertinent information about the economy of Utah, past and present, for use in formulating plans for the Utah of the Future.

---

[2] "After Victory, Plans for Utah and the Wasatch Front," Utah State Dept. of Publicity and Industrial Development, June, 1945.

> "The compilers of this Report are well aware that any course of action charted at this time must be subject to change as dictated by changing conditions. Planning must be a continuing effort. It is hoped that the Report may prove to be a logical starting point for further research and may be found useful in reaching decisions that will stabilize the peacetime economy in Utah along planes of high standards. It is hoped further that persons and agencies outside of this State, confronted with problems of readjustment that are fundamentally similar to those of the Wasatch Front, may derive some benefit from the Utah effort."

Major Bundy was a capable administrator, possessing a keen, analytical mind; and he had the welfare and growth of his state at heart, contributing many helpful suggestions for its future. He had a pleasing personality, made friends readily, and had the happy faculty of working constructively with others.

The passing of Major Bundy was a great loss to the community and, in fact, to the state, where men of real character and ability are so needed in the difficult times which lie ahead.

In 1926 Major Bundy was married to Lovina Singleton Lewis. He is survived by his widow; a son and daughter by a former marriage, John A. and Mrs. Dora Goddard; a stepson, Glen Lewis (Major, U. S. Army Air Corps); two brothers, Warren and Earl; two sisters, Mrs. Wilma Eubank and Mrs. Myrtle Mahon; and three grandchildren.

Major Bundy was elected a Member of the American Society of Civil Engineers on April 3, 1922.

ARTHUR GRAY BUTLER, M. ASCE[1]

Died September 7, 1947

Arthur Gray Butler, the son of Thomas J. and Mary Elizabeth (Lee) Butler, was born in Terre Haute, Ind., on September 20, 1888. He was the youngest in a family of four boys. After receiving his early education at the public schools in Terre Haute, he entered Rose Polytechnic Institute there. He was graduated in 1910 with the degree of Bachelor of Science in Civil Engineering and later he received the degree of Civil Engineer.

Shortly after graduation Mr. Butler was employed by the Vandalia Railroad at Logansport, Ind., where he remained until 1912. He became associated with the Henry Bickel Company at Louisville, Ky., in May, 1912, and worked for that firm until 1917. In the capacity of construction superintendent during this period he was in charge of construction of the High Street steam station built for the Louisville Railway Company and supervised the widening of the Louisville-Portland Canal. During World War I he was responsible for constructing the water supply and other camp developments at Camp Taylor in Kentucky.

---

[1] Memoir prepared by Ralph B. Horner and Harrison G. Roby, Members, ASCE.

After the armistice Mr. Butler became general superintendent of construction of the Byllesby Engineering and Management Corporation in charge of work for the Louisville Gas and Electric Company, and retained that position until 1929. This was a period of rapid development in the company's property, and he was directly responsible for a wide diversity of projects, including additions to the Waterside steam station, several large substations, the Bear Grass gas plant, several large gas holders, and many miles of pipe line in eastern Kentucky and in the vicinity of Louisville. Another project which he constructed during this period was the Ohio Falls (Ky.) hydro-electric plant, which has an installation of 80,000 kilowatts. Coincident with this, he was in charge of construction of dam No. 41 in the Ohio River at Louisville, built under contract with the government.

In 1929 Mr. Butler transferred to Pittsburgh, Pa., where he became manager of the Pittsburgh branch of the Byllesby Engineering and Management Corporation in charge of engineering and construction work for the Duquesne Light Company and other subsidiaries of the Philadelphia Company. Early in this association his integrity and straightforward manner won him the respect and loyalty of those with whom he was associated. In 1936, due to changes in organization, Mr. Butler became "Manager of Engineering and Construction" of the Duquesne Light Company. Until his death he was actively engaged in supervising a large number of projects, including two extensions to the James H. Reed power station rated at about 60,000 kilowatts each.

Before completion of the latter projects, the design and construction of a new power station (Frank R. Phillips station) was undertaken. This plant has been operating at about 75,000 kilowatts since it was placed in operation in the fall of 1942. Constructed for the most part during World War II, it is a tribute to Mr. Butler's diligence and energy. In spite of labor shortages, difficulties in obtaining materials, and other wartime obstacles, this plant was completed in time to render useful service for three years of the war, due in large measures to Mr. Butler's tireless efforts to complete the project at the earliest possible date.

In addition to his duties with the companies with which he was affiliated, Mr. Butler took an active part in related engineering activities. From 1938 to 1940 he was chairman of the engineering section of the Pennsylvania Electric Association, and served as a member of the executive committee. He also served in various positions with the Edison Electric Institute of New York, N. Y., being appointed in 1946 to the engineering division general committee.

He was an officer of the Lions Club in Louisville, and handled much organizational and charitable work for this group. After coming to Pittsburgh Mr. Butler became active in the work of the Pittsburgh Association for the Improvement of the Poor, having been appointed a trustee of that organization in 1936. He served as chairman of the men's industrial committee from 1943 to 1946, and was elected vice-president of the association in May, 1947.

One of the projects under his supervision for this organization was the design and construction of a fresh air camp for underpriviledged children. This was constructed about twenty miles from downtown Pittsburgh and provided facilities in the country, including dormitories, mess halls, a swimming pool, a recreation building, and playground equipment to accommodate nearly one hundred and fifty children at a time. Mr. Butler's interest in his development was intense; he spent much effort and many week ends studying plans to obtain the maximum facilities for the limited money which was availible, with the result that the camp provided an exceptionally efficient layout. The dormitories were placed on a wooded hillside, so located as to afford unobstructed views of the recreation facilities and surroundings, and so arranged as to keep removal of trees to a minimum.

Mr. Butler was also affiliated with the Federation of Social Agencies and was a member of the committee on plant and maintenance from 1944. Educational work actively interested him too. He served two terms as an alumni trustee of Rose Polytechnic Institute, and in 1932 was elected to life membership on this board. He proved to be a most valuable member, regular in attendance, sound in his judgment, and active on several important committees—including the building and ground committee, which was engaged in an expansion program for the school at his death.

Mr. Butler was a past-president of the Engineers and Architects Club of Louisville, and was a member of the Engineers Society of Western Pennsylvania. He served as a member of the house committee of the latter organization during the remodeling of their headquarters and club rooms in 1940, and was also chairman of a special committee appointed that same year to study methods of improving the society and of making it of greater benefit to its members.

Golf was his favorite recreation and for many years prior to his death he was a member of the Longue Vue Club in Pittsburgh. He was a member of the University Club and the F. and A. M. While in Louisville Mr. Butler was as elder of the Crescent Hill Presbyterian Church, and on coming to Pittsburgh became an elder in the Third Presbyterian Church in that city. He served for several years as chairman of the building committee, planning extension of the church facilities.

On September 25, 1912, in Terre Haute, Mr. Butler was married to Marie Rhoads. He is survived by his widow; four daughters, Harriet Ingold (Mrs. Thomas S. Stevenson), Anne Spottswood (Mrs. Harry B. Stewart, Jr.), Mary Gray, and Jean Lee; and four grandchildren.

Mr. Butler was elected a Junior of the American Society of Civil Engineers on June 23, 1916; an Associate Member on October 9, 1917; and a Member on April 18, 1927.

BENJAMIN LUCIEN CAMPBELL, M. ASCE[1]

DIED DECEMBER 9, 1944

Benjamin Lucien Campbell was born at Mankato, Minn., on January 24, 1883. He was the son of Benjamin and Carrie (Gillette) Campbell. His father and mother were both of Scotch-Dutch descent. Although most of his life was spent in and around Portland, Ore., his work took him to Boston, Mass., Providence, R. I., San Francisco, Calif., Seward, Alaska, and numerous other points. His elementary and high school training was received in Portland. He attended the Colorado School of Mines at Golden and Rensselaer Polytechnic Institute in Troy, N. Y., each for one year, studying mining engineering.

From 1900 until 1928 he worked as draftsman, surveyman, locator, construction supervisor, and designer on numerous mining and railroad projects throughout the United States and Alaska. In 1928 Mr. Campbell was engaged by the Corps of Engineers, United States Army (Portland District), as assistant engineer. He then served with the War Department continuously (except for a few months in 1933 and 1934), until his retirement in 1944 a few months before his death.

During World War II Mr. Campbell worked with the District Engineer Office in Seattle, Wash., as supervisor of construction of facilities at the Annette Island Air Base in Ketchikan, Alaska. The Signal Corps, U. S. Army, borrowed his services for special work while at this base. His failing health was partly responsible for his return to Portland in 1943.

As an amateur gunsmith Mr. Campbell held a noteworthy reputation; and his principal hobbies were hunting, target shooting, and boating. He was a member of the Society of American Military Engineers and the Professional Engineers of Oregon.

He was married at Kansas City to Sally Brown Skinner of Portland in 1903. He is survived by his widow and three daughters, Mrs. Ida F. Miller, Mrs. Esther Wright, and Mrs. Clarissa Bronn.

Mr. Campbell was elected an Associate Member of the American Society of Civil Engineers on August 17, 1931, and a Member on June 26, 1933.

EDWARD EMERY CARPENTER, M. ASCE[1a]

DIED OCTOBER 26, 1945

The death of Edward Emery Carpenter marked the passing of another of that group of pioneer engineers who had an important part in the building of the West. His engineering career began in the era of railway building and spanned the transition period well into the time when hydroelectric development became of primary importance on the Pacific Coast.

---

[1] Memoir prepared by Stanley E. Sporseen, M. ASCE.

[1a] Memoir prepared by C. E. Blee, M. ASCE.

Descended from pioneering stock, Edward Emery Carpenter, the son of Emery Wilcox and Maryette (Austin) Carpenter, was born in Americus, Kan., on November 12, 1872. Edward was one of a large family, having three brothers and one sister. His parents were living in Wisconsin at the time of their marriage and moved west in a series of migrations, stopping in Ohio, Kansas, Colorado, and other places. Some of the earlier steps were made by horse and wagon. Finally the family arrived in San Luis Obispo, Calif., when Edward was fifteen years old. This became the permanent family home. Edward was graduated from high school at San Luis Obispo and entered Stanford University at Palo Alto, Calif., with the class of 1896, one year after the founding of that institution. He was graduated from the university with the degree of Bachelor of Science in Civil Engineering in June, 1898, having found it necessary to remain out of school for two years in order to earn funds with which to continue his education.

Upon graduation, Mr. Carpenter entered railway construction work as chainman and rodman with the Atchison, Topeka and Santa Fe Railway Company and quickly advanced to the position of assistant engineer on maintenance of way for the Southern Pacific Railroad Company. In 1901 and 1902, he carried out preliminary surveys for a proposed power project on the Stanislaus River in California, one of the earliest major hydroelectric power developments in the United States and one with which he was later to be prominently identified. Returning to railway work, during the next three years he was in charge of difficult railway location assignments in Mexico, northern California, and Nevada. In much of this work he was associated with that master railroad builder, William Hood,[2] M. ASCE, chief engineer of the Southern Pacific Railroad.

In 1905 the Stanislaus power project again became active and Mr. Carpenter joined the organization of Sanderson and Porter, which firm designed and constructed the project. Here the young railway engineer had an opportunity to demonstrate his administrative ability and genius for organizing a construction project for it was a difficult job and had to weather the disruptive effects of the financial panic of 1907. He rose to the position of chief construction engineer and successfully completed the project at the end of four years.

Next Mr. Carpenter worked on the design and construction of the Jordan River power development as chief engineer for Sanderson and Porter. This project was in an almost unexplored section of Vancouver Island, British Columbia, Canada, without access save landing from boats on an open beach. In spite of the difficulties of penetrating into an unmapped territory covered by an exceedingly heavy timber growth and subject to a high rate of rainfall and snowfall, this project was completed in the scheduled time of three years.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 91, p. 1096.

In 1912 Mr. Carpenter became chief of the Department of Civil Engineering on the building of the Panama-Pacific International Exposition at San Francisco, Calif. This was an intricate job involving the placing of dredged fill and the installation of all the utilities, streets, and other facilities that would be required for a large city. The drawing together of these facilities so as to permit the opening of the Exposition on schedule was a constant battle against time and required the closest coordination.

When this assignment was completed Mr. Carpenter was forced to retire from active work for more than a year in order to undergo a serious operation on his eyes. His eyesight had been injured early in his career from running a transit in the bright sun over the snow fields of the high mountain country. This condition became progressively worse until he could scarcely use his eyes at all. The operation only partially corrected the trouble so he was subject to this affliction during most of his active career. It was characteristic of the man that he rose above this handicap and carried on in a normal manner, scarcely ever mentioning the impairment of his vision.

In 1917 he returned to active work as executive engineer and manager of a ship building plant at Raymond, Wash., for Sanderson and Porter. Starting from nothing but a tidelands site, a complete plant was constructed and ten wooden ships were turned out for the United States Shipping Board in a little more than two years' time.

On completion of the ship building job, Mr. Carpenter returned to San Francisco and together with the late Shirley Baker, M. ASCE, a close personal friend and associate since college days at Stanford, formed the engineering firm of Baker and Carpenter. During the next four years this firm carried on a general engineering business including the design and construction of the stadium at Stanford University. Also Mr. Carpenter was a member of the commission responsible for the design and construction of the Memorial Stadium of the University of California, at Berkeley.

In 1923 Mr. Carpenter was called to British Columbia to organize and head a construction department for the British Columbia Electric Railway Company, Limited, the utility serving the lower mainland and Vancouver Island. He continued in this position until retirement, about two years before his death. During these twenty years of service he was responsible for the design and construction of a number of major hydroelectric projects as well as other engineering services for the company.

Mr. Carpenter was a man of large physical stature and of outstanding personality. He conducted himself with a dignity that commanded the respect of his associates and of the contractors, labor representatives, and others with whom he had professional or business dealings. As an engineer and constructor, he had outstanding administrative ability and a genius for organization. In engineering design he never lost sight of fundamental principles. He had a well-earned reputation for sound judgment.

Being a great reader, Mr. Carpenter was well informed on a wide variety of subjects and was a most interesting conversationalist. He had a naturally genial nature which made him many friends. Moreover he was highly regarded and esteemed by those who worked for him and wherever he went on jobs from Mexico to Canada he was always accompanied by former associates from previous jobs.

On April 20, 1904, Mr. Carpenter was married to Aileen Morrison of Chico, Calif., who predeceased him by four years. He is survived by his son, Donald D. Carpenter, of Vancouver, British Columbia.

Mr. Carpenter was elected a Member of the American Society of Civil Engineers on October 1, 1912. He became a Life Member in January, 1943.

JOHN TAYLOR CHAMBERS, M. ASCE[1]

Died April 27, 1947

John Taylor Chambers, son of Henry E. and Ellen (Taylor) Chambers, was born in New Orleans, La., on March 10, 1885. After being graduated from the public high school, he matriculated in the College of Engineering of Tulane University, at New Orleans, and was graduated with the degree of Bachelor of Civil Engineering in the year 1906.

Following graduation, Mr. Chambers completed special study work at Harvard University in Cambridge, Mass. Later, in connection with his professional work, he was given special training in reinforced concrete design at the head office and laboratory of an outstanding fabricator. Although an excellent student, he found time to devote to athletics and other extracurricular activities. He captained football teams in both high school and college. His family connections gave him a position of prominence, but his athletic ability and attractive personality placed him high in popular esteem, and "Jack" Chambers was well and favorably known before he embarked on his professional career.

Mr. Chambers devoted the first five years of his professional life to engineering construction and was employed by the United States Corps of Engineers, and the Sewerage and Water Board of New Orleans on major assignments. In 1911 he formed the Chambers-Morris Company, a civil engineering firm, and this organization was responsible for the structural design of a large number of buildings in the New Orleans area. During the five-year period, from 1915 to 1920, Mr. Chambers operated a 5,000-acre cotton plantation in Chicot County, Arkansas, but his liking for engineering and construction asserted itself and he returned to the field he had selected for his life work. For the succeeding seven years (from 1921 to 1928), first as a partner in the firm of Chambers and Bowers, Contractors, and then as an individual contractor, he completed many contracts and professional engagements in the sewerage, water, and drainage fields.

---

[1] Memoir prepared by a Committee of the Louisiana Section consisting of John Riess, Chairman, and Frank C. Carey, Members, ASCE, and Charles M. Kerr, Assoc. M. ASCE.

Beginning in 1928, as a partner in the firm of Lewis-Chambers, this construction company undertook major levee, canal, and earth moving contracts involving millions of dollars. Lewis-Chambers owned some of the heaviest dirt handling equipment in the south. Limitations and the need for long-range equipment prompted Mr. Chambers to design, build, and later operate the "Chambers bridge," a large, mobile, steel structure powered by diesel engines, over which cable operated cars transported 12 cubic yards of excavated material for 350-foot distances in 50-second cycles. By use of the Chambers bridge many of the largest Mississippi River levees were constructed. These levees contained millions of cubic yards of fill obtained from borrow pits far from the crown of levees. The machine designed by Mr. Chambers was used in building a section of the proposed Atlantic-Gulf Ship Canal across Florida. It has also been profitable and economically used in coal stripping operations.

He was married to Marion Monroe, daughter of the late Judge Frank A. Monroe, distinguished jurist and chief justice of the Louisiana Supreme Court.

Mr. Chambers was elected an Associate Member of the American Society of Civil Engineers on September 3, 1912, and a Member on September 11, 1944. He became a Life Member in January, 1947.

CLEVELAND BEACH COE, M. ASCE[1]

Died November 29, 1945

Cleveland Beach Coe, the son of Charles C. Coe and Anna S. (Beach) Coe, was born in Kenova, W. Va., on March 12, 1893.

He received his elementary education in West Virginia and Tennessee. After being graduated from the Johnson City (Tenn.) High School in 1908, he enrolled in the Sewanee Military Academy. In 1909 he attended Hobart College in Geneva, N. Y., and received the degree of Bachelor of Science in 1914. He also attended the Carnegie Institute of Technology in Pittsburgh, Pa., doing postgraduate work in civil engineering from 1914 to 1916; and, after World War I, the École des Travaux Publics in Paris, France. As both teacher and student he displayed throughout his career a very active interest in engineering education and contributed much to the advancement of the profession. Several articles written by him were published in *Engineering News-Record* and the *Transactions* and *Proceedings* of the Society. He was a member of Sigma Phi and Theta Nu Epsilon fraternities.

Mr. Coe became interested in the civil engineering profession early in life. At the age of sixteen he was employed during the summer vacation as a rodman on railroad construction. His first position after graduation from college in 1916 was as draftsman and inspector for the Mead Paper Company of

---

[1] Memoir prepared by F. W. Webster, M. ASCE, and F. E. Bosland, Assoc. M. ASCE.

Chillicothe, Ohio. He resigned in June, 1917, to enlist in the 323rd Field Artillery, United States Army, as a Second Lieutenant. He participated in the Meuse-Argonne offensive and other active engagements of the 323rd Regiment and remained with the Army of Occupation until June, 1919, when he was relieved from active duty with the rank of First Lieutenant.

He immediately resumed his chosen profession and became associated with the O. K. Morgan engineering firm in Johnson City. In 1923 he became Commissioner of Streets and City Engineer for Johnson City, and in this capacity was responsible for the administration, engineering, and construction of municipal public works. He returned to private practice in 1927, and in addition to his regular practice became special valuation engineer for the Atlantic Coast Line Railroad Company and the Carolina, Clinchfield and Ohio Railway Company.

He continued private practice until October, 1933, when he joined the engineering staff of the Tennessee Valley Authority. His first assignment was to assist in the planning, layout, and construction of the Town of Norris, Tenn. He then was assigned to the relocation of highways in the inundated areas. His ability as a leader and engineer was soon recognized, and he advanced to the position of associate highway engineer, the position he held when he returned to active duty in the United States Army in November, 1940.

His first assignment in World War II was as Adjutant to the Commanding Officer, First Military Area, Knoxville, Tenn., and later he served as Commanding Officer. He attended the Command and General Staff School at Fort Leavenworth, Kans., after which he was assigned to Camp Forrest, Tullahoma, Tenn., and Camp McCain, Grenada, Miss., as Executive Officer. At Camp Butner, N. C., in addition to his duties as Executive Officer, he also served as Commanding Officer of the Redistribution Station. He was stationed at Fort Oglethorpe, Ga., when he received his overseas orders and was transferred to Camp Lee, Va., for processing. Following the Japanese surrender, his unit was deactivated and Colonel Coe, at the time of his death, was under orders to report to Fort Lewis, Wash.

Colonel Coe gave himself wholeheartedly to the service of others. His unceasing devotion to his church, his country, and his fellowmen was an inspiration to all who knew him. A member of the Episcopal Church from his youth, his interest in religious music had wide influence. He wrote a full choral communion service and more than one choir in Eastern Tennessee has sung his "Benedicite." Fittingly, at his burial service, the choir sang his own "Nunc Dimittis." He was a lay reader in the church and an active member of the vestry for many years; he became secretary of the vestry of Saint John's Church in Johnson City.

He gave himself unstintingly to the services of his community. The Community Chest, Rotary Club, Red Cross, Crippled Children, Salvation Army, and Boy Scouts suffered an irreplaceable loss in his passing. All kinds of people were fond of him. There was a quiet strength always manifest in him; Mr. Coe was gentle though manly, possessed of deep wells of human sympathy. What the trainees in the several camps he served and the young engineers with whom he was associated owe to him only they could measure.

Cleve Coe was an active member of the ASCE, serving as Secretary-Treasurer of the Chattanooga Sub-Section of the Tennessee Valley Section in 1939 and he was in charge of the arrangements for the Society's Spring Meeting held in Chattanooga that year. He was active in the American Legion, Reserve Officers' Association, and the Society of American Military Engineers. In spite of his many activities he somehow found time for his three hobbies: Designing and Collecting book plates, stamp collecting, and music.

In Johnson City, in 1924, Colonel Coe was married to Margaret Summers. He is survived by his widow and two sons, Robert and Kenton.

Colonel Coe was elected an Associate Member of the American Society of Civil Engineers on December 13, 1937, and a Member on August 24, 1942.

CLARENCE KNIGHT CONARD, M. ASCE[1]

DIED MAY 16, 1947

Clarence Knight Conard, the son of William and Adelaide (Zimmerman) Conard, was born in Washington, D. C., on March 3, 1876. His father, a native of Philadelphia (Pa.) and a Quaker, was a veteran of the Civil War. At the close of the war William Conard settled in Washington and represented claimants who brought actions against the government for many acts which occurred during the war and in the postwar period. The father later entered the postal service and became chief of the inspector's division of the Colorado district. His mother came of a Virginia family whose sympathies were with the Southern cause during the war.

Mr. Conard's early life was spent in Florida and in Maryland. He attended Brookville Academy in Brookville, Md., and the high school at Ithaca, N. Y. In 1894 he entered Cornell University at Ithaca and majored in civil engineering for two years, when the sudden death of his father caused him to leave the university and seek employment.

During the summer of 1896 he was a rodman with the United States Coast and Geodetic Survey and then engaged in the lumber business in Missouri conducted by his uncle. In April, 1898, when war was declared with Spain he enlisted in the second Missouri Infantry and remained in service until February, 1899, when he was mustered out. At the close of the war he returned to Washington and became a rodman on street railroad construction and a draftsman with the U. S. Coast and Geodetic Survey.

---

[1] Memoir prepared by John C. Riedel, M. ASCE, and Arthur S. Tuttle, Past-President and Hon. M. ASCE.

He left the latter position on July 15, 1899, to join a surveying party in Nicaragua headed by Thaddeus Merriman,[2] M. ASCE, under the general direction of Francis Lee Stuart,[3] Past-President, ASCE, who had been appointed by the newly created Isthmian Canal Commission to survey that part of the Nicaragua Canal route extending eastward from the lake. While engaged in this service, he was advanced from the grade of rodman to that of transitman.

On his return to the United States in August, 1900, he was employed by the Baltimore and Ohio Railroad Company as transitman, and later as resident engineer in the construction of the Quemahoning branch, and on preliminary surveys, with which work Mr. Stuart (a brother-in-law by marriage) was responsibly connected. From August, 1904, to March, 1905, he was a member of the staff of the surveyor general of Arizona. In 1905 Mr. Stuart was appointed chief engineer of the Erie Railroad Company and at once summoned Mr. Conard to join his staff as assistant engineer in charge of construction of forty-five miles of Erie and New Jersey Railroad, costing more than $7,000,000. He was also in charge of the four-track entrance into Jersey City (N. J.) through the Bergen Hill, costing $3,000,000, and of the location and construction of the Elmira, Corning and Waverly Railway, an electric interurban line in New York, costing $800,000.

Mr Conard remained with the Erie Railroad until 1912, when he became construction engineer of the Norfolk Southern Railway Company on the extension of the line from Raleigh to Charlotte in North Carolina. This work involved seventy-five miles of new lines, costing $3,000,000, and was completed in 1914. For the next two years he was assistant engineer of the Southern Railway Company, in charge of the double-track betterment from Orange to Charlottesville in Virginia at a cost of $1,500,000. When this work was completed in 1916, he went to Cuba as chief engineer for railroad surveys and located a line from the mines of the Davison Sulphur and Phosphate Company to sea level.

He was in Cuba during the outbreak of the Cuban revolution in 1917. The United States entered World War I in April, 1917, and on November 9, 1917, he was commissioned as Major in the Ordnance Section, United States Army. He was detailed as constructing quartermaster in charge of building the Raritan Arsenal in Metuchen, N. J., which was to cost $1,400,000. The area comprised nearly four square miles and the work consisted of the erection of barracks for about seven thousand men, a tank assembly layout, railroad facilities, and some two hundred magazines of various sizes. At the river front a dock two thousand feet long was built and the salt meadow area was protected by a dike. He remained in the Army until October 30, 1919, when he was discharged.

Mr. Conard entered the employ of the International Conveyor Corporation, working on the development of coal handling machinery, but found in about a year that the market was dead for new developments. He then worked for the J. G. White Engineering Corporation in 1921 as division engineer on a survey in Nicaragua for a railroad to extend from the east coast to the lake region. The surveys were completed within the year and he returned to the United States. The depression of 1921 caused a cessation of engineering opportunities and for a time he made local surveys in Hempstead, Long Island.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 107, 1942, p. 1799.

[3] *Ibid.*, Vol. 101, 1936, p. 1493.

In 1922 Mr. Conard was appointed railroad engineer on the staff of Arthur S. Tuttle, Past-President and Hon. M. ASCE, who was then chief engineer of the Board of Estimate and Apportionment and in charge of the design and construction of a freight and passenger railroad between Brooklyn and Staten Island, involving a tunnel under the Narrows. Mr. Conard was placed in charge of the surveys, extending from Arthur Kill in Staten Island to Brooklyn, and the final location of the line. The project also included the design of a large classification yard in Staten Island and connections with the Baltimore and Ohio Railroad near Arthur Kill, with the city piers at Stapleton, with the Long Island Railroad at Bay Ridge, and with the Fourth Avenue Rapid Transit System in Brooklyn. His work was well advanced and the city had taken title to the land required for the classification yard and for some of the right of way when the project was discontinued by the New York State Legislature, in 1925, owing to the strong objections which had been raised by some of the trunk line railroads operating in the metropolitan area.

In 1925 and part of 1926 Mr. Conard was construction engineer for the Conard Construction Company of Florence, S. C., on the extension of the Winston-Salem branch of the Piedmont and Northern Railway Company. Local political difficulties caused cessation of the work, however, and Mr. Conard returned to New York. Mr. Tuttle subsequently invited Mr. Conard to return to his staff, and on January 1, 1929, he became railroad engineer on grade crossing eliminations—a position which he held until his retirement in 1943. Many grade crossing eliminations affecting the privately operated rapid transit railroad on Staten Island and the Long Island Railroad in Brooklyn and Queens (the latter work including the entire Jamaica section) were carried out. Mr. Conard represented the chief engineer of the Board of Estimate on all these projects.

Mr. Conard was a man of sterling qualities and of the highest integrity. He had an amazing capacity for work and was precise in his determination. At Cornell University he was an athlete and he retained his athletic prowess until he was well on in his sixties, playing tennis long after men of his years had abandoned such activities. Modest in demeanor, he possessed countless friends; his associates esteemed him most highly. Mr. Conard was a member of the American Railroad Engineering Association.

He is survived by his widow, Rosalie Rives Conard, to whom he was married on May 6, 1903, and by four children: William of Metuchen; Clarence K., Jr., of Clark, N. J.; Elizabeth of New Paltz, N. Y.; and Rosalie (Mrs. Frank R. Switzer) of Baranquilla, Colombia. Also surving are two brothers, Charles Conard, Rear Admiral, U. S. Navy (Retired), and Robert Conard of Guntersville, Ala.

Mr. Conard was elected a Member of the American Society of Civil Engineers on October 5, 1909.

JOHN ROSE WILSON DAVIS, M. ASCE[1]

Died February 19, 1947

John Rose Wilson Davis, oldest of the five children of Thompson and Ann Supplee (Rose) Davis, was born in Phoenixville, Pa., on October 26, 1868. The Davis family came from Wales and settled in America in about 1650, in eastern Pennsylvania. Thompson Davis and his father, Thomas Davis, operated an overshot flour and feed mill on Pickering Creek, a tributary of the Schuylkill River. This mill dated back to Revolutionary days.

On his mother's side, the Rose forbears also came from Wales in about 1680. Part of the early Rose farm occupied the site of the present Pennsylvania Railroad Station at Thirtieth and Chestnut streets in Philadelphia, Pa. Grandfather John Rose, for whom the future engineer was named, had a sword—one of several extant— made in the prerevolutionary woolen mill of the Rose family. This factory was devoted to manufacturing swords for officers of the Colonial Army.

John Davis attended the public schools in Chester County, Pennsylvania, the West Chester State Normal School (from 1883 to 1885), and Schwartz's Academy in Bethlehem, Pa. (in 1886). He started the civil engineering course at Lehigh University in Bethlehem in September, 1886, and, after absence during the second term (in 1889–1890), he re-entered the senior class in September, 1890, being graduated in June, 1891, with the degree of Civil Engineer. In college, he was a serious student, a member of the university tug-of-war team, and active in the Engineering Society.

As he approached his professional career Mr. Davis selected the then prominent field of railroad maintenance. His whole adult life, for about five decades, was spent in this type of work. During the first few years, his employment and employer varied frequently, as he sought to gain basic experience. For a year, in 1891–1892, he was rodman for the New York, Lake Erie and Western Railroad Company at Port Jervis, N. Y., being promoted then to assistant supervisor of track. The following six years, until 1898, he was assistant engineer. He then left this road, to serve for two years as division engineer for the Chicago and Erie Railroad Company at Huntington, Ind. Again, for short periods, he worked for the Chicago and Alton Railroad Company at Bloomington, Ill., and the Erie Railroad Company at Jersey City, N. J.—in both instances as engineer, maintenance of way. In the latter position he was in charge of maintenance engineering from New York, N. Y., to Buffalo, N. Y., and Jamestown, N. Y.

With this excellent training, and with the reputation it provided him, he was prepared for larger responsibility. The opportunity came in 1903 when he was asked to take a similar, but more exacting position with the Great Northern Railway Company in St. Paul, Minn., as engineer, maintenance of way. James J. Hill,[2] F. ASCE, then president of the Great Northern, felt he needed a capable man in charge of maintenance, and so Mr. Davis was selected while employed by the Erie Railroad. It proved to be a wise choice. He remained with this line up to his retirement—thirty-six years later.

---

[1] Memoir prepared by George G. Smart, Edmonds, Wash.

He found the Great Northern had a main line of about two thousand track miles, with six thousand miles of secondary tracks, stretching from the Great Lakes to the Pacific Coast—a vast system on which the maintenance had been sadly neglected. The rail was light, no tie plates were in use, ties were in poor condition, and what little ballast existed was of poor quality. Prior to his arrival it had been the practice for several years to take ties purchased for renewals and use them in construction of new branch lines. It was generally too late to secure additional ties, and the renewal of ties having been neglected resulted in a very poorly maintained line with frequent derailments. This, of course, adversely affected the operation. It was a discouraging outlook for one coming from a well maintained road.

As a granger railroad, finances were a serious problem, especially during those seasons when crops were poor. For many years it was an uphill fight to secure sufficient appropriatons to improve the physical condition of the property. Mr. Davis was a man of great determination, not easily discouraged, and constantly fought for the needed improvements.

Gifted with unusual foresight, he could look into the future and see the problems that would confront the railroad before they became apparent to the average man. It was this ability which made him one of the outstanding maintenance engineers in the United States. His advice and counsel was sought by many of the large railways of the United States. In planning and carrying out his work he built for the future. He could see the constant increase in axle loads which would require a stronger track structure than was then in use. Many of the improvements he pioneered are now standard practice on American railways.

For example, his was the first line west of the Mississippi to use the 6-inch track spike, the large tie plate, the 8-foot 6-inch cross tie, a wider roadbed, and heavier ballast section. He encouraged his employees and the railway supply houses to use their ingenuity in developing and perfecting labor-saving devices and was always willing to test them under service conditions. Under his encouragement the following were developed and set in operation: The self-propelled ditching machine, the self-propelled weed burner, the bolt machine, the adzing machine, and the rail laying machine. These are now standard equipment on all large roads.

His activity in developing an improved tie plate was typical. In about 1920 Mr. Davis saw the need for a much larger plate than was then in vogue anywhere in the United States. The soft wood ties placed in service on the Great Northern Railway soon became badly damaged by rail cutting; and, looking ahead to the increased traffic and heavier equipment of the future, Mr. Davis designed and recommended a plate 9 inches by 11½ inches. The management was aghast at such a large plate, but after months of discussion 120,000 of them were ordered from the steel mills and used with new rail.

---

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXI, December, 1917, p. 1829.

The management, however, soon felt that a smaller plate might be satisfactory, using the same rails. Mr. Davis objected because the plate would be out of balance and would not give satisfactory service. His decision was overruled and a 7½-inch plate instead of a 9-inch plate became standard. During the succeeding five years many millions of these plates were placed in the track. Twelve years later, however, the plates started to give trouble, the breaking off of the ends caused the rail to tip or cant inward, tightening the gage. It became necessary to replace them with a larger plate and the smaller plates were used on less important lines. By the time of Mr. Davis' death, the tie plate he had orginally designed, with slight modifications, had become standard on eighty per cent of the main tracks of American railroads.

With the adoption of heavier rail sections similar problems were experienced. Over a period of many years successful increases of 5 pounds per yard were soon abandoned after a short service proved them too light. Mr. Davis personally designed and secured approval of a section known as G. N. (Great Northern) 110-pound section which was used for many years. In the late nineteen thirties the American Railway Engineering Association (A.R.E.A.) appointed a committee to study and adopt a rail section which could be used as a standard on all American lines, except for a few with very heavy traffic. After about three years of study the committee adopted the present A.R.E.A. 112-pound rail which is nearly identical with the G. N. rail designed by Mr. Davis. The fishing surfaces of both rails are the same. The committee hesitated to adopt any existing pattern, which was the reason for the slight change from the G. N. rail.

Mr. Davis constructed and placed in operation six ballast washing and crushing plants. About seventy per cent of the main line had been ballasted with this material when he retired. There were many other examples throughout his long service, in which his foresight and judgment were finally proved to be correct.

On May 1, 1925, Mr. Davis was promoted to chief engineer and the position of maintenance engineer was left vacant. The management felt that with his experience and ability he could handle both positions, in which estimate they were correct. After his retirement the position of maintenance engineer was again established.

During the period when he held both positions the Great Northern was extended from Bend, Ore., into California, and the main line Cascade Tunnel in Washington, whose length of 7.78 miles made it the longest tunnel in the western hemisphere, was constructed. Many line changes were completed and curve reductions carried out, and the line generally was improved in anticipation of faster train schedules and of the new streamlined "Empire Builder" since placed in service. During the last fifteen years of Mr. Davis' service from ten to eighteen million dollars were expended annually under his direct supervision.

Throughout his staff of some one hundred and sixty officials and seven thousand other employees, there was a feeling of loyalty and respect for his fairness and consideration. Employees were seldom dismissed from the service, but demoted and given a chance to redeem themselves and again work up to better positions. He was ever thoughtful, kind, and considerate of others.

When he retired on January 1, 1940 (at the age of seventy one), his loss was keenly felt by the management and employees, and the American railroads lost an outstanding authority in maintenance engineering.

The condition of the Great Northern, then one of the best maintained roadbeds in the west, was a monument to his ability and steadfastness of purpose. He received numerous tributes to his outstanding service. A particularly revealing one was from Ralph Budd, Hon. M. ASCE, a former president of the Great Northern who, as a result of almost forty years of personal knowledge, wrote in part:

> "No one in my acquaintance has been more continuously devoted to railroad service. * * * You [Mr. Davis] certainly have the right to look back on your thirty-six years with the Great Northern with a great deal of satisfaction. The changes in standards of maintenance, and in the road's ability to serve the territory, have been to a considerable extent due to your ingenuity and efficiency."

Following his retirement in 1940, Mr. Davis lived for a while in Portland, Ore., and finally, in Seattle, Wash. He devoted his time principally to his large grain and livestock ranch in Idaho, which he owned and managed. He always was a great reader and analyst. He never reached the point where he felt he "knew it all," but was still a student of large scope up to the time he passed on. Ever fond of outdoor activities, he enjoyed country life—mainly, farming, walking, and motoring.

On January 10, 1934, in Spokane, Wash., he was married to Ethel Margot Ronald of Seattle. He is survived by his widow. In his name she has established the John R. W. Davis Memorial at Lehigh University. A substantial capital fund is to be held and the income only to be allotted to meritorious and needy students in civil engineering. In this way the idealism that led him to help so many young men in his lifetime is to be maintained in a splendid "living memorial" that will perpetuate his memory through years to come.

Mr. Davis was a charter member of the American Railway Engineering Association and was active in that organization, particularly in the formulation of track standards. He was a member of the Presbyterian Church.

Mr. Davis was elected a Member of the American Society of Civil Engineers on November 4, 1903. He became a Life Member in January, 1938.

ORVILLE VOSBURY DERR, M. ASCE[1]

DIED NOVEMBER 23, 1947

Orville Vosbury Derr, the son of William Lloyd and Lillian (Kies) Derr, was born at Needham, Mass., on April 27, 1885. He attended the public schools and the high school in Elmira, N. Y., and from September, 1901, to June, 1904, studied civil engineering at the Stevens School, Stevens Institute of Technology, in Hoboken, N. J.

---

[1] Memoir prepared by H. F. King, M. ASCE.

From 1904 to 1910 Mr. Derr was an engineering employee of the Baltimore and Ohio and Lehigh Valley railroad companies in a subprofessional capacity; and from 1910 to the end of 1911 he was an engineering employee of the Boston and Albany Railroad Company in a professional capacity.

Early in 1912 he entered the employ of the Erie Railroad Company as resident engineer, a position he retained until April, 1918. He received a furlough from the railroad to enter military service during World War I. Commissioned a Second Lieutenant, Corps of Engineers, in the Railway Transportation Corps, he was honorably discharged from the Army as a Captain at the termination of hostilities, after serving in France with the United States Expeditionary Forces. Subsequent to his discharge from military service, Mr. Derr again entered the employ of the Erie Railroad Company in August, 1919, as resident engineer, and thereafter successfully advanced to general office engineer in 1929, and to valuation engineer in 1931, resigning in August, 1938, to enter private practice.

His practice consisted of consultation on valuation and construction projects, and he retained this practice until late in 1941, when he abandoned it to associate himself with Foley Brothers, Contractors, of Pleasantville, N. Y., as field engineer. He took charge of constructing a graving dock, piers, and warehouses (known as the St. Helena project) being constructed for the United States Navy at Norfolk, Va.

Mr. Derr continued in this capacity until ill health forced him to resign late in December, 1942. After recovering his health early in 1943, he was reemployed by Foley Brothers as field engineer to supervise the Republic Plant extension at Farmingdale, Long Island, N. Y. After the termination of this project, he became associated with the Merritt-Chapman and Scott Corporation. Subsequent to 1945 and early in 1946, at the behest of L. Morris Mitchell, Assoc. M. ASCE, former vice-president of Merritt-Chapman and Scott Corporation, he became a part of L. Mitchell, Incorporated, organized to carry out heavy construction and specializing in foundation work and pulp and paper mills. Mr. Derr continued in this capacity until his death.

While with the Erie Railroad Company he specialized in heavy construction work, and one of his most important achievements was the elimination of railroad grade crossings through Paterson, N. J., an undertaking ordered by the Public Utilities Commission of the State of New Jersey.

Mr. Derr came from a family of engineers starting, to available knowledge, with Isaac Derr, an engineer in Napoleon's army in Egypt, the Derr name appears in Napoleonic records of Egyptian surveys. Isaac came to America later with a brother and founded the Derr family here, and it is said that no Derr male lived a happy life unless he followed the engineering profession. Mr. Derr followed that profession with zest, giving his best to every position he held.

His work was always characterized by accuracy and good judgment. He was a gentleman of very likable personality and made many lasting friendships in business and in his home surroundings.

On Thanksgiving Day (November 29), 1934, at Melrose, Mass., he was married to Ruth Barry. He is survived by his widow, and four sons by a former marriage. Mr. Derr's sons, Thomas, Lewis, William, and Ralph, served in World War II.

Mr. Derr was elected a Member of the American Society of Civil Engineers on May 15, 1939.

RICHARD GRIFFITH DEVELIN, M. ASCE[1]

Died March 22, 1947

Richard Griffith Develin, the son of James and Mary (Aylward) Develin, was born in Philadelphia, Pa., on November 15, 1866. There was a family of eight children, equally divided between boys and girls. One boy died in infancy and Richard was the youngest of the three who survived.

His early education was received in the public schools, and he was graduated from the Philadelphia Central High School in 1884. In October of that year he entered the service of the Pennsylvania Railroad Company as a clerk in the office of the chief engineer. An aptitude for building childish structures was displayed in early boyhood, which no doubt pointed the way to an engineering career. During this clerkship his studies were continued in the evenings, and in 1888 he entered the department of civil engineering of the University of Pennsylvania at Philadelphia, taking a special two-year course in structural engineering.

The years from 1890 to 1894 were stepping stones; he was draftsman and designer with the New Jersey Steel and Iron Company (Trenton, N. J.), with Cofrode and Saylor (Pottstown, Pa.), and with the Pencoyd Bridge Company (Pencoyd, Pa.). In 1896 Mr. Develin returned to the service of the Pennsylvania Railroad Company and was appointed assistant engineer in the Maintenance of Way Department, where in due course he was placed in charge of masonary design, renewals, and plans for general maintenance structures on the lines east of Pittsburgh (Pa.), Erie (Pa.), and Buffalo (N. Y.) to New York (N. Y.). May, 1920, marked his course as assistant engineer of bridges under the chief engineer of the Pennsylvania Railroad lines east of Pittsburgh, Erie, and Buffalo, and in January, 1923, his promotion to assistant engineer of bridges and buildings took place.

To this position, in addition to regular bridge repairs and maintenance, were added the responsibilities of structural design, including foundations and superstructure of shops at Renova (Pa.), Wilmington (Del.), and Trenton, which consisted of locomotive erecting shops, blacksmith shops, roundhouses, planing mills, powerhouses, and other buildings. Other similar projects were under his charge in Philadelphia at Park Shops, Mantua

---

[1] Memoir prepared by Henry J. Sherman, M. ASCE.

Transfer, Gray's Ferry Shops, and the export warehouse for the Girard Point Storage Company, including powerhouses, a roundhouse, two machine shops, a storeroom, and so on. In addition he supervised a locomotive testing plant, a locomotive erecting shop, and a lathe and machine shop at Altoona, Pa.; a powerhouse and car shop at Enola, Pa.; and a steel-concrete coal wharf at Morrisville, Pa. Mr. Develin was honorably retired on pension in March, 1932.

In addition to regular employment with the railroad company, he was consulting engineer for the Philadelphia Suburban Transportation Company, serving suburban Philadelphia in the three thickly settled counties of Delaware, Chester, and Montgomery. In the early 1900's, when electric railway expansion was at its height, this company extended its lines into new areas where considerable bridge and viaduct projects were required. Mr. Develin was in responsible charge of the design and construction of these structures. After completion of these lines he continued with the company as consultant on maintenance and changes until 1942. He was the engineer for the New Hope-Delaware Bridge Company on the design and erection of a steel highway bridge across the Delaware River connecting New Hope, Pa., and Lambertville, N. J. The design of bridges and viaducts for the Cuba Eastern Railway Company were among his activities.

Recognizing early in his career the value of professional group contacts, he joined the Philadelphia Engineers' Club on February 5, 1898, continuing this membership until his death. As a director from 1908 to 1913, he served on many committees during this long membership and was active in promoting and maintaining the club's technical meetings from its early struggling days. Among his memberships was that of the American Railway Engineering Association.

Mr. Develin was deeply interested in the affairs of the Society and was seldom absent from the annual meetings in New York. Through the inspiring leadership of his college friend, Richard L. Humphrey,[2] M. ASCE, who was a member of the Committee on Development, he took an active part in the reorganization of the early 1920's. Following this accomplishment and the establishment of the Philadelphia Section, Mr. Develin was a regular attendant at its meetings, and he participated in its proceedings, exerting his best efforts to increase the membership and growth of the section. Mr. Develin was almost, if not quite, the last of those who had close association with the older group of distinguished Philadelphia engineers, among whom were Lewis M. Haupt,[3] and John C. Trautwine, Jr., Members, ASCE, William H. Brown, and Joseph T. Richards.

Early in life he formed good reading habits and found time to read more widely during his retirement. In addition to keeping abreast of engineering developments, he included the subjects of biography, economics, and to a lesser degree, the better class of fiction. He kept himself well informed on the topics of the day and took great pleasure in discussing them with many friends.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 93, 1929, p. 1839.

[3] *Ibid.*, Vol. 103, 1938, p. 801.

Mr. Develin was an agreeable companion and his ample background of knowledge supplied a full range of interesting conversational subjects. He was small of stature, and in manner mild, dignified, and reserved. Although firm and persistent in his opinions, tolerance of those who did not agree with him was always in evidence; he was keenly aware of his social responsibilties and his charities kept pace with his income.

Mr. Develin was a devout, consistent church member all his adult life, serving as teacher in the church school, as a member of the choir, and as a trustee of the Centenary-Tabernacle Methodist Church of Camden, N. J. Twenty-three years ago, at the time of his moving to Moorestown, N. J., he became identified with the First Presbyterian Church and served many years as a trustee. His recreations were travel, golf, sailing, and music. He made extensive trips throughout the United States and Canada, often combining them with Society meetings. With his wife he made an extensive tour of Europe in their early married life.

On November 3, 1892, Mr. Develin was married to Helen Archer of Camden. They had two children, a son, F. Archer, and a daughter, Dorothy A. (Mrs. Charles P. Walnut). Mrs. Develin died on November 23, 1924. He was married to Mrs. Anna (Sharp) Carson, a childhood friend, on June 26, 1926. She died in March, 1937.

Mr. Develin was elected a Member of the American Society of Civil Engineers on May 1, 1907.

ELBERT HERMON DRESSER, M. ASCE[1]

DIED MAY 21, 1943

Elbert Hermon Dresser, the son of Hermon L. and Phebe (Rhoades) Dresser, was born in Jefferson, Iowa, on October 9, 1878. His parents were of New England ancestry and he followed in the footsteps of his father in choosing the profession of a railway civil engineer.

After graduating from the Jefferson High School, he moved with the rest of the family to Duluth, Minn., in 1896, and spent a year in business school and two years as a clerk for the Zenith Paper Company.

He then found work for about a year with a survey crew of the Duluth, Missabe and Northern Railway, leaving in the fall of 1900 to enter Rensselaer Polytechnic Institute, Troy, N. Y., from which school he was graduated with the degree of Bachelor of Science in Civil Engineering. His summer vacations were spent on survey work for the "Missabe Railway," and after graduation he continued with the same company.

The Mesabi Iron Range was greatly developed during the next few years, and the young engineer was kept busy on a variety of work, as locating engineer, resident engineer, and maintenance engineer, under the supervision of his father then chief engineer of the railway. This rapid expansion was necessary to keep up with the mining industry.

---

[1] Memoir prepared by a Committee of the Duluth Section consisting of Gordon H. Butler and Wayne A. Clark, Members, ASCE.

In August, 1918, he entered the Corps of Engineers of the United States Army, Railway Division, with the rank of Captain, and served until January, 1919.

On return to civilian life, Mr. Dresser spent a few months in the contracting business in Texas and then became manager and later president of a concrete (products) business, with plants in Duluth and St. Paul, Minn. He sold out his interest in December, 1927.

In January, 1928, he returned to the Duluth, Missabe and Northern Railway Company (which, in 1937, became the Duluth, Missabe and Iron Range Railway Company) as chief engineer in charge of all construction and maintenance of way and structures. He held this position at the time of his death. This position had been held by his father up to 1919 when he retired.

Among the professional, business, and social organizations to which he belonged were: The Society of American Military Engineers, United States Army Officers Reserve Corps, American Legion, Sons of the American Revolution, American Railway Engineering Association, Duluth Chamber of Commerce, Kitchi Gammi Club, Northland Country Club, and Chi Phi fraternity.

Mr. Dresser was also a member of Palestine Lodge No. 79, F. and A.M.; Duluth Commandery Knights Templars; and AAD Temple of the Mystic Shrine.

In January, 1911, Mr. Dresser was married to Isabel Meads, who survives him. He is also survived by two sisters, Lulu (Mrs. Ed Barrett) and Ethel (Mrs. Harry Deutschbein).

He was of a kindly disposition with a keen sense of humor and a dislike of sham and pretense. With his strong character and sterling integrity he made friends easily and was intensely loyal to them. He was fond of home life, but one of the greatest pleasures was traveling with his wife.

Mr. Dresser was elected a Member of the American Society of Civil Engineers on September 9, 1919.

CLIFFORD GEORGE DUNNELLS, M. ASCE[1]

Died April 15, 1947

Clifford George Dunnells, the son of Clifford Charles and Susan Emma (Christy) Dunnells, was born on July 8, 1875, at Glenfield, Pa. His father was a pioneer furniture manufacturer in Pittsburgh, Pa., where the family had moved during his boyhood. He attended the public schools and was graduated from the Pittsburgh Central High School in June, 1893. He then entered Lehigh University in Bethlehem, Pa., in September of that same year, and was graduated in June, 1897, with the degree of Bachelor of Science in Civil Engineering.

---

[1] Memoir prepared by a Committee of the Pittsburgh Section, consisting of Eugene N. Hunting, Chairman, Louis P. Blum, and George S. Richardson, Members, ASCE, and C. A. Keelen, Assoc. M. ASCE.

During the summer college vacations he worked for the Pittsburgh Bridge Company and, after graduation, continued working with this company until June, 1900, when he became estimator for the American Bridge Company in Pittsburgh, remaining with that company until March, 1910. After that he entered the office of Charles Bickel, a Pittsburgh architect, as structural engineer. Later in the same year he became a member of the firm of Hunting, Davis and Dunnells, being associated with Eugene N. Hunting, M. ASCE, and Lawrence Davis, in Pittsburgh, engaging in the design and construction of many important industrial buildings and structures throughout the eastern United States. This association continued during his entire lifetime.

With his associates he developed a large practice as consultant on the design of steel and reinforced concrete structures. Simultaneously with his professional practice, Mr. Dunnells became a professor on the faculty of the Carnegie Institute of Technology in Pittsburgh. He began as assistant professor of mathematics and physics in the School of Engineering in 1910, and in 1912 he organized the Department of Building Construction in the School of Applied Industries—the first course of this kind organized in any American college. The work of this school has been a permanent influence on the building construction industry of the Pittsburgh district. In 1918 he became associate professor, and in 1933, professor of civil engineering, continuing in this position until his retirement in 1943. This culminated a noteworthy and continuous teaching career of thirty-three years.

Realizing that a college should give a student more than mere technical education, he urged extracurricular activities. During his entire association with Carnegie "Tech," he was a director of the college Young Men's Christian Association (Y.M.C.A.) and served a term as its president. He was active in community affairs as a member of the Pittsburgh Chamber of Commerce, the Highland Country Club, and the Neighborhood Men's Bible Class, in addition to being a director of the Northside Y.M.C.A. and state director of the Y.M.C.A. He belonged to Trinity Episcopal Church and held many church offices.

Professor Dunnells was a member of Alpha Tau, honorary engineering fraternity. He also served as a member of the Building Code Commission of the State of Pennsylvania. For many years he was an enthusiastic member of the F. and A. M., a member and past-master of McKinley Lodge, No. 318; a past high priest of Shiloh Chapter, No. 257, Royal Arch Masons; a member of the Pennsylvania Consistory, Ancient Accepted Scottish Rite; and a member of Syria Temple, Ancient Arabic Order Nobles of the Mystic Shrine.

He took an active part in the formation of the Pittsburgh Section of the Society in January, 1918, and served as its President from 1935 to 1937. In October, 1936, the convention of the Society was held in Pittsburgh, and his work as President of the section during this convention was outstanding. In 1939 he was appointed to fill a vacancy in the Society's Board of Direction occasioned by the election of Director Roland P. Davis, M. ASCE, as Vice-President, serving until January, 1943. He was enthusiastic in the performance of his duties as a Director, and gave especially fine service to the Committee on Publications, being its efficient chairman for the year 1942.

He was also a member of the Engineers' Society of Western Pennsylvania and the American Concrete Institute, and was a registered engineer in the states of Pennsylvania and Ohio.

He is survived by his widow, Inez E. (Mullian) Dunnells; a son, Clifford, Jr., of Port Washington, N. Y.; four daughters, Dorothy R., Margaret E., Mary S. (Mrs. Theodore J. Lutz, Jr.) of Pittsburgh, and Elizabeth C. (Mrs. Victor Greulach) of Houston, Tex.; a sister, Cora (Mrs. R. H. Harris); and nine grandchildren.

"His works do follow him." A master workman has finished his earthly structure, leaving a record of achievement to serve as an inspiration to the many younger members of the profession whom he has been privileged to guide and assist.

Mr. Dunnells was elected a Junior of the American Society of Civil Engineers on February 4, 1902; an Associate Member on January 2, 1907; and a Member on March 4, 1913. He became a Life Member in January, 1944.

JOHN CONRAD FITTERER, M. ASCE[1]

Died March 12, 1947

John Conrad Fitterer, the son of J. S. and Rosina E. (Moop) Fitterer, was born in Clyde, Ohio, on December 15, 1871. His formal education resulted in acquiring the degrees of Bachelor of Science from Ohio State University at Columbus, in 1898, and Bachelor of Science (Civil Engineering) in 1904, and the degree of Civil Engineer from the University of Colorado at Boulder in 1912. In 1913 and 1914 he secured additional training in mathematics at the University of Chicago, in Chicago, Ill.

He was employed by the American Clay Machinery Company of Bucyrus, Ohio, prior to graduation in 1898, and after receiving his degree, he was in charge of the purchasing department with this firm until 1903. He was with the United States Geological Survey in the summer of 1904 as transitman on water supplies in Montrose, Colo., and later joined the Bureau of Reclamation in various capacities on the La Plata project in New Mexico, Kremmling Reservoir in Colorado, and the North Platte project in Wyoming and Nebraska. His design and construction of reclamation projects secured for him the position of assistant engineer with the Bureau of Reclamation which organization he left in the fall of 1906. From the fall of 1906 until the spring of 1908, he was connected with the Central Colorado Power Company in survey and construction of a hydroelectric plant on the Colorado River. Then, from spring to fall of 1908 he worked with the Orchard Mesa Irrigation Project on triangulation, topography, and line surveys.

---

[1] Memoir prepared by R. L. Downing, M. ASCE.

Mr. Fitterer was professor of civil and irrigation engineering at the University of Wyoming in Laramie from September, 1908, to September, 1928. He was dean of the College of Engineering and head of the Agricultural Experiment Station from 1922 until 1924. During his association with the University of Wyoming, Professor Fitterer developed this department into one of the strongest at the university. From September, 1928, until his death, he was professor of mathematics there; and he became head of the department of mathematics at the Colorado School of Mines in Golden, in 1929.

His record of educational attainment clearly indicates the high standards he believed necessary in each field of work. This concept is further emphasized by his contemporaries, who elected him to outstanding professional societies, in which he took an active part. He was a member of Tau Beta Pi, Phi Kappa Phi, the American Society for Engineering Education, the Mathematical Association of America, the American Mathematical Society, the American Association for the Advancement of Science, the National Education Association, and the Colorado Society of Engineers. Professor Fitterer's counsel was regularly sought by his associates; his interest and competence are further demonstrated by many engagements as consultant, and in various publications.[2,3] These engagements as consultant covered work in water supply, irrigation, drainage, and sewerage.

Professor Fitterer's understanding, friendliness, and wise counsel endeared him to students and associates. His early professional development in reclamation remained a strong interest, and he continued to take an active part in the progress of the west by irrigation, water supply, and drainage. Long and successful experience in engineering education gave him many friends and a wide acquaintanceship in engineering in the Rocky Mountains.

On December 27, 1899, he was married to Lucia E. Kemp of Perrysberg, Ohio, who survives him.

Professor Fitterer was elected an Associate Member of the American Society of Civil Engineers on April 2, 1912, and a Member on October 22, 1924.

JAMES BENTON FRENCH, M. ASCE[1]

Died December 2, 1947

James Benton French was born at New Hartford, N. Y., on September 12, 1863. He was the son of Thomas Paine and Sarah Brooks (Benton) French.

---

[2] "Reclamation by Drainage," by J. C. Fitterer, *Bulletin No. 90,* Wyoming Agri. Experiment Station, Univ. of Wyoming, Laramie, 1911.

[3] "Meteorology for Twenty Years," by J. C. Fitterer and H. G. Knight, *Bulletin No. 100,* Wyoming Agri. Experiment Station, Univ. of Wyoming, Laramie, 1913.

[1] Memoir prepared by Frederick Auryansen, M. ASCE.

His paternal ancestor, William French, emigrated from England to Cambridge, Mass., in 1635, removing to Billerica, Mass., in 1653, where he was the first representative from that town, and also was a Lieutenant of the Militia. In 1850 Thomas Paine French went to California to seek gold, but later returned to central New York, where he became a farmer.

A second paternal ancestor was Roger Gillmore, one of the original settlers of Jaffrey, N. H. As First Lieutenant, then Captain, of the first military company organized in 1775, he served during the Revolutionary War. He was the first Justice of the Peace in Jaffrey, and a delegate to the New Hampshire State Constitutional Convention in 1791.

Sarah Brooks Benton was the daughter of James Benton who came from England. He became a builder at Utica, N. Y., where he constructed important buildings and also served as mayor of that city.

From such sturdy pioneering stock James French inherited the firm, steady purpose and high character which were clearly evident to all who knew him, and which prompted a friend to remark, "You can't say too much that's fine of him."

Mr. French attended the public schools at New Hartford and Utica, and was graduated from Cornell University in Ithaca, N. Y., in 1885, with the degree of Bachelor in Civil Engineering (later changed to Civil Engineer). The following year he held the McGraw fellowship in engineering at Cornell.

For the subject of his graduation thesis he chose the Niagara cantilever bridge, a structure for which Charles Conrad Schneider,[2] Past-President, ASCE (then chief engineer of the Pencoyd (Pa.) Bridge Company), was consulting engineer. Mr. Schneider welcomed the young engineer who sought his counsel and helped him with data and suggestions for his thesis.

When Prof. Charles D. Marx,[3] Past-President and Hon. M. ASCE, recommended Mr. French for the position of rodman on construction of a branch line of the Missouri Pacific Railroad Company in Kansas in 1886, he asked Mr. Schneider's advice, and following it, "went west." The next year he became transitman on location of the Fort Worth and Denver City Railway Company across the Texas Panhandle.

As these field experiences confirmed his preference for bridge engineering, Mr. French then spent a short time as draftsman with the Groton (N. Y.) Bridge Company. At that time various bridge companies were in active competition, each with its special designs, usually tendered on a lump sum basis, so that designs and costs were not readily comparable. The Groton Bridge Company was a small company and not to be classed with the Keystone Bridge Company at Pittsburgh, Pa., the Edgemoor Company in Delaware, the Phoenix Company at Phoenixville, Pa., the Union Company at Athens, Pa., or the Pencoyd Company near Philadelphia, Pa.

An inspector at Groton advised Mr. French to transfer to a larger and better company, so in 1888 he applied at the Pencoyd Company, where he was welcomed by Mr. Schneider, who was not only a good judge of ability, but a world leader in the art of high-grade bridge design and construction. Under such favorable auspices the young assistant engineer was fortunate in being charged with planning original designs and stress sheets, developing details for tracers, and making erection plans, bills of material, and shipping bills—the entire paper work for the bridge. His work at Pencoyd included steel structures for the Reading Terminal at Philadelphia and the arched train shed of the Pennsylvania Railroad at Jersey City, N. J., which was removed in 1922.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 81, 1917, p. 1665.

[3] *Ibid.*, Vol. 105, 1940, p. 1785.

In 1889 Mr. French was granted a leave to join fifty other members of the Society, together with members of the American Society of Mechanical Engineers and the American Institute of Mining and Metallurgical Engineers, on a visit to European countries and the Paris exposition in France. His experiences are delightfully recounted, in concert with three other members of the group, in *Civil Engineering.*[4] In port his first observations were on the Liverpool, England, landing stage, providing for a 30-foot tidal range, and connected to the shore by hinged bridges—prototypes of his later specialty.

By 1892 Mr. French had become so thoroughly experienced in the best structural steel practice of the period that Mr. Schneider recommended him for the position of assistant engineer of the Chesapeake and Ohio Railway at Richmond, Va., where he later served as bridge engineer until 1898. The New York, New Haven and Hartford Railroad Company engaged him in 1899 to design a number of bridges. These were based on E 40 live loading, then considered ample provision for current and future capacity. In 1900 Mr. French was appointed bridge engineer by J. V. Davies,[5] M. ASCE, chief engineer of the West Virginia Short Line, a new railroad (later part of the Baltimore and Ohio Railroad system) built between Clarksburg and New Martinsville, W. Va., to develop a region rich in coal and oil resources. The fifty-four bridges were designed for E 40 loading and all structural steelwork was under Mr. French's direction.

Mr. Davies became chief engineer of the Atlantic Avenue improvement of the Long Island Railroad in 1901, and appointed Mr. French bridge engineer for this important grade crossing elimination through the heart of Brooklyn, N. Y. This work comprised three miles of steel viaducts and two and a half miles of cut-and-cover subway[6] with a complicated subsurface passenger terminal at Flatbush Avenue, Brooklyn, which was later surmounted by an elevated freight terminal with a large angular divergence between the two. With bold assurance Mr. French developed a cellular grillage of heavily reinforced concrete to distribute the column loads of the elevated structure over the roof of the passenger terminal. Although cracked and seriously undermined by a subsequent excavation for a city subway, causing subsurface column settlement up to 6 inches, this reinforced concrete grillage is still carrying the load of a surface freight station and an overhead bottle storage warehouse after forty years of service.

---

[4] "Engineers' Odyssey to Europe—1889," by A. Prescott Folwell, James B. French, Andrew J. Provost, Jr., and T. Kennard Thomson, *Civil Engineering*, January to May, 1945.

[5] For memoir, see *Transactions*, ASCE, Vol. 105, 1940, p. 1826.

[6] *Railroad Gazette*, April 25, 1902.

This and other pioneer work in the design and use of reinforced concrete, when its theory was still being formulated and its practice evolving, was thoroughly justified by the endurance of the structures he built. Another example is the "concrete-steel," 3-inch slab fence surrounding the Sixth Avenue depressed freight yard in Brooklyn, which is still in good condition after forty years of exposure.

From 1904 to 1908 Mr. French was bridge engineer of the Long Island Railroad, continuing to employ conservative yet progressive elements of good construction.

Subsequent to 1908 he was in private practice as consulting engineer for various contractors, as well as for the Erie Railroad, the Lehigh Valley Railroad, the New York Central Railroad, the Long Island Railroad, and the Hudson and Manhattan Railroad Company. His unique work during this period was the development of a special type of screw-suspended transfer bridge,[7] with a "contained apron" operated as a unit with the bridge itself, but free to rise as cars left a float to go shoreward on the main span of the bridge. Seventeen of these bridges have been built for the aforementioned railroads, and one for the Bronx market—all in New York (N. Y.) harbor .

Other notable work under his charge was a series of nineteen railroad and thirty-five highway bridges, and a 3,535-foot-long, four-track reinforced concrete tunnel built for the Bay Ridge improvement of the Long Island Railroad —the important freight link from Bay Ridge, N. Y., over Hell Gate Bridge to New England. The extensive shop and inspection buildings at the Hudson and Manhattan Railroad Company terminal in Jersey City were also designed by him during this period.

Mr. French was a charter member of the American Institute of Consulting Engineers, and a former member of the American Society for Testing Materials, the Cornell Society of Engineers, the Brooklyn Engineers Club, and the New York Railroad Club. He presented papers before the Brooklyn Engineers Club and the Connecticut Society of Civil Engineers, and his discussions of papers are recorded in the *Transactions* of the Society.

Whatever work Mr. French undertook was always completed with the sincere purpose to do better than before, so that his work exemplified not only good practice of the time, but improvement wherever feasible. He was an ardent, skilful practitioner and displayed sound judgment in his chosen profession. His friends cherish the fine example of his exemplary life of service, his dignified bearing, his gracious and cordial friendship, and his unswerving loyalty to principle. He was a devout member of the Protestant Episcopal Church, and one of the founders of the Young Men's Christian Association at Jamaica, N. Y.

In 1891, he was married to Flora Williams of Groton, who died on January 13, 1945; he is survived by two sons, Thomas Morton French, and William Gillmore French, and by a brother, Charles G. French.,

Mr. French was elected a Junior of the American Society of Civil Engineers on February 6, 1889; an Associate Member on February 7, 1894; and a Member on November 2, 1898. He became a Life Member in January, 1929.

---

[7] *Engineering News*, December 28, 1911, p. 770.

PIERCE POWERS FURBER, M. ASCE[1]

DIED DECEMBER 19, 1947

Pierce Powers Furber, the son of Pierce Powers and Kate (Montgomery) Furber, was born in St. Louis, Mo., on October 23, 1885. The family moved to Northfield, Minn., when he was a small boy, and there he received his education in the public schools. Later, he attended the University of Minnesota, in Minneapolis, from which he was graduated in 1908 with the degree of Civil Engineer. While in college he joined Sigma Alpha Epsilon and Theta Tau fraternities.

Mr. Furber's early experience was with the Minneapolis Steel and Machinery Company, and with C. A. P. Turner, M. ASCE, consulting engineer. Working under the guidance of Mr. Turner he received a fundamental training in the art of reinforced concrete, from the standpoint of practical construction, as well as design and detail. A broad field was covered in bridge and building work, setting the pattern for his career in later years.

In 1912 he was assigned to the Chicago (Ill.) office of the C. A. P. Turner Company as district engineer, holding this position for four years. During this time he handled the estimates, designs, and sales promotion of the "mushroom" system, which applied principally to heavy building construction.

In 1917 the advent of World War I, brought Mr. Furber into the Boston (Mass.) office of Stone and Webster, as engineer in the structural division. His work included supervision of the structural designs and specifications for various important buildings at the Rock Island (Ill.) Arsenal—the field and siege building, the boiler house, and various storehouses—and also the designs for the plant buildings of the Westinghouse Lamp Company at Trenton, N. J. During 1918 he was transferred to the American Shipbuilding Corporation at Hog Island, Pa., as assistant to the superintendent of materials in the hull fabrication department.

Early in 1919 when the Hog Island work slowed down, Mr. Furber returned to St. Paul, Minn., as agent for the Paul J. Kalman Company, later the Kalman Steel Company. For the following ten years he continued in the general capacity of manufacturers' representative, estimating, designing, detailing, and selling reinforcing steel, fire-proofing materials, and steel building products. In St. Paul he designed the reinforced concrete buildings for the complete publishing plant of the Louis F. Dow Company; also, for the Butler Brothers Company, he designed and supervised general concrete construction. In 1922 he became district engineer for the Corrugated Bar Company at St. Paul.

In Danville, Va., during 1923–1924, as a partner in the firm of "Wiseman and Furber," Mr. Furber continued to act as manufacturers' representative and distributor for the Berger Manufacturing Company and others. After working for a short time in Washington, D. C., in 1925, he went to Jacksonville, Fla., where he continued as sales representative for about five years.

---

[1] Memoir prepared by Wallace E. Belcher, M. ASCE.

Returning to Philadelphia, Pa., in 1930, Mr. Furber was employed by the United Engineers and Constructors, Incorporated, in the structural division as checker and designer. He was engaged on the Pennsylvania Railroad improvements in Philadelphia; in the design of the manufacturing plant for the Solvay Process Company at Baton Rouge, La., and on the design of the Pittsburgh Plate Glass Company factory in Newark, N. J.

From 1941 to 1943 Mr. Furber was supervising structural designer for Ford, Bacon and Davis, Incorporated, on the project at the Jacobs Aircraft Engine Company in Pottstown, Pa. Working under wartime pressure, his general health became somewhat impaired. However, he had apparently recovered, and for several years prior to his very sudden and untimely death he maintained an office in the Philadelphia Fidelity Building as consulting structural engineer.

On September 5, 1928, Mr. Furber was married to Helen Minium of Jacksonville. He is survived by his widow and by their two daughters, Frances Minium and Mary Montgomery.

Mr. Furber took an active interest in the affairs of the Society, and his community. He had an even, affable disposition, and possessed a ready wit that made and held many friends. He was a member of the Sons of the American Revolution, the Minnesota Historical Society, the American Concrete Institute, and the Republican party. A frequent contributor to technical discussions, he was also the author of several articles.[2, 3]

Mr. Furber was elected a Member of the American Society of Civil Engineers on September 10, 1923.

JAMES EDWIN GIBSON, M. ASCE[1]

DIED OCTOBER 15, 1947

James Edwin Gibson, the son of John Wilson and Mary Elizabeth (Dickinson) Gibson, was born near Pine Bluff, Jefferson County, Ark., on December 19, 1874. He received his early education in his home state and was graduated from the University of Arkansas at Fayetteville with the degree of Bachelor of Mechanical Engineering in 1894.

His engineering activities began in 1895 in the employ of Jay M. Whitham, consulting mechanical engineer, of Philadelphia, Pa. During the fifteen months with Mr. Witham he assisted in more than three hundred boiler and engine efficiency trials and conducted as principal more that one hundred boiler tests.

---

[2] "The St. Croix River Bridge," by Pierce P. Furber, *Engineering News*, December 28, 1911.

[3] "Reinforced Concrete Columns," by Pierce P. Furber, *Proceedings*, A. C. I., Vol. 12, 1916.

[1] Memoir prepared by John Anderson, M. ASCE.

In 1896 he was employed by the Moro Phillips Company in Camden, N. J. (later General Chemical Company) as a mechanical engineer. During this time he designed and rebuilt Glover and Gay Lussac acid towers, and a phosphorus plant.

Although well on his way to becoming a chemical engineer, Mr. Gibson entered the civil engineering field in 1897 when he became an assistant engineer for the American Pipe and Construction Company in Philadelphia. The chief engineer of this company was the very well-known J. W. Ledoux,[2] M. ASCE, of whom Mr. Gibson always spoke with greatest respect and admiration. The American Pipe Company manufactured pipes for water systems but also designed and constructed works and owned and operated some thirty plants throughout the eastern states. During his employment of twenty years with this company, Mr. Gibson's activities covered a wide range. At first he was concerned with the design and construction of a number of hydroelectric and gas plants but eventually his sphere was restricted to the design and construction of water works.

He served in 1897 as manager of the Waukesha (Wis.) water works, supervising the sinking of two 1,800-foot artesian wells and the installation of steam pumping and auxiliary equipment. One of the largest projects on which he was engaged was the development of the water supply system for the main lines of the Pennsylvania Railroad Company between New York, N. Y., and Washington, D. C., Philadelphia, and Pittsburgh, Pa. This work embraced every type of water supply and included more than fifty impounding dams, innumerable steel tanks and standpipes, and more that five hundred miles of pipe. The cost of construction was more than fifteen million dollars. A similar project involved design and construction of three systems for the New York Central and Hudson River Railroad at Buffalo, Rochester, and Syracuse in New York.

In 1903 Mr. Gibson made his first acquaintance with Charleston, S. C., when he was sent there to make studies for the proposed Goose Creek supply for that city. The plant was constructed in 1904 and was at that time unique. A tidal stream was dammed by a low earth dike to impound fresh water upstream and keep out salt water downstream. Climatic conditions at times caused the evaporation from the surface of the reservoir to reach twenty million gallons daily—about four times the city's requirements.

When the Charlestown Light and Water Company which owned and operated this water works system was purchased by the City of Charleston, Mr. Gibson was in charge of the operation of the plant. He accepted the city's offer of the position of manager and engineer of the water works, retaining the position until his death.

Mr. Gibson was a leader in the use of cement lining for cast iron pipes. In cooperation with the American Cast Iron Pipe Company in Birmingham, Ala., he contributed greatly to the development of this method of protecting cast iron piping. Experimental lines installed in Charleston in 1922 were so successful that no other type of lining has been used there since. In the summer of 1939 a number of mains totaling two and a half miles were lined in place by the Tate method. At the time of his death a research project on the effectiveness of this cement lining was under way on a line supplying the City of Summerville, S. C., which draws water from the Charleston supply.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 104, 1939, p. 1956.

What is regarded as Mr. Gibson's outstanding achievement was the conception and construction of the twenty-three mile Edisto-Goose Creek tunnel aqueduct for Charleston. This is an unlined tunnel constructed through a marl formation at an average of thirty feet below sea level for its entire length. The boldness of this project can be realized when it is remembered that the area was visited by a violent earthquake in 1886. However, no signs of faulting were discovered in the tunneling operations.

Another noteworthy engineering accomplishment was the extension of the water supply system of Charleston to the west side of the Ashley River, involving the construction of a subaqueous supply main on the bottom of the river. At the time of his death Mr. Gibson had practically completed an entirely new treatment and pumping plant.

With his death there passed from the City of Charleston an outstanding water works engineer and a citizen of the highest standards. A man of greatest integrity, he was a rugged individual who never failed to exert himself for the best interests of the community he served for thirty years. His efficient administration of the Charleston municipal water works made it an exception to the usual gloomy story of public operation of utilities.

It may be said of him, as it was said of Christopher Wren: "If you wish to see his monument, look around you." The Charleston water works, with which Mr. Gibson was associated in one way or another for more than forty years, although not so easily seen as the great architect's cathedral, is nonetheless concrete evidence of a great achievement.

Mr. Gibson was a pioneer in spirit, boldly undertaking new and untried engineering feats, but he was not by any means a romantic adventurer. All his ventures were carefully planned. He took nothing on faith, but practiced St. Paul's admonition: "Prove all things." It was said among his associates that he knew all the answers but invariably checked them with his slide rule, an instrument so long and so well used that hardly a figure or a graduation remained on it.

He served as a contact member for The Citadel Student Chapter of the Society from 1937 until 1942. He took a very active interest in the work of the chapter, being a frequent vistior at meetings and always ready with helpful advice and suggestions.

His alma mater honored him in June, 1941, by conferring on him the honorary degree of Doctor of Science. In the same year the American Water Works Association bestowed on him the George W. Fuller Memorial Award. The citation accompanying this award reads:

> "For his distinguished leadership in water supply construction in North America; for his effective administration of the water supply system of the city of Charleston; and for his worthy contribution to the activities of the Association."

Mr. Gibson was an honorary member and past-president of the American Water Works Association; a member of the New England Water Works Association; a member of the American Society of Mechanical Engineers; and a charter member and past-president of the South Carolina Society of Engineers. He was also a past-president of the Charleston Rotary Club and a Royal Arch Mason.

In 1903 he was married to Florence A. Blair in Waukesha. He is survived by his widow; two children, Edwin Emmons Gibson and Henrietta Blair Gibson; and one grandchild.

Mr. Gibson was elected a Member of the American Society of Civil Engineers on September 6, 1910.

EDWARD GODFREY, M. ASCE[1]

DIED JUNE 25, 1947

Edward Godfrey was born in Pittsburgh, Pa., on March 7, 1871. His parents were James and Eliza (Ferguson) Godfrey.

When a young man of seventeen his first interest in engineering developed in the employ of G. W. G. Ferris and Company in 1889 as a draftsman on the detailing of the famous ferris wheel operated at the Chicago World's Fair in the early eighteen nineties. This interest culminated in his being graduated as a civil engineer from the University of Pittsburgh (then the Western University of Pennsylvania) in that city in 1893. Following graduation, Mr. Godfrey joined the organization of engineers known as the Robert W. Hunt Company and was continuously associated with this company until his death, except for two years early in the nineteen hundreds when he taught structural engineering at the University of Pittsburgh.

In his active work for the Robert W. Hunt Company, Engineers, which continued until his untimely death as a result of an automobile accident, he had interesting, diversified, and unique experience. This extended from mill, shop, and erection experience on structural steel for bridges and buildings to the testing of erected structures; the checking of designs of important and unique structures built over the period of his fifty-four years with the Robert W. Hunt Company; the examination and correction of structures deemed unsafe to the public; and also the investigation of failures in steel and reinforced concrete structures.

His life and experience extended over a period in which there were marked developments in engineering design for structures of steel and reinforced concrete. It was only natural that in his direct and continuous contacts—from checking the design of others through to following up failures—he early recognized and saw certain weaknesses in engineering theories of design, particularly in the early stages of design development.

---

[1] Memoir prepared by H. H. Morgan, Vice-Pres., and Chf. Engr., Robert W. Hunt Co., Pittsburgh, Pa.

Threfore, it is not surprising that in his personal writings and in his participation in engineering discussion, he was quite prone to bring out the weaknesses of contemporary practices for correction. He did, however, feel sincerely that no early changes could be effected unless he was to take the position of an iconoclast, so that his discussions and his writings manifest a spirit which was truly not a personal characteristic. However, it has since been generally recognized that a great number of his criticisms of those practices in design were sound and his improvements have become an integral part of present engineering practice. Many of his recommendations regarding the design of reinforced concrete and dam construction are illustrations.

Mr. Godfrey was a lover of nature, a lover of children, and a profoundly religious man. He was an elder of the Point Breeze Presbyterian Church in Pittsburgh, conducting Bible classes and nature studies for children. In the early days of the Westinghouse radio station KDKA, he was "Uncle Ed" on a children's program, telling bedtime stories.

He was an artist and one of the most lovable and sincere persons one could ever know. He is one of the few men who gave to charity a fixed percentage of his annual gross income throughout his business life.

Edward Godfrey was an engineer and a man revered and beloved by all who knew him. His contributions in literature to the advancement of his profession are recognized and appreciated.

On September 12, 1894, Mr. Godfrey was married to Clarinda Clyde Marks in Washington, D. C. He is survived by a son, Norman F. Godfrey.

Mr. Godfrey was elected a Member of the American Society of Civil Engineers on October 5, 1909. He became a Life Member in January, 1942.

ALFRED COOKMAN GREGORY, M. ASCE[1]

DIED NOVEMBER 30, 1946

Alfred Cookman Gregory, the son of Benjamin and Louise (Parshall) Gregory, was born in New York, N. Y., on March 26, 1872. He studied at the public schools in New York City and in Newark, N. J., and at the Model School, in Trenton, N. J. He then attended Rutgers College in New Brunswick, N. J., where he was a member of Delta Kappa Epsilon fraternity. After completing a four-year course he received the degree of Bachelor of Science in 1896.

Immediately after graduation he accepted employment with the Lehigh Valley Railroad Company, spending the summer as rodman. Following a few months as transitman with the county engineer of Mercer County, New Jersey, he spent his first term of service with the City of Trenton as transitman and draftsman, from February, 1897, to October, 1900. Then, after a brief intermission of a few months as assistant supervisor for the Philadelphia and Reading Railway Company on the Bethlehem (Pa.) branch, he returned to the employ of the City of Trenton as transitman for a year and a half. Again, a few months intervened during which he worked for Mercer County, this time as assistant county engineer on the design and construction of county roads and bridges.

---

[1] Memoir prepared by N. A. K. Bugbee, Assoc. M. ASCE.

With Mr. Gregory's third employment by the City of Trenton, beginning in April, 1903, the association became permanent—he remained until his death. During the first eight years, until 1911, his position was that of engineer of sewers, in charge of the design and construction of sewerage and drainage systems. Beginning in 1911, the position was broadened to that of engineer, sewers and water, with the additional responsibility for planning and building a water filtration plant and a sewage disposal plant. A public campaign for the adoption of a modern sewage disposal system was under way, and Mr. Gregory had the satisfaction of seeing the adoption of his own plan for this project, and also of supervising its construction. Other work under his charge included the city crematory and the important concrete retaining wall along the Delaware River and Assumpink Creek.

In 1935 Mr. Gregory was appointed chief engineer and director of the department of public works for the City of Trenton, in which capacity he served for the terms, 1935–1936 and 1937–1938. After 1938, he was again sewer and water engineer. These changes corresponded with modifications in the form of city government. Mr. Gregory had the distinction of serving under three types of administration. When he first entered the city employ, it was under the control of a common council, with appointment subject to a commissioner. In 1935 the council manager type of government was inaugurated. Finally, in 1939, the city commission organization was adopted.

One of Mr. Gregory's outstanding interests and contributions was in the Engineers Club of Trenton. Indeed, he received most of the credit for its very existence. During its planning and actual formation, he was most active, agreeing to take the responsibility for the organization; and, as a result of his enthusiasm and hard work, the club was not only inaugurated, but also successfully administered. Recognizing its indebtedness to him, the club adopted a Resolution on the occasion of his death. Mr. Gregory, the Resolution stated:

> "* * * affectionately known by all of us as 'Pope' was very prominent in the formation of the Engineers Club of Trenton in 1914, and served as its second President in 1915; and was the first member of the Club to be awarded a Life Membership in 1942, and was one of the Club's most enthusiastic members."

The Resolution also paid tribute to his "kindly personality, his cooperation and his advice."

Mr. Gregory was also a member of Trenton Lodge No. 5, F. and A. M., Crescent Temple, and the Sons of the American Revolution. In Trinity Cathedral (Episcopalian), of which he was a member, he sang in the choir for forty years. He was a member of the American Geophysical Union and the Rutgers Club of Trenton.

On October 14, 1905, in Trenton, he was married to Ethel Wimpenny, who survives him.

Mr. Gregory was elected an Associate Member of the American Society of Civil Engineers on June 5, 1907, and a Member on November 12, 1913.

HEINRICH EDUARD GRUNER, M. ASCE[1]

Died November 28, 1947

Heinrich Eduard Gruner was born in Basel, Switzerland, on February 8, 1873. He acquired the preparatory education for a technical college course in his home town. His father, a noted civil engineer, enjoyed an extended practice in Switzerland and southern Germany, and this may have been a deciding factor in the son's following in his father's footsteps.

After an interim sojourn as apprentice in a mechanical factory in England, Mr. Gruner entered the Swiss Federal Technical University in Zurich, from which institution he was graduated in 1897 as a civil engineer.

Two years of practical engineering in the office of Herman Laub,[2] M. ASCE, who specialized in structural steel design of bridges and factory buildings in Pittsburgh, Pa., gave the young engineer a broadened outlook on life and on his chosen profession.

At that time Mr. Gruner's father had begun preliminary studies for a hydroelectric power development of 70,000 horsepower on the Rhine River at Laufenburg above Basel. After the elder Gruner died, this enterprise was supervised and carried to completion by his son from 1899 to 1918.

The successful consummation of this project opened the way for the establishment of an engineering office in Basel for the consultation and the direction of projects of major magnitude. From 1913 to 1918 he was engaged on the construction of the Fala hydroelectric power plant (40,000 horsepower) in Austria (later Jugoslavia), and in 1918 he supervised the design and construction of the hydroelectric plant (24,000 horsepower) at Broc, Switzerland, involving the then novel construction of a slender arch dam, 185 feet in height. From 1919 to 1924 Mr. Gruner directed the construction of the Chancy-Pougny power plant (43,000 horsepower) on the River Rhône, and, from 1929 to 1936, the design and construction of the Albruck-Doggern power plant (100,000 horsepower) on the River Rhine. When large earth dams were constructed for the latter project, he established a laboratory for soil mechanics which later led to the installation of a similar laboratory at the Federal Technical University at Zurich.

---

[1] Memoir prepared by A. L. Sonderegger, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXIII, 1919–1920, p. 2263.

The Albruck-Doggern plant built across the border of Switzerland and Germany is generally credited as a work of major magnitude in power development.

These projects extended Mr. Gruner's reputation as an authority on hydroelectric development throughout the European continent and resulted in his being called for consultation by the governments of Austria, Czechoslovakia, Hungary, and Poland, as well as by industries and banks in Spain, France, Belgium, and Norway. He spent considerable time as consultant on irrigation works for the governments of Iran and Turkey, where, thanks to his diplomatic accomplishments and political acumen, he succeeded in bridging the contrasting European and Oriental ideologies and business methods to obtain the confidence of his clients.

Mr. Gruner followed with steady interest the scientific investigation of hydraulic problems, and with other engineers, he was instrumental in establishing, against considerable opposition by older colleagues, the now famous hydraulic laboratory at the Federal Technical University. This institution in Zurich offers consultations and experimental research to private engineers who are confronted with hydraulic problems.

A professorship offered him at Zurich was declined because he preferred the practical application of his vast experience to that of teaching. In recognition of his outstanding accomplishments in hydraulic engineering his alma mater conferred upon him the title of Doctor of Technical Science, *honoris causa*.

For many years Dr. Gruner was the chairman of the Swiss Commission on High Dams and the Swiss delegate to the Commission Internationale des Grands Barrages. In addition to the Society, he was also a member of the Swiss, English, and Austrian civil engineering societies.

In 1904 the young engineer was married to his cousin, Jenny Kern, and thus was initiated a happy home and a life companionship. The cheerful, buoyant nature of the young woman and her deep, religious convictions were an ever-animating support in the life of the husband whose exacting business called for frequent and often protracted absences in almost every part of Europe.

This marriage was blessed with three children who grew up to mature years during their parents' lifetimes. The sons, Eduard (M. ASCE) and Georg, following their father's profession, took over the business at his death. A daughter, Irène (Mrs. Rudolph Gally) and the sons survive.

In the summer of 1947 the writer had the pleasure of visiting the country estate of Dr. Gruner in Switzerland after more than forty years of separation. The friendship, developed during college days, continued through life despite the long separation. Although at the time Dr. Gruner was still grieving over the passing of his wife in 1945, his untiring energy and old enthusiasm for great pending works were in evidence as much as ever. A project of major proportions and importance, the development of hydroelectric power on the Aswan Dam on the Nile, was then nearing the successful consummation of planning and design. For many years Dr. Gruner had been consultant for the government of Egypt and a member of a board charged with the second raising of this dam (1929). This gigantic project undertaken in collaboration with two English firms formed an appropriate finis to a colorful life.

Personal responsibility always rested heavily on a man like Dr. Gruner who fought not only the vicissitudes of nature, but also the opposition and the rivalries which always seem to arise with large and international enterprise. It is in the nature of such a career that success is contingent upon undaunted courage, uprightness, moderation, and persistency in all phases of the work. These qualities combined with technical ability of the highest order carried him to success. His was the satisfaction of having accomplished works of lasting benefit to mankind. To quote the poet, Robin Atthill, Dr. Gruner was "* * * the whole man, compass of whose being swings past magnetic fields to his true North."

The poet Alexander Reid wrote:

> "It is not our business to be successful—
> What is important is only to be faithful
> To the inner vision."

The simple truth implied in these lines was strickingly borne out in the career of Dr. Gruner. His was a life of uprightness of purpose and of persistent application of his technical knowledge to the best of his strength and ability; and so it followed, as the night the day, that all those other things were added unto him—success and honor, a happy home life, and the reasonable enjoyment of the modern comforts of living to very mature years.

Dr. Gruner was elected a Member of the American Society of Civil Engineers on June 1, 1925.

JULIUS REED HALL, M. ASCE[1]

Died March 26, 1947

Julius Reed Hall was born in Elmira, N. Y., on September 18, 1880. He was the son of Robert A. and Augusta (Pratt) Hall.

His engineering career began in 1899, four years before he entered college. From July, 1899, to September, 1903, he was employed as a draftsman and detailer of machinery by such well-known designers, builders, and manufacturers as the Barnett and Record Company of Chicago, Ill.; the Skillen and Richards Manufacturing Company of Chicago; the Sterling Company of Barberton, Ohio; the Brown Hoisting Machinery Company of Cleveland, Ohio; and the American Bridge Company (plants at Elmira, Ohio, Athens, Pa., and Chicago). In several of these engagements he was entrusted with designing machines as well as detailing work.

During the two years from September, 1903, to September, 1905, Mr. Hall was enrolled as a special student in bridge engineering at Lehigh University at Bethlehem, Pa. He then became associated with his brother, Charles F. Hall, in Chicago, designing and manufacturing special machinery, until March, 1906. This was followed by detailing and designing steel mill buildings and coal-loading machinery during 1906 and 1907. The following two years he was treasurer and assistant manager of the Hall Machine Company in Chicago, designing and developing special machinery.

---

[1] Memoir prepared by Theodore L. Condron, M. ASCE.

In 1909, after a few months as detailer and designer of structural steel for buildings for the Purdy and Henderson Company of Chicago, he was engaged by the Strauss Bascule Bridge Company there as designer, then as chief draftsman, and, from 1912 to 1915, as designing engineer. At the Strauss Company he designed or supervised the preparation of specifications and estimates, approved the shop drawings, and directed the erection of more than one hundred bascule bridges. Included among these structures were: A 336 ft double-leaf simple span for the Canadian Pacific Railroad Company; four single-leaf railroad bridges with spans of from 118 ft to 235 ft; another bridge with a double deck; a bridge with four tracks; two direct lift bridges for the United States government of 210-ft span; and another of 248-ft span for the City of Chicago. Also, these designs included bridges for the Russian, Canadian, Egyptian, and Norwegian governments.

During World War I he was commissioned a Captain, and from 1916 to 1918 he served in the armed forces of the United States (515th Engineers) in charge of building locomotive shops and warehouses at Gieves, France. Following the close of World War I in 1919, Mr. Hall returned to the United States.

During 1920 he was employed by the City of Chicago as engineer of bridge design, and from 1921 to 1923 the Chicago Sanitary District employed him as principal assistant engineer in charge of the design and construction of all sewage work. From 1923 through 1929 he was superintendent for John Griffiths and Son Company, general contractors for the Northside sewage treatment plant, the Grant Park Stadium, and the Civic Opera House—all in Chicago. For the next three years Mr. Hall was general superintendent of construction for the same company on buildings, utilities, and roads for the Century of Progress Exposition at Chicago, and in 1935 he was superintendent on the building of the cofferdam and pile substructure of the Mississippi River lock No. 26, at Alton, Ill. While on this project estimates for several other Public Works Administration (P.W.A.) projects were prepared by him.

Mr. Hall was engaged from 1935 through 1937 by the Village of Oak Park, Ill., as engineer in charge of the design and construction of a $2,000,000 intercepting sewer, having a maximum diameter of 9 ft. and a length of 20 miles. At the completion of that work, the designs for several swimming pools, as well as an intercepting sewer for Decatur, Ill., were made by him. Also, he served from 1939 through 1942 as examining engineer (P.W.A.), at Chicago, under the assistant regional director, Federal Works Agency at Chicago, examining and making recommendations on applications for federal grants for engineering projects. From 1942 to 1944, Mr. Hall was advisory engineer on purchasing engineering equipment for United States Army Engineers and United States Navy Sea Bees. In addition, he completed reports on plants for the Reconstruction Finance Corporation. From January, 1947, until his death in the following March, he was associate engineer of Consoer, Townsend and Associates, Consulting Engineers in Chicago.

He was married to Rita Sabin in 1906, who died on March 25, 1925, and to Mary Owen on October 21, 1928. He is survived by his widow; a son, Norman Reed; and a daughter, Priscilla Jean (Mrs. Chester Demus).

A man of extreme modesty, Mr. Hall was devoted to his family, active in church and community affairs, and a conscientious engineer. His home was in Oak Park.

Mr. Hall was elected a Junior of the American Society of Civil Engineers on June 6, 1905; an Associate Member on December 3, 1912; and a Member on January 18, 1916.

LESLIE STANDISH HALL, M. ASCE[1]

DIED JULY 5, 1947

Leslie Standish Hall, the son of the late Leslie Chapman and Bertha York (O'Neill) Hall, was born on February 1, 1892, in Corning, N. Y. He was a descendant of Myles Standish and ordinarily used the name of L. Standish Hall.

His early education was received in Albany, N. Y., and Boston, Mass., where he completed high school. He was graduated from the Massachusetts Institute of Technology in Cambridge, in June, 1914, with a degree of Bachelor of Science in Civil Engineering (hydraulic option).

On completion of his formal education Mr. Hall was appointed a civil engineer student with the United States Office of Public Roads and was promoted to junior highway engineer on surveys and supervision of the construction of roads in California, Virginia, and Maine. After this assignment, he was engaged on survey, design, and drafting work, including nearly a year on master plans for an industrial village for the Delco Company, south of Dayton (Ohio), and he spent six months as structural steel draftsman for the United States Navy in the Bureau of Yards and Docks.

He became associated with H. L. Haehl, M. ASCE, of the consulting engineering firm of Duryea, Haehl and Gilman of San Francisco, Calif., in November, 1917. Mr. Hall spent most of the next seven years with this organization on the investigation of irrigation projects, including the study of stream flow and location of storage reservoir sites, the design of diversion dams, and the location and design of canals. Other work involved duty of water measurement and the investigation of ground-water conditions in the Sacramento-San Joaquin delta in California and other areas. He also made a study of the application of statistical methods of probability to hydrology and geological studies of fault lines and earthquake hazards in the San Francisco Bay

---

[1] Memoir prepared by J. S. Longwell, M. ASCE.

(California) area. Mr. Hall spent short periods during these seven years with various irrigation districts and consulting engineers, performing work along lines similar to his assignments with Mr. Haehl.

In July, 1924, Mr. Hall entered the service of the then newly organized East Bay Municipal Utility District of Oakland (Calif.); under the direction of Arthur Powell Davis,[2] Past-President, ASCE, he served as assistant engineer on the preliminary studies and the final plans for the $39,000,000 Mokelumne River water supply project. In 1926 he was advanced to chief hydrographer in charge of extensive investigations, that involved water rights litigation, to determine the effect of the district's diversion from the Mokelumne River on the water supply in the Mokelumne River Basin. He played a very important part in litigation concerning water rights on the Mokelumne River, both in preparing engineering data for court hearings, and in giving expert testimony in court.

Mr. Hall was made hydraulic engineer in 1936, and later, principal hydraulic engineer, a position he held at his death. During this period he served under J. S. Longwell, M. ASCE, chief engineer and general manager of the district. In addition to the water rights and ground-water investigations, his professional work with the district included stream gaging and hydrographic surveys; hydrology; river regulation and flood control; hydraulic research; land use analyses; municipal water supplies; erosion and reservoir sedimentation control; and operation studies of dams, spillways, and hydraulic structures, together with water supply and sewage disposal studies.

During the two years prior to his death he directed long-range planning in connection with the growth of the area served by the district, both for water supply and sewage disposal—the latter in connection with the newly formed Special District No. 1. These studies required exhaustive investigations on population increases, probable water consumption, and sewage quantities. His reports on these surveys were comprehensive and were generally considered outstanding achievements.

At an early stage in life, Mr. Hall developed a keen interest in hydraulics and enlarged this interest to the point where he was a well-recognized authority in the hydraulic engineering field. He was an excellent mathematician, and a lifelong student, devoting considerable time and effort after graduation to university extension courses in engineering, business administration, and related fields which would be of value to him in his life's work.

Mr. Hall did considerable original work on the design of spillways and the flow of water through pipes and orifices. He contributed greatly to the field of hydraulics through published writings in the *Transactions* of the Society, both original reports and discussions. One paper[3] resulted in his being awarded the Collingwood Prize for Juniors. In 1943 another paper[4] brought him the award of the Karl Emil Hilgard Prize for hydraulics. He was invited to attend the Third Hydraulics Conference at the University of Iowa

[4] "Open Channel Flow at High Velocities," by L. Standish Hall, in "Entrainment of Air in Flowing Water: A Symposium," *ibid.*, Vol. 108, 1943, p. 1394.

(Iowa City) in June, 1946, at which time he presented a paper entitled, "The Influence of Air Entrainment on Flow in Steep Chutes."

Mr. Hall served as consultant on hydraulic problems for several organizations. His work was always of a high order as he possessed unusual aptitudes for the analysis of engineering data. He rendered useful and valuable service to the organization with which he was connected and to the engineering profession as a whole. Mr. Hall was extremely interested in the professional advancement of engineers, serving on the Committee on Professional Standards of the San Francisco Section of the Society.

On October 30, 1923, he was married to Geraldine Adeline Bohannon. He is survived by his widow and their three children, Ruth Josselyn (Mrs. John Paul Juhl), Emily Patricia, and John Standish.

Mr. Hall was a member of the American Water Works Association, the American Geophysical Union, the American Philatelic Society, the American Academy of Political Science, the American Geographical Society, the East Bay Engineers' Club, the Athens Athletic Club, the Society of Mayflower Descendants, the Scottish-Rite bodies, and the Rockridge Masonic Lodge. His religious affiliation was Episcopalian.

Mr. Hall was elected a Junior of the American Society of Civil Engineers on May 13, 1918; an Associate Member on January 17, 1921; and a Member on November 10, 1941.

BORDEN BAKER HARRIS, M. ASCE[1]

DIED OCTOBER 26, 1947

Borden Baker Harris, the son of Edward Enoch and Lydia (Baker) Harris, was born in Vernon County, Wisconsin, on September 20, 1875, at the farm of his maternal grandfather, Alvin Baker.

He received his early education in the public schools of Quincy, Ill., and Evansville, Ind., being graduated from the high school at Evansville. He completed three years of liberal arts training at Chaddock College in Quincy, in addition to a one-year business course at Monmouth Business College in Monmouth, Ill., and three years of civil engineering at the University of Illinois in Urbana.

From 1903 to 1906 he was assistant to the chief engineer of the Midland Valley Railroad Company, in Fort Smith, Ark., remaining with the company from the commencement of location surveys to the completion of construction. In 1906 he became office engineer in the firm of J. G. White and Company, Incorporated, Engineers and Contractors, in St. Louis, Mo. Mr. Harris was placed in charge of the preparation of plans, estimates, and reports for the proposed construction of lines of the Philippine Railway Company on the islands of Panay, Negros, and Cebu; he was soon sent to the Philippines as assistant chief engineer in direct charge of the engineering organization and construction forces engaged in building the Philippine railway. He remained in the Philippine Islands, carrying on this work until 1912.

---

[1] Memoir prepared by Ray Baker Harris, Washington, D. C.

From 1912 until 1928 Mr. Harris was associated with Col. Frederic A. Molitor,[2] M. ASCE, in New York, N. Y., in private practice as a consulting engineer. During this period he was engaged in making out project reports including the following: The Kansas City, Mexico and Orient Railway Company of Texas (the Texas Mexican Railway Company); the railway situation in the New England States; the West Side Terminal in the Borough of Manhattan (New York), for the Board of Estimate and Apportionment; the Brazil Railways, for the receiver, covering the physical condition of properties, additions, and betterments required, future traffic trends, and operation methods; the proposed extension of the South Carolina and Western Railway Company; the possibility of constructing new lines for the Delaware and Hudson Company; the operation and physical condition of the Chicago, Milwaukee, St. Paul and Pacific Railroad Company; and the National Railways of Mexico for the Committee of Foreign Bondholders. After making his reports for the Brazil Railways Mr. Harris was retained by that company to analyze and report on monthly operating results.

In 1929 he was placed in full charge of the affairs and operation of street railway and bus companies owned by the United Coach Company in New York, as manager of the railway and bus department of the Utility Management Corporation (formerly the J. G. White Management Corporation). He was named vice-president, director, and member of the executive committee.

As a result of the widespread changes in policy and personnel made by the Securities and Exchange Commission in the utility management field, Mr. Harris retired from the Utility Management Corporation in 1941 and resumed practice as a consulting engineer. He did considerable survey and special report work on transportation properties owned by H. E. Salzberg and Company in Maine (Lewistown-Auburn Transit Company, Portland Coach Company, and others) and on the British Columbia Electric Railway Company properties at Vancouver, B. C. He also contributed numerous articles to publications in the transportation field.

He died suddenly in New York of acute coronary thrombosis on October 26, 1947. His death occasioned many expressions of respect and admiration from professional associates who deplored the loss of his wide experience and progressive thinking in the engineering and transportation fields. All spoke of his personal qualities of dignity, courtesy, and consideration for others. Funeral services were held from his home in Washington, D. C., and interment was in the family plot at Cedar Hill Cemetery there.

Mr. Harris is survived by his widow, Mary Allen Harris, to whom he was married at Hull, Ill., on September 21, 1898. He is also survived by a son, Ray Baker Harris, a daughter, Eleanor Harris—all of Washington, and by a brother, Phil B. Harris, M. ASCE, of Los Angeles, Calif.

His memberships included those in the American Institute of Consulting

---

[2] For memoir, see *Transactions*, ASCE, Vol. 103, 1938, p. 1838.

4

Engineers and the American Railway Engineering Association. He belonged to the Lotus Club, Metropolitan Club, Railroad-Machinery Club, and the National Republican Club, all of New York.

Mr. Harris was elected an Associate Member of the American Society of Civil Engineers on April 3, 1907, and a Member on March 13, 1917. He became a Life Member in January, 1942.

HERBRAND HARVEY, M. ASCE[1]

DIED FEBRUARY 22, 1947

Herbrand Harvey (Alexander St. John Herbrand Harvey) was born at Bellary, India, on October 10, 1872, of a Scotch family of merchants, statesmen, and diplomats. His father was an East India merchant.

At about six years of age, he was sent to Great Britain to be educated, and obtained his preparatory education at Marlborough School. He was then an apprentice for five years (1889 to 1894) with A. and W. Smith and Company, Eglington Engine Works, Glasgow, Scotland, and in 1896 received a Certificate of Engineering Proficiency for the civil engineering course at Glasgow University.

During the next four years (1896 to 1900) Mr. Harvey was engaged on surveying in British Honduras and on gold and silver mining and railroad construction in the State of Oaxaca, Mexico. In 1900 and 1901 he worked as draftsman for the American Bridge Company at St. Louis, Mo., and for D. H. Burnham and Company in Chicago, Ill., and was employed on construction work with the Hillman Land and Iron Company in Kentucky.

In 1902 and 1903, he was superintendent of construction on the Whitehall Building and the Fourteenth Street Store in New York, N. Y., for the George A. Fuller Company. The following year, he went to Guam for Milliken Brothers of New York as superintendent of construction of the Commercial Pacific Cable Company's station there.

Mr. Harvey then, in 1905, became associated with S. Pearson and Son, Limited, of London, England. It was an association that, but for an interval of a year and a half, lasted eighteen years. At first he was in charge of construction of a section of the Thuántepec National Railway, including the Atlantic terminal, and also the complete construction of the Port of Mexico at Coatzacoalcos, Mexico. This project included the construction of jetties at the mouth of the river; dredging the channel across the bar; building extensive steel pile wharves and wharf sheds and warehouses; the erection of a power plant; and the installation of wharf cranes. This was a busy port until after the building of the Panama Canal.

On the completion of this job, Mr. Harvey was sent to Belém, Pará,

---

[1] Memoir prepared by George H. Bayles, M. ASCE.

Brazil, where he had charge of the construction of the Port of Pará. This consisted of building a bulkhead wall a mile and a half long of massive concrete blocks, a broad wharf with several railroad tracks the length of the wall, and eight large wharf sheds, in addition to dredging the basin and channel—a job that was completed in 1912. Both of these ports stand today—the one practically abandoned, the other, the busy port of entry to the whole Amazon Basin—as monuments to the thoroughness and fidelity of their construction.

When the latter was finished, Mr. Harvey went to New York as a director of S. Pearson and Son, Incorporated, of New York. There he directed the work of the New York office and had personal charge of contract 20 B on the New York State Barge Canal.

During the first three years of World War I, he was occupied with munitions for the British Navy and in inspecting small arms manufacture for Great Britain in America. This work having been reduced to routine, he went to Chuquicamata, Chile, in the latter part of 1917, for the Chile Exploration Company as resident engineer on construction of large extensions to the then existing plant. Through a staff of seventy, he directed the work of twenty-five hundred men. The project included, besides building extensions to crushing, screening, leaching, dechloridizing, and electrolyzing plants, the construction of a large steel frame machine shop, a reinforced concrete foundry building, houses for thirteen thousand people, sewerage and sewage disposal for two towns, concrete water storage tanks, and a ninety-four kilometer steel pipe line across the world's driest desert. In addition, he made a study and estimate of cost of a proposed hydroelectric development in the near-by mountains.

Shortly after the end of World War I, the construction program at Chuquicamata was abandoned, and Mr. Harvey returned to England where he became resident engineer on the erection of steel mills for the Appleby Iron and Steel Company, near Lincoln. In early 1920, he rejoined S. Pearson and Son, Limited, and was sent to Mexico as general manager of the Minatitlán Refinery of The Anglo-Mexican Oil Company, where work on an extensive enlargement of the refinery was about to begin. After two years' work, the failure of the company's production in the Tampico field caused the curtailment of the program and Mr. Harvey was sent to India for the Whitehall Petroleum Company on oil exploration. After spending two years in India, he severed his connection with the Pearson firm and spent the next year mainly in designing and constructing a home for himself and Mrs. Harvey on the highest ridge of The Downs, midway between London and Portsmouth.

During 1925 and 1926, Mr. Harvey directed, for Balfour and Beatty, the construction of the Lochaber Project of the British Aluminum Company, near Fort William, Scotland, consisting of a sixteen-foot tunnel eighty thousand feet long, a steamship pier, a connecting railway, and auxiliary works. In 1927, he joined old Pearson friends as director of Sir Ernest Moir and Company, remaining until the death of Sir Ernest in 1929.

He then became general manager of the Port of La Guaira in Venezuela, and continued managing and improving the property until he negotiated its sale to the Venezuelan government in 1938. He returned later, however, and prepared an estimate of the cost of further extensive improvements.

Before leaving La Guaira, he became a director of the Manaos Harbor Corporation, a Booth and Company property, a thousand miles up the Amazon River, and was their consulting engineer, as well—a connection he maintained until his death.

When the Germans damaged the harbor works at Scapa Flow in Scotland, early in World War II, he was called on to assist in the reconstruction. The location of his home, unsurpassed for beauty in England, now proved a handicap. The almost constant flight of war planes, British, American, and German, over it eventually impaired Mrs. Harvey's health and he was compelled to give up the work at Scapa Flow and, after 1942, devoted almost his entire time to her.

At times during his career, he found the opportunity to make surveys for the harbors of Buenaventura and Cartagena in Colombia; to make preliminary studies for the port work at Valparaiso, Chile, and Fortaleza Ceará, Brazil; to study and estimate engineering works in Mesopotamia; and to prepare the estimate for a bidder on raising the Aswan Dam in Egypt.

Mr. Harvey was a man of profound learning and broad culture. He was thoroughly grounded in the principles of engineering and had an unsurpassed capacity for detail and thoroughness. He possessed a quick perception and keen insight and was an infallible judge of character. His capacity for friendship was unlimited. He enjoyed the society of his friends who, in turn, admired his vigorous personality and clear intellect. He was six feet tall and of slender build, but was nevertheless an active participant in athletic sports. In his fifties he still bowled respectably at cricket and played above average tennis.

Having worked in ten or more countries and traveled in many others, he had a lively interest in world politics and finance and for years had kept up an active correspondence on these subjects with friends throughout the world. Besides his loss to the engineering profession, these friends and younger men to whom his life was an inspiration will miss him sadly.

While working in Mexico, Mr. Harvey met Bessie Kingsland of St. Louis, daughter of Lawrence D. Kingsland, manufacturer of farm and saw mill machinery. In 1895 she had been the second Veiled Prophet Queen of St. Louis. He gave up his work in Mexico and went to St. Louis where he got a job. They were married in 1903 and thereafter she was his companion on every job until the last one at Scapa Flow.

While working with his gardener and in his usual good health and spirits, Mr. Harvey suffered a heart attack and died within a few minutes. His wife survived him only five days. They had no children.

He was a member of the Institute of Civil Engineers, a Fellow of the Royal Geographical Society, and belonged to the Devonshire Club of London.

Mr. Harvey was elected a Member of the American Society of Civil Engineers on April 2, 1913.

PHILIP WALTER HENRY, M. ASCE[1]

DIED NOVEMBER 7, 1947

Philip Walter Henry was active in his chosen profession from the time he started working on a surveying party at the youthful age of sixteen, until a very few weeks before his death at the notable age of eighty three. These sixty-seven years of action and service were far beyond those allotted to the average man. He obtained his engineering education through sacrifice, and was honored by his alma mater with the positions of trustee and vice-president for many years. As a consulting engineer Mr. Henry was deeply conscious of his professional obligations and was delegated to serve the American Institute of Consulting Engineers, both as secretary and as president. As he served his fellow engineers, he was honored by them. His devotion to them was returned in full by their affection and respect.

The account of his life as an engineer, builder, and manager of construction projects throughout the United States, South America, Spain, and China presents a colorful and romantic picture. The details given here are to be accepted as Philip Henry's autobiography, presented in the modest style so familiar to those who knew him.

This outstanding engineer was born at Scranton, Pa., on March 24, 1864. He was the son of Eugene T. and Emma E. (Walter) Henry. In 1865 his father moved to Oxford, N. J., where he became general manager of the Oxford Iron Company in the erection and operation of a blast furnace, rolling mill, and nail factory. As the discovery of the cheaper iron ores of the Lake Superior region brought about the discontinuance of much of the iron industry of northern New Jersey, this circumstance (combined with the long illness of his father, who died in 1883) made it necessary for young Henry to go to work at sixteen years of age. Fortunately, he obtained employment in the engineer corps of the Delaware, Lackawanna and Western Railroad Company where he remained for three years on location and construction in western New York State. Through the kindness of a friend of his father, Mr. Henry was able to enter Rensselaer Polytechnic Institute (R. P. I.) in Troy, N. Y., and he was graduated in 1887.

Then his connection began with the Barber Asphalt Paving Company which was rapidly expanding under the business genius of Amzi L. Barber. Serving first at Buffalo, N. Y., and then at St. Joseph, Mo., Omaha, Nebr., and New York, N. Y., as superintendent, he became vice-president and general manager in 1894, and he was responsible for the cost and quality of pavements laid in some sixty cities—ranging from Boston, Mass., to Denver, Colo., and from St. Paul, Minn., to New Orleans, La. In 1893 he made surveys for loading asphalt on piers and tramways from Pitch Lake in Trinidad, British West Indies, and started construction the next year. In 1894 he sent the organization to lay the first asphalt pavements in Buenos Aires, Argentina.

---

[1] **Memoir prepared by Enoch R. Needles and Howard C. Baird, Members, ASCE.**

In 1902, owing to change in ownership, Mr. Henry left the Barber Company and became vice-president of the Medina Quarry Company in Albion, N. Y., having charge of operation and sales. From 1904 to 1909 he was again associated with Mr. Barber in the development of oil and asphalt properties in Mexico and Venezuela. The company in Mexico of which Mr. Henry was vice-president had oil and asphalt leases to the extent of 80,000 acres in the State of Vera Cruz (60 miles south of Tampico) for which development he made investigations. These leases, among which were those of "Juan Casiano" and "Cerro Azul," were sold in 1907 to the Huasteca Petroleum Company (Doheny), forming the basis for the great oil production of that company; one well alone produced 100,000 barrels of oil per day for a number of years.

In Venezuela the company of which Mr. Henry was vice-president purchased asphalt from the Venezuelan Government from the so-called Bermudez Lake, shipped it to New York, and refined and sold it to paving contractors throughout the United States. Owing to the previous seizure of this property by the Venezuelan Government from another American company for alleged failure to live up to its concession, litigation ensued as well as diplomatic correspondence between the Venezuelan and American governments. Since the company with which Mr. Henry was associated had the support of President Castro of Venezuela, it did a profitable business until 1909 when both President Castro and the company were ousted by the revolution that placed Mr. Gomez in the presidency for twenty-six years. Mr. Henry regarded this as the most entertaining and exciting experience of his entire business life. It led to his writing an article which appeared in the *North American Review*.[2]

While Mr. Henry was busy with his Mexican and Venezuelan affairs, he was also president of the South American Construction Company (from 1906 to 1910) during which time it built 125 miles of railroad in Bolivia from Viacha to Oruro on the plateau 12,000 ft above sea level. The road was constructed at a cost 5% under that estimated by the chief engineer of the Bolivia Railway Company, for which it was built. This was due to his selection of two competent general managers—the late F. C. Hitchcock, M. ASCE, who, upon his retirement (because of the altitude) was succeeded by J. P. Hallihan,[3] M. ASCE. Both engineers later had distinguished careers.

In 1908 Mr. Henry was appointed by the Hon. Charles E. Hughes, then Governor of New York State (later Chief Justice of the United States) to represent the state at the First International Roads Congress called by the French government to meet in Paris. Here he presented a paper which was reprinted in *The Kings Highway*,[4] with the following editorial comment: "The author Mr. P. W. Henry of New York, is to be congratulated on his prophetic vision."

[2] "Has the United States Repudiated International Arbitration?" by Philip Henry, *North American Review*, December, 1907.

[3] For memoir, see *Transactions*, ASCE, Vol. 109, 1944, p. 1483.

[4] "The Future Road—The Wearing Surface," by Philip Henry, *The Kings Highway*, April, July, and October, London, 1938.

In addition to the discussions, excursions were made in buses and motor cars from Paris to Versailles; in carriages from Melun to Fontainebleau; and in automobiles from Nice through the Maritime Alps to l'Authion, 7,000 feet above sea level, returning via Mentone—a distance of ninety miles. At these places the members of the Congress were entertained by the city officials—in Paris there was a reception at the City Hall and a special performance of the Comédie Française; at Versailles, a luncheon in the Orangerie of Louis XIV in the palace; at Fontainebleau, a reception in the Salon of Henry II in the palace; at Nice, a dinner by the mayor; at Peira Cava, a mountain resort 5,000 feet above sea level, a luncheon; and, at Monte Carlo, a luncheon by the Mayor of Monaco and a special concert in the theater. Mr. Henry considered this the most delightful business trip he ever took.

In 1910, in company with Mr. Hallihan, he made a reconnaissance by automobile of 700 miles of a proposed railroad in Spain (Bilbao to Madrid and thence to Valencia), detailed surveys having been made by Spanish engineers. On this trip they were accompanied by representatives of the National City Bank and of the financial house, Hallgarten and Company, both of New York. They met the Prime Minister, Señor Canalejas, who greatly desired to have American engineers and contractors develop the public works of his country. Unfortunately, the assassination of Señor Canalejas a year later discouraged the American bankers, who had been favorably disposed toward this project, but who had delayed committing themselves.

From 1909 to 1917 Mr. Henry was president of the Central Railroad of Haiti, in the construction of the wharf at Port-au-Prince and in the operation of railroads and public utilities in that country. During this period he also maintained an office as consulting engineer and was employed for three years by the Southern Pacific Railroad Company, in relation to the management of its oil properties in California, Texas, and Mexico.

In 1915, in company with a vice-president of the National City Bank, Mr. Henry made a trip to Brazil, Argentina, and Bolivia, with special reference to the railroad situation in those countries. He made a special investigation of the properties of the Antofagasta (Chile) and Bolivia Railway Company, Limited, the purchase of which was being considered by a certain American financial group.

Mr. Henry was vice-president of the American International Corporation from 1916 to 1923; he would pass on the economic soundness of many engineering projects submitted to that corporation for financing from all over the world. From 1917 to 1923 he was vice-president of the Siems-Carey Railway and Canal Company (a subsidiary of the American International Corporation) and was responsible for the selection of engineers to make railroad and canal surveys in China to the extent of more than $2,000,000. As a result he was made an honorary member of the Association of Chinese and American Engineers, of which the late J. A. L. Waddell, M. ASCE, John F. Stevens,[5] Past-President, ASCE, and John R. Freeman,[6] Past-President, ASCE, were also made honorary members in recognition of their work in China. During this period he had much to do with the International Products Company (another subsidiary) which erected packing and quebracho plants in Paraguay and a packing plant in Colombia.

---

[5] For memoir, see *Transactions*, ASCE, Vol. 109, 1944, p. 1440.

[6] *Ibid.*, Vol. 98, 1933, p. 1471.

From 1933 to 1935 Mr. Henry was a member of the technical board of review composed of fifteen prominent engineers, which passed on the economic soundness of engineering and construction projects presented for financing to the Public Works Administration in Washington, D. C. In 1936 he made an investigation of the transportation system of Buenos Aires for a New York investment trust which had a large investment in overdue notes of the American built subway.

Although Mr. Henry's experience was largely that of an executive, his consulting practice took him into various parts of the world and into diverse fields. As an executive or consultant, his work in engineering or construction embraced Argentina, Bolivia, Chile, China, Colombia, Haiti, Mexico, Paraguay, Peru, Spain, Trinidad, and Venezuela. In the United States it was concerned with oil in California, Colorado, Texas, and Wyoming; coal in Tennessee and Wyoming; railroads and utilities in various states; and the low temperature process for artificially curing alfalfa and other forage crops in the eastern part of the United States, Canada, and England.

As Mr. Henry's activities had taken him to various Spanish speaking countries, he undertook, at the age of forty-nine years, the study of Spanish, mostly at home with grammar, dictionary, and phonograph. He became so interested in the philosophy of Calderón de la Barca, noted Spanish dramatist of the seventeenth century, that he put into English several of his dramas and "autos sacramentales" (morality plays). Selected scenes from his translation of "La Vida es Sueno" were staged by the R. P. I. Players in March, 1939.

From 1942 to 1945 Mr. Henry was chairman (representing the Society) of the Joint Committee on Inter-American Engineering Cooperation formed by the five societies (representing the civil, mining, mechanical, electrical, and chemical engineering fields) which worked in cooperation with the Inter-American Development Commission of which Nelson A. Rockefeller was chairman.

Mr. Henry early became interested in outside activities. Shortly after coming to New York in 1892 he became a member of the Committee of Management for the Young Men's Christian Association (23d Street branch) of which he was chairman from 1916 to 1921. He was a trustee of the United States Savings Bank from 1916 until its merger with the Dry Dock Savings Institution in 1933. From 1918 he had been a member of the Council of the American Geographical Society, serving as vice-president from 1920 to 1941, and as chairman from 1922 to 1939. He was a charter member in 1912 of the Pan-American Society and served on its council from 1919 to 1944. He served the New York City Mission Society as a director in 1922, and as a vice-president from 1927 to 1944.

In 1911 Mr. Henry became a trustee of Rensselaer Polytechnic Institute and in 1938 was vice-president. His memberships included those in Sigma Xi; the American Institute of Mining and Metallurgical Engineers; and the American Institute of Consulting Engineers (a charter member from 1911), serving as secretary from 1924 to 1947, and as president in 1940. He was a fellow of the Royal Geographical Society. Early in his career he joined the Engineer's, University, Union League, and Century clubs of New York, and for a time was a member of the Cosmos Club in Washington, D. C., and the Saturn Club in Buffalo.

In politics Mr. Henry was a Republican, and his religious affiliation was Presbyterian. He served as an elder in the Madison Avenue Presbyterian Church of New York and in the Scarborough (N. Y.) Presbyterian Church. As his mother's family was Moravian, he was baptized in the Moravian Church (Nazareth, Pa., which was his mother's home before her marriage).

Throughout his long and successful career Mr. Henry was both technical and professional. In addition, he had a knowledge of administration and finance, that made him a capable business executive. His quiet and circumscribed boyhood was followed by wide travels into many parts of the world, from which he derived the fullest benefits and inspiration. A practical, realistic, and productive engineer and executive, he was happy in his more esthetic attainments as a reader, writer, student, and linguist. Mr. Henry was an idealist (as so many engineers are) and, since he was born into a religious atmosphere, he continued to be an active churchman throughout his life; he was very forceful but, at the same time, a true gentleman.

He was a man who had friends and treasured them; quiet and modest, he was strong and unswerving in support of his principles. He was gentle and receptive, but his loyalty and determination made him a valuable ally in a chosen cause.

The American Institute of Consulting Engineers had an unusual place in the heart and life of Philip Henry, particularly in his later years. The integrity and advancement of the institute were almost an obsession with him as he gave to its affairs the attention and devotion which are beyond price. In the most minute details he was the servant of the institute and its members and his only compensation was in seeing the institute prosper and in receiving the heartfelt thanks and deep affection of those with whom he worked.

The engineering profession provided a means for the exercise of Philip Henry's particular talents which could hardly have been excelled. His engineering education was followed by engineering experience which fitted him in excellent manner for management, administration, and consultation pertaining to engineering projects. His engineering success was combined with business success, and his service to his fellow man as a professional engineer was merely typical of his service through his church, charities, and societies. He honored his profession as it honored him.

Mr. Henry was married on January 22, 1906, to Clover Cox of Chicago, Ill., and from 1918 they resided at Scarborough. Mrs. Henry died on January 12, 1946. He is survived by a daughter, Clover (Mrs. David Graham), and three grandsons, one of whom was named for him.

Mr. Henry was elected an Associate Member of the American Society of Civil Engineers on January 3, 1894, and a Member on November 2, 1908. He became a Life Member in January, 1929.

CHESTER JAMES HOGUE, M. ASCE[1]

Died November 4, 1946

Chester James Hogue, the son of Harvey A. and Sarah L. (Abrams) Hogue, was born in Portland, Ore., on September 19, 1875. During 1895 and 1896 he had private instruction in drafting and architecture, and then entered Massachusetts Institute of Technology in Boston, as a special student, completing courses in architecture and engineering in 1899.

Mr. Hogue began his professional career in Boston with the firm of Wheelwright and Haven, Architects, in 1899. In 1901 he worked on the construction of the building for the Massachusetts Horticultural Society; then, he entered the employ of the Eastern Expanded Metal Company where he became construction engineer. He joined the Concrete Engineering Company in 1908, in a similar capacity. At this time, Mr. Hogue aided in the development of reinforced concrete construction and had charge of the design and construction of many large structures, utilizing this combination of construction materials, which was then new.

In 1913 he left Boston to return to his native city, Portland, to form a partnership with Edward Foulkes, practicing architecture under the firm name of Foulkes and Hogue. Many of the fine homes of this young and lusty city were conceived on their drafting tables, in addition to the Oregon Building for the Panama Pacific International Exposition at San Francisco, Calif., in 1915.

In 1916 Mr. Hogue became manager of the Portland office of the West Coast Lumbermen's Association and, except for a period during World War I, he remained with this organization until his retirement in January, 1946. During World War I (1917–1918), his services were loaned to the Bethlehem Shipbuilding Corporation to construct shipyards in the San Francisco Bay area.

The completion of the Panama Canal opened markets along the Atlantic seaboard for lumber manufactured in the Pacific northwest. Therefore, he was transferred to New York, N. Y., in 1919, where he effectively introduced west coast species of lumber for construction uses and proved their value. In 1926 he returned to the west to take charge of Trade Promotion and Technical Service with headquarters in Longview, Wash. In 1928 the organization moved to Seattle, Wash. Although his headquarters and his home were nominally in Seattle, his interests and his work carried him to all parts of the United States, to Japan, and to South America. In 1939, he dropped the trade promotion work and devoted all his time to his principal interest, timber engineering—remaining in charge of technical service until retirement. His work became his hobby, and Mr. Hogue was engaged in writing a textbook on timber engineering at his death.

---

[1] Memoir prepared by William Thornton King May, Assoc. M., ASCE.

Constant research in wood technology and in its mechanical properties made Mr. Hogue a well-known authority on the uses of this material during his thirty years with the lumber industry. He was active in the development of the American Lumber Standards which instrumented the grading of lumber for specific use requirements. All important improvements in the use of timber as an engineering material were advanced by his fund of knowledge and his cooperation. He prepared a handbook on the structural uses of west coast species, and wrote many papers and publications on the technical uses of lumber. He always found the time to serve on many technical committees and to aid in solving the numerous problems set forth by professional and nonprofessional men alike.

On January 16, 1901, Chester Hogue was married to Marian L. Chase of Boston. He is survived by his widow; two daughters, Dorothy (Mrs. T. A. Clarridge) and Margaret (Mrs. J. F. Malony); and two grandsons, Arthur Preston Clarridge, II, and Chester Hogue Clarridge.

He was a member of the American Society for Testing Materials, the American Railway Engineering Association, the American Wood Preservers' Association, and the American Petroleum Institute. He was also a member of the F. and A. M.

Mr. Hogue had an exceptional capacity for work, and he was accomplished in every field which attracted his interest. His unfailing friendliness won him many friends throughout the world. A man extremely well versed in his lines of endeavor, his opinions were constantly sought by experts, and he never was too busy to devote time to younger men. Personal integrity distinguished him throughout his life.

Mr. Hogue was elected an Associate Member of the American Society of Civil Engineers on December 6, 1905, and a Member on June 6, 1911.

HENRY MACY JONES, M. ASCE[1]

DIED JULY 18, 1947

Henry Macy Jones was born on April 17, 1892, in Los Angeles, Calif. His father, Elmer E. Jones, came to Los Angeles from Delaware, Ohio; his mother, Mary (Macy) Jones, was graduated from the old Hanna College on Temple Street in Los Angeles. This was an exclusive finishing school in the early days of the city. Her parents, originally from Kansas, owned one of the early orange ranches in Riverside, Calif.

---

[1] Memoir prepared by Donald M. Baker, M. ASCE.

At the time when Macy Jones was born, Los Angeles was a small town with a population of about 60,000 and Los Angeles County had a population of little more than 100,000. Before his death he saw the city grow to a size of 1,800,000 and the county reach a population of 3,750,000, and he knew that he had a definite part in this development.

Mr. Jones received his early schooling in Los Angeles, attending the old Hoover Street Grammar School when it was first opened, and he was graduated from the Los Angeles Polytechnic High School in 1913. He enrolled in the civil engineering course at Stanford University (Stanford University, Calif.) immediately afterward, and in the spring of 1917, a few months before graduation, he left Stanford to take his first engineering job as assistant on the construction of the Copco Dam for the California-Oregon Power Company in southern Oregon. He returned to Stanford in the summer of 1918 and received the degree of Bachelor of Arts in Civil Engineering on October 4, 1918.

After entering military service in August, 1917, Mr. Jones rose, successively, through the ranks of Private, Corporal, Sergeant, and Second Lieutenant. His regiment, the 154th United States Engineers, was waiting to embark overseas in New York, N. Y., on Armistice Day in 1918.

Mr. Jones entered the office of the county surveyor in Los Angeles County on February 26, 1919, as a junior draftsman, and he passed, successively, through the positions of senior draftsman and chief draftsman before being appointed office engineer and deputy county surveyor on July 1, 1925. This period saw an extremely rapid growth in the population of Los Angeles County. Subdivisions (literally in the thousands) were filed with the county surveyor's office for approval and checking, large numbers of roads were built involving acquisition of rights of way, and many plans and specifications were prepared for municipal improvements—all this work coming under Mr. Jones' supervision as office engineer.

He resigned to accept an appointment as chief engineer of the Harold G. Ferguson Engineering Corporation in November, 1928, and held this position until February, 1931. During this time the company laid out several imposing residential subdivisions along the Roosevelt Highway in the famous Malibu Ranch on the coast, north of Santa Monica, Calif., making plans and supervising the construction of improvements on a number of these subdivisions. It also laid out and constructed improvements for Canoga Estates, south of Ventura Boulevard, in Los Angeles (in the San Fernando Valley). He resigned as chief engineer of the Ferguson Engineering Corporation in March, 1931, and from this time until August, 1932, he was engaged in private practice as a consulting engineer in Los Angeles.

In September, 1932, he was appointed secretary to the California State Board of Registration for Civil Engineers, and in June, 1935, he became executive secretary for the board. The California board had been created during 1929 by the legislature, and under the "grandfather clause provision" of the Civil Engineers Registration Act, more than 5,100 certificates of registration were issued. Following the issuance of these certificates, few applicants for registration were considered for several years, as engineering employment (because of the economic depression of that period) was not very active. This opportunity enabled the board to organize itself in order to sell the idea of registration—not only to the civil engineering profession, but also to the employers of engineers, to numerous city and county civil service commissions in particular, and to the state civil service organization.

This work during the formative period of the state board was carried on under Mr. Jones' direction, and the best testimony of its effectiveness lies in the fact that by the middle of the 1930–1940 decade civil engineering registration in California was strongly supported by the profession (including the Society), and also by both public and private employers of engineers. One of the most important accomplishments of this period was to sell the idea to public agencies that civil engineers taking civil service examinations for jobs which involved engineering responsibility should, as a prerequisite to taking such examinations, be registered. As all administration of regulatory statutes exposes certain weaknesses in the original statute, various amendments were made to the act to overcome them.

In the late 1930's applicants for examinations increased and the examinations became more standardized. The board worked in close cooperation with the four sections of the Society in California, and much of this excellent cooperation was the result of Mr. Jones' endeavors. He was active on numerous committees in the Los Angeles Section and was Secretary during 1931–1932, Vice-President in 1935, and President in 1939.

Because of ill health, Mr. Jones took a leave of absence from his position with the board on August 15, 1945, and moved to Balboa, Calif., where he resided until his death. He resigned as executive secretary on October 3, 1945.

While at Stanford Mr. Jones met Elizabeth Mitchell Judah, to whom he was married on December 5, 1921. It was a very happy marriage as they were ideal companions, and her solicitous care of him during his last illness was a tribute to their attachment to each other. He is survived by his widow and a sister Mariam N. Jones of Los Angeles.

Mr. Jones was elected an Associate Member of the American Society of Civil Engineers on October 15, 1923, and a Member on June 26, 1933.

MARION REED KAYS, M. ASCE[1]

Died March 13, 1946

Marion Reed Kays, the eldest child of Emory and Emma (Track) Kays, was born on January 22, 1881, at Tonica, Ill. His parents and their four children moved to Phoenix, Ariz., in 1886, and by 1889 were operating a small dairy ranch four miles outside that city.

---

[1] Memoir prepared by H. J. Morrison, Assoc. M. ASCE, and Lynn Perry, M. ASCE.

The energy of Marion, together with that of his two younger brothers, provided the essential help in feeding, milking, irrigating, and performing the myriad of ranch chores while they were attending the rural grammer school and city high school. The dairy prospered and after a few years Emory Kays became manager of a cooperative creamery. After graduation from the Phoenix High School in June, 1899, Marion was employed at the creamery, which provided his first business experience.

Mr. Kays registered in the mining engineering department at the University of Arizona, in Tucson, in the autumn of 1901. He studied there only one year and the following September he entered the alma mater of both his father (Class of 1879) and mother (Class of 1881), the University of Illinois, in Urbana. He was graduated from the civil engineering department in June, 1906. His formal education was interrupted and his graduation delayed by an engagement with the United States Reclamation Service from June, 1903, to August, 1904. During this period he was engaged on location surveys for the Roosevelt Dam in Arizona and its connecting roads and canals. He spent the following summer vacation on similar work on the North Platte project in Wyoming. These engagements with the U. S. Reclamation Service provided him with some practical engineering experience and a close acquaintance with able engineering personnel; it also fired his imagination and stimulated his sense of accomplishment, leading him directly to the field to which he devoted the productive years of his profession.

After receiving the degree of Bachelor of Science in Civil Engineering Mr. Kays was immediately employed by the U. S. Reclamation Service as assistant engineer and remained with that service for three years. During this time he engaged in surveying, designing, constructing, and operating irrigation works on the North Platte project in Wyoming and Nebraska, and the Salt River project in Arizona. He resigned in November, 1909, to join his father in business; within a few months, however, he joined some of his former associates and returned to reclamation work—this time with the Idaho Irrigation Company.

On this project he served as assistant construction superintendent for J. G. White and Company with headquarters at Richfield, Idaho, from February 1, 1910, to November 30, 1911, when he became vice-president and general manager of the Idaho Irrigation Company. He served the company in this capacity for more than eight years, during which time he was responsible for the business management of the irrigation project and "allied features"; the collection and disbursement of all funds; public relations; incidental construction; all maintenance and operation, including the reservoir and canal system; repairs and improvements; precipitation and stream flow measurement and records; and water supply between project lands and decreed rights in cooperation with the state authorities. Mr. Kays conducted duty-of water studies and demonstrations; negotiations over water supply and project acreage, frequently leading to litigation; and the grouting of dam foundations. In addition, he promoted land ownership and use. The "allied features" included laying out two town sites, together with the construction of their public buildings, hotels, deep wells, pumping stations, water distribution systems, an electric light and power plant, miles of telephone network, and two 160-acre fully improved demonstration farms.

In August, 1920, Mr. Kays became associated with the Beckman and Linden Engineering Corporation of San Francisco, Calif., in charge of its Phoenix (Ariz.) office. He acted as project engineer for the Paradise-Verde Irrigation District (later known as the Verde River Irrigation District) in Arizona, with headquarters in the Heard Building in Phoenix. He was in charge of the analyses and estimates of available water and the area which it would serve, and the design of dams, reservoirs, diversion works, and canals. A part of his attention was devoted to the Carrick and Mangham, and to the Maricopa and Queen Creek projects in Arizona. In July, 1923, he became special field engineer for the Salt River Valley Water Users' Association. Some features of the Verde River district were: Measurements on canal water loss, studies to determine the quantity of water that could be saved by lining the canals and the additional area it would serve, and the remodeling and enlargement of the power plant at the Roosevelt Dam.

He was appointed manager of the Lake Worth Drainage District in Florida, in January, 1924, upon the suggestion of those who had participated in financing the Idaho Irrigation Company previously. This appointment brought to the drainage district a thorough, practical knowledge of the principles of the artificial control of water for agriculture; the relation between soil moisture and plant growth; the construction, operation, and maintenance of reclamation works; the financial and economical aspects of such developments; and an appreciation of the responsibilities of public agencies engaged in such service—accumulated in Mr. Kays' seventeen years experience in the west.

The Lake Worth Drainage District originally provided an area with a system of canals and laterals to dispose of excess water, and control works to prevent overdrainage and to maintain proper ground-water levels. At the time Mr. Kays became manager the canals were from two to six years old and had not been systematically or adequately maintained. The system of canals was incomplete, and the control works were insufficient; there were no pumps. As manager, he was retained to salvage a failing enterprise, which required construction and personnel, use of land and collection of assessments, and the payment of the interest on bonds and the reduction of debt. As manager of the district, he was also chief engineer, secretary, and treasurer.

After a rehabilitation policy was approved by the bondholders, a program of improvement and maintenance was adopted and successfully carried out. Small-scale land development was encouraged at first which led to larger projects. To advance agricultural development, many houses were built. Finally, the improved growing conditions aroused interest and attracted capital. The collapse of land values in 1925, the hurricanes of 1926 and 1928, bank failures in 1927, the crash of 1929, and ensuing years of depression left their scar. They disrupted business and presented unexpected problems which Mr. Kays faced with characteristic ability and patience. He never lost sight of his duty to build a successful and profitable agricultural system on a foundation of water control suited to local conditions. His program had been laid out and he adhered to its fundamental provisions tenaciously. Methods and practices suitable to local conditions were devised and demonstrated. Irrigation by ground-water control was perfected and developed into large-scale use.

In 1938 he relinquished the management of the district and prepared an exhaustive and detailed report dealing with the engineering phases of the development, making recommendations for future construction and operation, all of which were based on the principles which had been established and in harmony with the long-time program which he had adopted fifteen years before.

Mr. Kays was appointed chief engineer of the West Palm Beach Housing Authority in Florida in August, 1939. He was in charge of construction of the 246-unit "Dunbar Village," a low rent housing project (colored), and the 122-unit "Southridge" project (white), with an administration building for each. The buildings were of concrete block construction, completely equipped with electricity, gas, water, sanitary sewers, and storm water drainage, and they were landscaped when they were ready for occupancy.

Following this project, in 1941 he served as resident manager of the "Morrison Homes," a 150-unit defense development of which the West Palm Beach Housing Authority was managing agent. The tenants were the military and civilian personnel at Morrison Field, an Army air base near West Palm Beach. He became construction engineer of District No. IV of the Federal Public Housing Authority in Atlanta, Ga., in September, 1942, a position which he held at the time of his death.

Active in religious affairs as well as in technical, business, and civic matters, Mr. Kays was a leader in every undertaking with which he was associated. He was a trustworthy friend, respected and beloved by all who were privileged to know him. He will be remembered for his intelligent and enthusiastic handling of the drainage problems in the Everglades of Florida and for his tenacity in striving to accomplish the long-time objective. He was a builder and developer; in the wake of his activity were houses and green fields.

Mr. Kays was a charter member and the first president of the Palm Beach County Engineers' Club; secretary of the Association of Florida Drainage Districts; past-president of the Palm Beach County Chapter of the American Red Cross, and chairman of its Preparedness and Relief Committee; president for five years of the Palm Beach County Council of the Boy Scouts of America, serving as its representative on the National Council; past-president of the Miami Section of the Society; director and vice-president of the West Palm Beach Chamber of Commerce and the West Palm Beach Zoning Board; and a member of the Rotary Club and of the Presbyterian Church there.

He was married to Alice Adeline Grier of Phoenix. Surviving are his widow; a son, Marion Reed Kays, Jr., of West Palm Beach; and a daughter, Mrs. Arnold G. Asp, of Fair Lawn, N. J.

Mr. Kays was elected an Associate Member of the American Society of Civil Engineers on December 6, 1910, and a Member on October 10, 1927. He became a Life Member in January, 1945.

JOSEPH GRANT KELLEY, M. ASCE[1]

DIED NOVEMBER 14, 1941

Joseph Grant Kelley was born in Orono, Me., on August 14, 1864. He was the son of Jones Shaw Kelley and Harriet (Brown) Kelley. Mr. Kelley attended the University of Maine at Orono and received a degree in civil engineering in 1884.

Upon his graduation, he engaged in surveying and lumbering activities in the State of Maine. In 1886 hearing the call of the West, he went to work for the Shasta County (California) engineer. Later he was employed by the Shasta Lumber Company locating timber lands and constructing timber flumes. Mr. Kelley went back to Maine in 1887 and until 1892 was engaged on engineering and surveying at Bar Harbor, Me., and other towns along the eastern seaboard.

However, in 1892 he returned to the West undertaking both contracting and engineering work in Eugene, Ore. In 1896 he was employed by the Portland (Ore.) District of the United States Engineers, remaining with that organization for about four years during which time he was engaged on river and harbor surveys and construction and on the construction of fortifications at the mouth of the Columbia River. After leaving the United States Engineers, Mr. Kelley was superintendent of the Port of Portland for two years.

During the remainder of his professional life, he was primarily engaged in private practice—the location and the construction of irrigation canals and flumes; the installation of pumping plants and small hydroelectric power developments; and the investigation and the evaluation of hydroelectric power sites, water rights, and water systems in Oregon and Washington.

In 1886 Mr. Kelley was married to Cora Oliver of Redding, Calif. Two sons, M. S. Kelley and J. G. Kelley, Jr., survive him.

Mr. Kelley was elected a Member of the American Society of Civil Engineers on October 7, 1914. He became a Life Member in January, 1939.

---

[1] Memoir prepared from information on file at Society headquarters.

JOHN EDWARD KEMP, M. ASCE[1]

DIED JANUARY 19, 1946

John Edward Kemp, the oldest child of John McMillan Kemp and Elizabeth (Atteridge) Kemp, was born in Chicago, Ill., on January 14, 1878. His maternal grandfather, Thomas Atteridge, came from Northern England to Skibberee, County Cork, Ireland, where he was married to Mary Cole, a pretty Irish girl, and together in the early part of the nineteenth century, they came to the United States. Thomas Atteridge purchased land from the government and built his home, in what later became Lake Forest, Ill., a suburb of Chicago.

In later years, the family had among its most precious possessions, the papers signed by Martin Van Buren and by James K. Polk, former Presidents of the United States, transferring these grants of government land to Thomas Atteridge, whose descendants still live in or near Lake Forest.

The paternal side of the Kemp family was of English and Scotch extraction. John E. Kemp's father was employed as chief telegrapher of the Western Union Telegraph Company at the Union Station in Chicago.

When John Edward was seven years old, his father bought seven acres of the old Atteridge homestead, where his wife had lived as a girl, and built a comfortable home on it. The family then moved from Chicago to Lake Forest, since the elder Kemp felt a city was "no place to raise a family." There, with a younger brother and three sisters, John E. Kemp grew to young manhood.

He attended Lake Forest Academy, after completing grade school, being graduated as valedictorian of his class, in 1895. He then entered Lake Forest College, where he finished his four-year course in 1899. He continued his education in civil engineering at the University of Illinois, in Urbana, being graduated in 1901 with the degree of Bachelor of Science in Civil Engineering. In 1908 he received the degree of Civil Engineer. At the University of Illinois, Mr. Kemp ranked in the top four of his class and was elected to membership in the honorary engineering fraternity of Tau Beta Pi. He was also a member of the social fraternity of Phi Delta Theta.

During his vacation time, while not attending school, he served in 1898 as stadiaman for the United States Engineering Corps on the Hudson River. In 1901 and 1902, he was rodman and instrumentman for the Chicago and North Western Railway then being built in Iowa.

From 1902 to 1904 Mr. Kemp was city engineer, superintendent of the Water Department, and plumbing inspector for Kewanee, Ill. As city engineer, he designed and constructed pavements, ten miles of sidewalks (concrete), six miles of six-inch and eight-inch water main and half completed the installation of a $30,000 sanitary sewer system. In March, 1912, he was made secretary of the City Water Commission to recommend a new water works system for Kewanee. He resigned as city engineer to become civil engineer at the Kewanee Works National Tube Company which position he held from 1904 to 1917. Later this plant was sold to the Walworth Company.

---

[1] Memoir prepared by Pauline King Kemp, Kewanee, Ill.

In July, 1917, Mr. Kemp enlisted in the Engineering Reserve Corps of the United States Army, being commissioned a Captain, and, on September 4, 1917, was ordered to Fort Leavenworth, Kans., for officers' training camp. In November, 1917, he sailed, with the first 100,000 Americans, for France, where he was in the United States Ordnance Department as Construction Engineer for Ordnance Depots (built for repairing the munitions of World War I). He made a record for speedy construction of this type of building and was placed in charge of ordnance depot construction at various places in France. Since he spoke French fluently, he often did the necessary purchasing in France of army building materials such as concrete, sand, etc., which were not furnished by the United States Army. He spent a little more than one year in France, returning to his home in Kewanee on December 18, 1918.

In January, 1919, Mr. Kemp was again employed by the Walworth Company—as superintendent of maintenance—and served in that capacity until 1931. During this period, he designed and constructed a new steel skelp mill building, 120 feet by 230 feet with a 60-foot crane to replace the old structure (without interrupting mill operations); a steel and brick pipe storage building 80 feet by 150 feet with an 80-foot crane; a three-story reinforced concrete pattern storage building 50 feet by 110 feet; and a modern boilerhouse. He was in charge of all sewer, water-main, tracks, oil-storage, fire protection systems; boiler installations; furnace construction; and buildings in the Walworth plant.

From 1932, until his retirement on January 1, 1946, Mr. Kemp was chief engineer and director of training. He organized the training department of the Walworth Company, laying out the three-year course offered to the employees, assigning the instructors, writing a number of the textbooks used, and teaching several hours each week.

Mr Kemp was most proud of his work during World War II, and it was doubtless the cause of his death. Great responsibility, the rush of the work, which had to be completed quickly, and the lack of skilled labor made his load a heavy one. For a long time he had had heart trouble but his sincere patriotism would not allow him to rest while his country had war work for him to do. He designed and erected two shell-plant buildings, one 80 feet by 320 feet and one 60 feet by 177 feet where anti-aircraft shells for World War II were made.

On January 17, 1942, he was appointed resident engineer "to inspect, approve and expedite all items of labor, material, construction and engineering details in connection with the construction of a plant for the Navy at Washington Park, Illinois," near East St. Louis, Ill. This plant consisted of five main buildings; a light finishing building, 120 feet by 400 feet; a heavy finishing building, 86.8 feet by 400 feet; a steel foundry, 86.8 feet by 400 feet; a pattern shop, 50 feet by 125 feet; and an office building, 56 feet by 160 feet. These buildings were of steel, concrete, and brick.

Eight months after Mr. Kemp went to Washington Park, he turned the buildings over to the new manager for operation. Walworth valves, fittings, etc., were made here for the new ships built by the United States Navy. This was a big job and Mr. Kemp gave seven days each week to its accomplishment.

After living at Collinsville, Ill., a town near this Navy plant, for eight months, Mr. Kemp returned to the Walworth Company in Kewanee, where more construction work, necessitated by the war, awaited him. At the Kewanee plant, he designed and erected a steel iron foundry extension and cupola addition, 81.6 feet by 163 feet; an extension to the steel valve finishing department; a new plant hospital; and an extension to the main office, increasing it to three times its original size.

Mr. Kemp was a charter member of the American Legion and helped organize Kewanee Post No. 31, of which he was commander. He was active in Masonic circles and assisted in forming the Commandery of Knights Templar in Kewanee, serving as its second commander. He belonged to the Illinois American Foundrymen's Association, the Rotary Club, Midland Country Club, and Lake Calhoun Association. Among his other interests was his Boy Scout Troop, one of the largest and most active in the city, of which he was scoutmaster for over twenty-five years, receiving the national honor award of the Silver Beaver. He organized and taught a Sunday School Class of ex-service men of both World War I and World War II for more than a quarter of a century, called "The Yanks Class," in the Presbyterian Church, where he was an elder, and an active worker.

He was an outdoor man and enjoyed golf, fishing, bird hikes, and nature study. He loved to write poetry as a pastime and published for his friends, a clever collection of his poems, entitled "Kemp Kodaks." Each January, he sent out an original poem for the New Year.

On September 4, 1906, John Edward Kemp was married to Pauline Harris King, daughter of Theodore F. King and Ida (Harris) King, at their home, "The Maples," near Prescott, Iowa. To this union, were born two sons, John Theodore Kemp, a practicing physician in Michigan City, Ind., and Harris Atteridge Kemp, an architect in Dallas, Tex. Mr. Kemp is survived by his widow; his two sons; and four grandchildren, John Edward, Jr., David Anders, Barbara Ann, and Peter Alan Kemp.

Mr. Kemp was elected an Associate Member of the American Society of Civil Engineers on April 1, 1908, and a Member, on May 28, 1912. He became a Life Member in January, 1943.

RICHARD SMITH LEA, M. ASCE[1]

Died November 11, 1945

Richard Smith Lea was born on April 11, 1866, in Victoria, Prince Edward Island, Canada. An original settler of this community, a Lincolnshire (England) yeoman and an ancestor of Mr. Lea, landed on Prince Edward Island early in the 1800's, intent on making a new home for himself in the colony. Accompanied by his wife, several married sons and daughters, and their children, he settled on a farm in Victoria, on the Northumberland Straits shore, a few miles west of Charlottetown.

In due course Richard Lea was sent to the local school and on to Prince of Wales College in Charlottetown, then and now the island's best preparatory school. Because he showed more than ordinary ability in mathematics and the physical sciences, he decided, rather against his family's wishes, to study mechanical engineering at McGill University in Montreal, Que. From this institution he received the degree of Bachelor of Science with distinction in 1890. Postgraduate work at Cambridge University in Cambridge, England, and active practice in Boston, Mass., with Joseph P. Frizell,[2] M. ASCE, and Marshall M. Tidd,[3] M. ASCE, followed. In 1893 his alma mater, McGill University, granted him the degree of Master of Engineering and added him to her staff.

By 1903, with ten years of additional experience accumulated by working summers and in his spare time with Freeman C. Coffin,[4] M. ASCE, he had become assistant professor of civil engineering. In 1899 he was appointed consultant to the newly formed Provincial Board of Health of Quebec, and in 1900 formed a partnership with Mr. Coffin for handling the latter's Canadian commissions which were rather numerous at the time. In 1903 Mr. Lea established the independent consulting practice he was to follow for the rest of his life.

Up to this time his experience had been mostly in the municipal field—a field in which his major interest always lay—although later he was to be recognized as an expert in the broader aspects of hydraulic power development and in engineering legal matters. However, he made not infrequent excursions into other fields; he was a good example of the versatility which is now less common.

Detailed mention of the many commissions he executed during the forty odd years of his active practice is not possible here; most of the larger Canadian cities and corporations and many smaller ones retained him at one time or another. He made friends readily and his talents were evident enough to secure many return engagements. Some of the work he considered his more important included: The preliminary investigations for the hydroelectric plants on the Winnipeg River for the City of Winnipeg, Man.; the design and construction of extensive improvements to the water supply and power system of Medicine Hat, Alberta; the repair of serious damage to Winnipeg's ninety-mile Shoal Lake aqueduct, caused by unforeseen foundation conditions; the planning in broad outline of the Greater Vancouver (B. C.) sewerage system; the rehabilitation of the water distribution system of Ottawa, Ont.; similar work on a much larger scale for the City of Montreal; the Bassano Dam across the Bow River in Alberta; a group of earthquake resistant buildings in Kingston, Jamaica, B. W. I.; many of the studies on which the proposed St. Lawrence Waterway is based; and, finally, the many arbitration and legal cases in which he appeared as an engineering adviser.

---

[1] Memoir prepared by R. DeL. French, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXIII, September, 1911, p. 501.

[3] *Ibid.*, Vol. XXXVII, June, 1897, p. 568.

[4] *Ibid.*, Vol. LVIII, June, 1907, p. 532.

Fortunately, Mr. Lea's practice was always large enough so that he could choose his clients with a great deal of freedom. Although he had a strong sense of professional responsibility, he was quite aware of the field in which he excelled, and never hesitated to advise a client to take his work elsewhere, if he thought it would be to the client's advantage. Naturally, this trait made him popular with his less well-established confrères, who looked upon him as a sort of fatherly adviser.

Beginning in 1911 the writer was in his employ for some years, seeing him not infrequently after leaving his employ, and thus writes from personal knowledge in noting that he concealed a kindly personality under a gruff exterior. Being of the most straightforward character, Mr. Lea found it hard to think ill of anyone, but woe to those who imposed upon him. The writer recalls with relish the occasion on which he skillfully and ruthlessly flayed a younger engineer who had been using Mr. Lea's advice, freely and cheerfully given, to impress one of his own clients.

Mr. Lea did not marry until his consulting practice was well established, which perhaps accounts for his love of travel. It was his custom to visit England and the Continent every three or four years, partly for pleasure, no doubt, but mainly to see what was going on in engineering circles. It was on one of these trips in 1914 that he was interned in Austria, disappearing completely for many months. He was ultimately released and made his way to Switzerland, crossing France and the Channel to England before finally returning to Canada. His experiences provided the material for many stories, all of which reflected credit upon Austria and its people.

He retired from active practice in 1931, after admitting his younger brother, William S. Lea,[5] M. ASCE, to partnership some years before. His death is regretted by his many professional acquaintances in Canada, the United States, and abroad. He was one of the few remaining "old time" engineers.

Mr. Lea was a member of the Institution of Civil Engineers; the Engineering Institute of Canada, from which he had received both the Gzowski and Julian C. Smith medals, and had served on the council; and the Association of Consulting Engineers in England. He also belonged to the University Club of Montreal and the Royal Montreal Golf Club.

---

[5] For memoir, see *Transactions*, ASCE, Vol. 113, 1948, p. 1493.

Brought up in the Methodist faith yet never a church member, after that church lost its identity in the United Church of Canada in 1925, he attended both Anglican and Presbyterian churches as opportunity offered and remembered both the "Auld Kirk" of Charlottetown and the United Church at Victoria generously in his will.

In 1914 Mr. Lea was married to Mrs. Wanda Schador. He is survived by his widow and two sisters, Mrs. Edward Boswell and Mrs. J. T. Windsor.

Mr. Lea was elected a Member of the American Society of Civil Engineers on July 1, 1908.

WILLIAM SCHURMAN LEA, M. ASCE[1]

DIED JULY 5, 1947

William Schurman Lea was born on May 10, 1877, at Victoria, Prince Edward Island, Canada. His parents were William Charles and Annie Lea. He was educated at Prince of Wales College at Charlottetown, Prince Edward Island, and at McGill University in Montreal, Que., Canada, from which he was graduated in 1908, a Medallist with the degree of Bachelor of Science.

His engineering experience, both before and after graduation, extended over a period of forty-five years. His advice was sought by municipalities in every province of Canada, as well as by provincial and dominion governments and industrial organizations, including many pulp and paper firms and power companies. He appeared as an expert before the International Joint Commission on questions of pollution of boundary waters, of water storage, and of runoff control. In large measure he was responsible for design and construction of large-scale sewerage and sewage treatment projects for Montreal, Winnipeg, Man., and Vancouver, B. C.; of water supply systems or extensions in these cities and in scores of others; and of hydroelectric developments in many parts of Canada.

Mr. Lea's early engineering experience was had with two leading sanitary engineers in Boston, Mass., the late Freeman C. Coffin, and the late Frank A. Barbour, M. ASCE. While working with Mr. Barbour, he was engineer in charge of construction for the Fredericton Filter Plant in New Brunswick, the first modern type filter plant built in Canada. He then operated this plant for six months. From 1908 to 1911 he lectured in municipal engineering and hydraulics at McGill University. In 1911–1912 he was engineer in charge of the Department of Water Works and Bridges for the City of Vancouver, and in 1913 he joined his brother, R. S. Lea,[2] M. ASCE, in the partnership of R. S. and W. S. Lea. Together they were consulted on many outstanding projects, among the more outstanding of which were the Vancouver and Districts Joint Sewerage and Drainage project; the Slave Falls Hydroelectric Plant for the City of Winnipeg; the Manitoba Power Company's 200,000 horsepower hydroelectric plant on the Winnipeg River; the Canadian Niagara Company's plant for the Ontario Government; the Hydroelectric Power Commission of Ontario's Queenston-Chippewa development and the proposed St. Lawrence Power and Navigation Development; the Nesbitt Thompson plant of about 100,000 horsepower on the Back River at Montreal; Price Brothers Kenogami Dam and later their paper mill dam; dams built by the Quebec Streams Commission; a dam for the Spanish River Pulp and Paper Company and several of their small storage dams; development of the aqueduct power for the City of Montreal, and many other large projects.

---

[1] Memoir prepared by J. Long, Secy., William S. Lea, Cons. Engr., Montreal, Que., Canada.

[2] For memoir, see *Transactions*, ASCE, Vol. 113, 1948, p. 1491.

The partnership continued until the retirement of R. S. Lea in 1930. Since that time, William S. Lea had been retained by municipalities in every province of Canada and by the following large corporations: The Laurentide Pulp and Paper, Canadian International Paper, Building Products, Brown Corporation, Spanish River Pulp and Paper, St. Maurice Paper, Lake of the Woods Milling, Aluminum Company of Canada, Limited, as well as the Hydroelectric Power Commission of Ontario, Quebec Streams Commission, Quebec Public Service Commission, and others.

Mr. Lea acted as technical expert for the City of Winnipeg and the Winnipeg Electric Railway Company on a number of occasions. For nine years he was a member of the Montreal Sewers Commission and consulting engineer on its twenty million-dollar trunk sewer construction program and at his death was retained by the City of Montreal on the design of the St. Pierre River Sewage Pumping Plant. He was consulting engineer to the City of Winnipeg for the design and construction of trunk sewers and a 25,000,000 gallons per day sewage treatment plant for the Greater Winnipeg Sanitary District—a four million dollar project. As a member of the commission appointed by the Quebec Government he investigated and reported on the contract between the City of Montreal and the Montreal Tramways Company and on the general question of transportation for the Greater Montreal District. He was also consultant to the cities of Windsor, Ont.; Brantford, Ont.; Saint John, N. B.; Charlottetown; Fredericton; and many others in connection with water, sewage, or electrical power problems.

Mr. Lea was a member of the American Concrete Institute committee appointed many years ago to draw up standard specifications for plain and reinforced concrete sewers. As a result of the findings of this committee, reinforced concrete came to be more widely used for large sewers and other similar structures.

As a student, Mr. Lea played on the McGill intercollegiate football team, and throughout his life maintained a very keen interest in sports. He was an active supporter of all Montreal and McGill University teams, and well known to the players, coaches, managers, and sports editors in that city.

In 1927, Mr. Lea was married to Mildred Florence Parkins who survives him.

He was a member of the Engineering Institute of Canada, the Corporation of Professional Engineers of Quebec, the Association of Professional Engineers of Manitoba, the American Water Works Association, the McGill Graduates Society, the University Club of Montreal, and the Senneville Golf Club.

Mr. Lea was elected a Member of the American Society of Civil Engineers on January 14, 1918.

GEORGE ALLEN LEE, M. ASCE[1]

DIED JULY 13, 1945

George Allen Lee was born in Dunedin, New Zealand, on July 1, 1881. From late pioneering days, his father, William Lee, had been prominently identified with the commercial and industrial development of Otago Province, especially in the mining of coal and scheelite and shale oil and in the dredging, sluicing, and reef mining of gold. George, his eldest son, was thus brought up in close contact with engineering problems.

At the age of eighteen, after having received part of his schooling in England, he commenced an apprenticeship with a Dunedin firm of mechanical engineers. This firm had been prominent in the design and construction of mining dredges (at that time a development pioneered in New Zealand and later perfected in California and elsewhere).

After a three-year apprenticeship, he became a cadet in the office of C. L. Watt, consulting mechanical engineer, and at the same time began night classs in the Otago School of Art and in the Otago University School of Mines at Dunedin.

His first responsible appointment was as mechanical engineer and surveyor with the Kaitangata Coal Mining Company. Later he was assistant to J. Blair Mason, engineer to the Otago Harbour Board, who had an extensive consulting practice with various colonial organizations. Subsequently, after some years as assistant engineer for the Otago Harbour Board and as engineer for the Bluff and Napier harbour boards, Mr. Lee, in 1918 entered partnership with Mr. Mason, and, during the following fourteen years, this firm became prominently identified with the harbor engineering of the Dominion, constructing various projects or reporting on possible developments in the majority of the ports. The most extensive engagements were on the remodeling of Otago Harbour and on the construction of the breakwater port of New Plymouth.

On the retirement of Mr. Mason, the partnership of Mandeno, Lee and Brown was formed. As a member of this firm, one of Mr. Lee's major responsibilities was the selection of a site and the design of the new breakwater harbor near the Town of Mackay, the port for the principal sugar-producing district of Queensland, Australia. Completed during World War II, this new harbor introduced profound changes in the transport system of Queensland. The breakwaters exceed two miles in combined length and are nearly seventy feet in total height at the entrance.

---

[1] Memoir prepared by Lloyd Mandeno, Cons. Engr., Mandeno, Lee & Brown, Auckland, New Zealand.

Mr. Lee came into the profession "the hard way" so that the natural skill of his hands became fully developed. It was ever his pleasure to utilize this dexterity, and he applied it in a wide variety of ways. For years he added to the admirable collection of insects commenced in boyhood, and he achieved high standards in the art and technical excellence of his photography. Although so proficient himself, it was his delight to have those less skilled gain experience in the mechanical and wood-working workshop at his home.

In 1911 he was married to the sweetheart of his boyhood, Fan McAdam, by whom, with his two daughters, Mary (Mrs. John S. Stronge) and Frances Betty (Mrs. James R. Steer), he is survived.

Mr. Lee was elected a Member of the American Society of Civil Engineers on December 31, 1913.

CARLOS LOBO, M. ASCE[1]

DIED SEPTEMBER 29, 1946

Carlos Lobo was born in Curacao, N. W. I., on September 22, 1873. He received his prepartory school education in Caracas, Venezuela.

Having decided to become a civil engineer, he came to New York, N. Y., in 1889 and in the fall of that year entered New York University (New York) as a member of the class of 1893. After completing the civil engineering course, which at that time was the only engineering course offered at the university, he received the degrees of Bachelor of Science (1893) and Civil Engineer (1894), after completing the required postgraduate work.

In October, 1894, Mr. Lobo joined the engineering staff of the Bureau of Water Supply, Department of City Works, Brooklyn, N. Y. He worked mainly on the distribution system, and in 1911 he was placed in full charge of the operation, maintenance, and repairs of that system for the then Borough of Brooklyn. This was part of the work of the Department of Water Supply, Gas and Electricity which was responsible for the entire water system of the City of New York. In October, 1914, Mr. Lobo was appointed borough engineer supervising all the water supply work for the Borough of Brooklyn under the Department of Water Supply, Gas and Electricity.

Resigning in September, 1919, he entered the Kelvin Engineering Company of which his brother, Gustavo Lobo, an electrical engineer, was president and treasurer. This company manufactured and exported machinery mainly for South American countries. In January, 1932, Mr. Lobo became vice-president and director of the company. He retired from active duty in January, 1936.

---

[1] Memoir prepared by William W. Brush, M. ASCE.

Mr. Lobo and the writer were classmates and fellow workers until he left the New York City Water Department in 1919.. He was a man who, as an engineer, citizen, and friend, lived up to his high ideals and was outstanding in his loyalty to the organizations and persons with whom he was connected. His kindness and generosity were also noteworthy.

Following his graduation from the university he was the perennial secretary of his class and one who could always be depended upon to be present at alumni meetings.

In June, 1904, Mr. Lobo was married to Edith Eder, who was born of American parents in Colombia and whose family had very extensive sugar interests in that country. He was a devoted husband and father and was constantly with his wife during the long period of illness prior to her death in 1942. He is survived by a daughter, Mrs. Clarita L. Collins, and a son, Walter E., who is a chemical engineer and a graduate of Massachusetts Institute of Technology in Cambridge.

Mr. Lobo was elected an Associate Member of the American Society of Civil Engineers on May 3, 1905, and a Member on March 14, 1916. He became a Life Member in January, 1940.

JAMES BUTTON CLYDE LOCKWOOD, M. ASCE[1]

DIED DECEMBER 2, 1945

James Button Clyde Lockwood was born on May 27, 1863, in Marshalltown, Iowa. He was the son of Edwin Wallace and Phoebe Anne (Putnam) Lockwood who were of Scotch and English descent.

Mr. Lockwood attended Iowa State Agricultural College at Ames, from which he was graduated in 1885 with the degree of Bachelor of Science in Civil Engineering. Immediately thereafter, he began his professional career as draftsman and estimator with the Chicago Forge and Bolt Company. Two years later he severed this connection and joined the Berlin Iron Bridge Company as a designer.

In 1889 Mr. Lockwood moved to Seattle, Wash., where as engineer and manager he opened a branch office of the San Francisco Bridge Company. During the following ten years he actively directed the operations of this branch, engaging in a wide variety of construction projects. They included the design and erection of a bridge across the Columbia River for the Spokane Falls and Northern Railway, the building of two steamers for the Boston and Alaska Transportation Company, and the execution of various dredging contracts throughout the Pacific Northwest. In 1898, without change of ownership or management, the operations of the company were transferred to the newly organized Puget Sound Dredging Company, with Mr. Lockwood serving as president and chief engineer. Shortly thereafter, this company purchased the Bowers hydraulic dredges *Anaconda* and *Python,* which were immediately redesigned and rebuilt. These two dredges were among the earliest hydraulic machines built in the United States. Under his supervision, much dredging and bridge building was undertaken and successfully completed.

---

[1] Memoir prepared by H. W. McCurdy, M. ASCE.

Mr. Lockwood moved temporarily to Washington, D. C., in 1900. There he designed and had charge of the construction of a hydraulic dredge for the Atlantic Gulf and Pacific Company, an affiliated organization. On completion of this work in 1902, he returned to Seattle, severed his connection with the Puget Sound Dredging Company, and entered a private consulting practice.

His unusual experience in the design and construction of dredges was becoming widely and favorably known, and he was soon engaged by the Port of Portland, Ore., to design and supervise the construction of two hydraulic dredges. They were the *Portland* and the *Columbia,* twenty-inch and thirty-inch dredges, respectively.

In 1903 Mr. Lockwood moved to Portland and opened an office as consulting engineer, specializing in the design and construction of dredges and bridges. The Port of Portland continued to make use of his services in the construction of its first floating dry dock, which was of ten thousand-ton capacity; the hydraulic filling of a lowland area in central East Portland; and the filling of terminal yards and wharf sites. In addition, he was the city's representative in connection with the Spokane, Portland and Seattle Railway bridge across the Columbia River.

He purchased a substantial interest in the Drummond Lighterage Company of Seattle in 1907, and later became its president. Simultaneously, he retained his interest and position in the company with his wide consulting practice until 1923, when he disposed of his ownership stock.

Mr. Lockwood entered the full-time employ of the Port of Portland as its chief executive and engineer in 1908. He continued in this capaciy until late in 1909, when he was retained as a consultant. In 1911 he designed and supervised the construction of the port's hydraulic dredge, *Willamette,* and, in 1916, its hydraulic dredge, *Tualatin,* both of which were thirty-inch dredges and among the largest and most powerful in the United States at that time. In 1913 he designed two large hydraulic dredges for the United States Engineer office in Portland, and, a year later, the hydraulic dredge, *Duwamish,* for the Duwamish Waterway Commission in Seattle.

Mr. Lockwood returned to Seattle in 1919 and continued his consulting practice. He undertook much work for the Puget Sound Bridge and Dredging Company, the successor to the Puget Sound Dredging Company of which he had been president. Among his many activities for this company was the design and supervision of construction of the hydraulic dredges, *Seattle* and *Olympia;* the electrification of the hydraulic dredge, *Tacoma;* the rebuilding of the dipper dredge, *Puget Sound;* and the design and supervision of construction of two dump scows, the hydraulic dredge, *T. B. Noble,* at Mabelle, Tex., and the hydraulic dredge, *Seattle,* at Garza, Tex.

The General Construction Company of Seattle engaged Mr. Lockwood in 1933 to rebuild and modernize its floating plant, including the redesign and rebuilding of the hydraulic dredges, *Washington* and *Missouri.* During this period he was simultaneously managing his many investments, which included extensive mining interests in Alaska.

He returned to the employ of the Puget Sound Bridge and Dredging Company in 1944 and designed a new hydraulic dredge to be built at the cessation of World War II. Throughout his life he had taken an interest in the operations of this company; for many years, for sentimental reasons, he kept his name on its payrolls at one dollar a year.

As a young man Mr. Lockwood was married to Mabel Dana. After her death and on September 5, 1906, he was married to Mary Reynolds who, with four children, survives him. The children are James Button Clyde, Jr.; William Putnam; Lucile (Mrs. Kenneth Chisholm); and Marie (Mrs. John R. Martin).

Mr. Lockwood was an energetic, capable, and friendly gentleman. He was a pioneer in the dredging industry, and during the sixty years of his business life he was a leader in his profession, probably designing more dredging plants than any other individual. His good health and vigor were retained until shortly before his death.

Mr. Lockwood was elected a Member of the American Society of Civil Engineers on March 6, 1901.

CHARLES HARVEY MACCULLOCH, M. ASCE[1]

DIED JUNE 24, 1947

Charles Harvey MacCulloch, the son of Charles and Emma (Harvey) MacCulloch, was born in Albany, N. Y., on February 23, 1877. He attended the public schools in Albany, graduating from the Albany High School; he then pursued an electrical engineering course at Union College, in Schenectady, N. Y., from which he was graduated in 1900 with the degree of Electrical Engineer.

Mr. MacCulloch began his engineering career in the employ of the state engineer and surveyor of New York State as a rodman in 1900. He then was engaged in surveying for the Erie Barge Canal and in highway work until 1905, at which time he became an instructor in the engineering department of Union College.

In 1907 he returned to the state engineer's office in charge of barge canal construction work and in 1909 was made responsible for the preparation of plans and specifications for electrical equipment in connection with the operation of canal locks, powerhouses, substations, and gasoline engine generating stations. He also designed electrical equipment for canal terminals and the state-owned grain elevators at Oswego, N. Y., and Gowanus Bay, New York City, together with electrical equipment for the 8,000-horsepower generating plants at Crescent and Vischer Ferry in New York.

---

[1] **Memoir prepared by H. O. Schermerhorn, M. ASCE.**

Ill health forced Mr. MacCulloch to relinquish temporarily his strenuous duties in 1926. After nearly a year's rest, he became associated with the firm of Whitman, Requardt and Smith in the preparation of plans for a new water supply system for the City of Albany.

He again returned to the employ of the New York State Department of Public Works in 1931, and from that time was engaged on all kinds of electrical design and estimate work connected with the department's activities. On January 31, 1947, Mr. MacCulloch retired after forty-one years of state service.

In 1916 Mr. MacCulloch was married to Angeline Emery. Besides his widow he is survived by a son, Charles MacCulloch, and a daughter, Elizabeth (Mrs. R. H. Mattox), all of whom are Albany residents.

He was a member of the Society of Professional Engineers, the Psi Upsilon fraternity, and the Calvary Methodist Church of Albany; for many years he was actively engaged in Boy Scout activities in the Albany area.

Mr. MacCulloch was beloved by all who had the good fortune to know him. He was devoted not only to his family and to his profession, but was loyal to all his friends and acquaintances as well. He enjoyed the respect of all who knew him, and his passing is mourned by a host of friends.

Mr. MacCulloch was elected a Member of the American Society of Civil Engineers on April 1, 1914.

GEORGE ALFRED MANEY, M. ASCE[1]

DIED MAY 10, 1947

George Alfred Maney was born in Minneapolis, Minn., on December 9, 1888. He was the son of Thomas A. and Ella (Hallum) Maney. His education was received in the public schools of Minneapolis, and at the University of Minnesota (Minneapolis), from which institution he was graduated with the degree of Civil Engineer in 1911.

In 1912 he was appointed to a research fellowship in theoretical and applied mechanics at the University of Illinois in Urbana, receiving the degree of Master of Science in 1914. As a student, Mr. Maney early displayed the marked originality of thought and deep interest in research which were to become such outstanding characteristics of his later professional career.

Mr. Maney began his long career in teaching as instructor in structural engineering at the University of Minnesota in 1914. He was promoted to assistant professor in 1921, and to associate professor in 1926. His work at the University of Minnesota was interrupted by World War I, during which, while on leave from the university, he performed outstanding services—first as special analyst from the Forest Products Laboratory investigating stresses in aeroplane propellers, and later as engineer in charge of the analyses and design of the frame sections of concrete ships for the Emergency Fleet Corporation, United States Shipping Board. In the summer of 1918 he enlisted in the United States Army rising to the rank of Second Lieutenant before his discharge at the end of the war.

---

[1] Memoir prepared by M. B. Lagaard, M. ASCE, with the cooperation of J. I. Parcel, L. T. Wyly, and Alvin S. Cutler, Members, ASCE.

In 1927 he accepted the appointment as professor of civil engineering at Northwestern University in Evanston, Ill., becoming administrative chairman of the School of Engineering in 1936. He contributed largely to the remarkable growth of the school, and, when the new technological institute was established in 1939, he became chairman of the Department of Civil Engineering, a position he held until his death.

Professor Maney's career in engineering practice was as interesting as his teaching career. In 1919 he designed a 10,000-ton floating and lifting dry dock for the United States Navy in competition with twelve other structural engineers. His design won the competition, but, because of the passing of the war emergency, the project never was built.

He served as special consultant to L. R. Whitson, architect, in 1920 on the design of the eighteen-story First Mortgage Building in El Paso, Tex. In 1923 he again acted as consultant to Mr. Whitson on the design and construction of the $4,000,000 Santa Fe Terminal Building in Dallas, Tex. At the time of its construction this twenty-one story structure was the tallest reinforced concrete building in the United States. Acting as consulting engineer to the Minneapolis Bridge Company, Professor Maney prepared the design for the $750,000 continuous truss highway bridge over the Mississippi River at Savanna, Ill., in 1931.

In 1939 he undertook the extraordinarily difficult and unusual assignment of designing an eight-story building to be placed on top of an existing building (which had already been increased from four to six stories), and which had to be constructed while the building underneath was occupied, and without making any use of the original foundation; Mr. Whitson was the architect. Professor Maney organized a group of engineers in 1933, with L. T. Wyly, M. ASCE, as principal associate, known as G. A. Maney and Associates. This group promoted and designed an $8,500,000 highway bridge over the Mississippi River connecting Missouri Avenue in East St. Louis (Ill.) with Franklin Avenue in St. Louis (Mo.). Construction of this project was begun after his death under the direction of this group as joint engineers and with C. P. Hazelet, M. ASCE, and Ingolf Erdal, as executive officials.

His contributions to research in the field of structural engineering were many and varied. His first publication[2] was an outstanding contribution and has become widely known in the profession as "Maney's Method." In 1915 Professor Maney made perhaps his greatest contribution to the theory of structures, and one which was to win for him international recognition when he presented to the profession the slope-deflection method.[3] Although the slope-deflection equation had been developed by O. Mohr in 1892 and applied extensively to the analysis of secondary stresses by European engineeers, no other use of the principle appears to have been made and it was practically unknown to American engineers.

---

[2] "Relations Between Deformation and Deflection in Reinforced Concrete Beams," by G. A. Maney, *Proceedings*, A.S.T.M., 1914.

The Maney presentation included: (1) A method of successive approximations for the secondary stress problem; (2) a rational solution of the wind stress problem of a building frame; and (3) a general solution for the rigid frame with loads applied between the joints. This presentation of the slope-deflection method was thus the first of the so-called "modern" methods of rigid frame analysis. It opened the door for the remarkable development which has since occurred in this field. It is worthy of note that Professor Maney developed the slope-deflection theory independently, without any knowledge of prior work, while a research fellow at the University of Illinois in 1913–1914.

Also, in 1915, he published, in collaboration with W. M. Wilson, M. ASCE, the first successful attempt to analyze rationally and in numerical terms a large building frame.[4] This treatment became a classic in the field. In 1922 Professor Maney, in collaboration with John I. Parcel, M. ASCE, published the results of an analytical and experimental study of the secondary stresses in a 512-foot riveted railway bridge.[5] This investigation was the first to reveal and explain the serious discrepancy which exists between actual secondary stresses occurring in practice in a large bridge and the computed stresses obtained by the conventional analysis.

In 1926 Professor Maney published in collaboration with John I. Parcel a textbook on indeterminate structures, which achieved a place as one of the standard treatises on the subject.[6] During the period from 1929 to 1931, Professor Maney published an important series of articles on shrinkage and plastic flow in concrete in the magazine *Engineering and Contracting.* These studies, which he continued for the next ten years, brought out the fact that shrinkage was predominant in producing compressive stresses in the reinforcing steel and in causing increased deflections in beams and slabs under working loads. The results were published in 1940[7] in a joint article with M. B. Lagaard, M. ASCE, and again in 1941.[8]

He prepared in 1932 (in collaboration with John E. Goldberg, Assoc. M. ASCE) a remarkable simplified approximate solution of building frames by the slope-deflection method.[9] This paper presented for the first time the one and one-half cycle procedure. In 1936 Profeson Maney received the Wason Medal from the American Concrete Institute for his paper on "The Analysis of the Multiple Rigid Frame Bridge by the Slope-Deflection Method."

[7] "Stress Increases in Compressive Steel Under Constant Load Caused by Shrinkage," by G. A. Maney and M. B. Lagaard, *Proceedings,* A.C.I., June, 1940.

[8] "Studies in Engineering, No. 1," by G. A. Maney and M. B. Lagaard, Northwestern Technological Inst., Evanston, Ill., 1941.

[9] "Simplified Methods for the Analysis of Multiple Joint Rigid Frames," by G. A. Maney and John E. Goldberg, *Northwestern University Bulletin,* Vol. XXXIII, No. 7, October 7, 1932.

During the World War II emergency Professor Maney undertook a comprehensive series of investigations for the War Production Board including: (*a*) A new type of pre-cast reinforced concrete arch for airplane hangers; (*b*) a reinforced concrete barge with a continuous metal seal for watertightness; (*c*) the use of wood fiber as a filler for cement; (*d*) pre-stressed spirally reinforced concrete columns (with M. B. Lagaard); and (*e*) an independent rail-supporting reinforced concrete railroad tie (with H. A. LaRoy). He also carried on (with L. T. Wyly) an extensive investigation of riveted joints for the National Advisory Committee for Aeronautics.[10]

The failure of the Tacoma Narrows Bridge in Washington aroused Professor Maney's interest in the problem of preventing the vibration of suspension bridges under wind loads. His solution of the problem was to introduce diagonal cable members under dead load tension; laboratory models which he built indicated that a ninety per cent reduction in the vibration was effected. The results of his study were presented in addresses to the Western Society of Engineers in 1941 and aroused very wide interest.[11] During the last two years of his life Professor Maney's principal research interest was concentrated on an investigation with L. T. Wyly of the fatigue of riveted and bolted joints.[12] He was one of the men who made up the original group which developed into the Rivet and Bolt Research Foundation.

In 1946 Professor Maney suffered a very serious illness from which he never entirely recovered. He died at the Evanston Hospital, in Evanston, on May 10, 1947.

He possessed one of the most brilliant and original minds in the profession and during his entire professional life he devoted himself to research and development in his technical field with a zeal and single-mindedness rarely equaled. His untimely death when at the peak of his career was a tragic loss to the profession. On the personal side, his wide range of interests, keen sense of humor, and capacity for good fellowship won him a large circle of friends.

Professor Maney was married on April 7, 1920, to Mabelle O. Draxton. His widow and two children, Thomas D. and Elizabeth K., survive him.

He was a member of Tau Beta Pi, Sigma Xi, the American Railway Engineering Association, the American Concrete Institute, the Western Society of Engineers, the American Society for Engineering Education, the American Association of University Professors, and the University Club of Evanston.

Professor Maney was elected a Member of the American Society of Civil Engineers on March 5, 1928.

WAYNE DICKSON MAXWELL, M. ASCE[1]

DIED FEBRUARY 2, 1947

Wayne Dickson Maxwell was born in Prescott, Iowa, on August 18, 1881. He was the son of Benjamin N. and Lucy (Simmons) Maxwell.

He attended the public schools at Prescott, and Des Moines (Iowa) and was graduated from East High School in Des Moines, in 1899. Mr. Maxwell received the degree of Bachelor of Civil Engineering in 1906, from Iowa State College in Ames. He earned the professional degree of Civil Engineer from the same school in 1911, after five years of engineering work; during the last three years of this period, he was office engineer in the engineering department of the City of Des Moines, where he remained until 1913. His outstanding piece of work was designing the Walnut Street Bridge over the Des Moines River, and the supervision of its construction. This bridge, which bears his name on a bronze plate, is one of the main downtown bridges, and it is in constant use.

During the period from 1913 to 1925, Mr. Maxwell was county engineer of Sac County, Iowa, and was in direct charge of construction and maintenance on bridges, drainage structures, and one hundred and fifty miles of county and primary road. From 1920 to 1925, he managed much of the road administration of Sac County; and in the capacity of county drainage engineer, he was active in reclaiming marshlands for agricultural purposes, an activity of high priority during World War I.

Following his administration as county engineer of Sac County, he was made secretary of the Associated Pennsylvania Constructors (State Constructors' Association, State Branch of the Associated General Contractors of America). This position was most interesting to Mr. Maxwell since in his office management he continually handled road contractors' problems. It was a subject with which he was well qualified to deal because of his broad experience and technical training in such matters. He held this position until December, 1933.

Mr. Maxwell moved to Greeley, Colo., in December, 1933. He was connected with many projects in the Rocky Mountain region, on which he served as superintendent of construction for structural steel projects, concrete foundations, and the sewage treatment plant in Windsor, Colo. He was representative for Greeley, a city of eighteen thousand persons, on construction of the sewage treatment plant there.

In the early years of World War II, he engaged in defense work; first, as utilities engineer on the new unit constructed at Fort Francis E. Warren in Cheyenne, Wyo., and later in the same capacity at the Denver (Colo.) ordnance plant in Denver. During his residence in Greeley, Mr. Maxwell was also engaged in consulting and general engineering work, and he was always keenly interested in civic affairs, doing much to further sound engineering development.

---

[1] Memoir prepared by Carl A. Gould, Regional Engr., U. S. Forest Service, Denver, Colo.

His hobby was reading literature of varied subject matter—fiction, history, travel, and technical studies. He was a member of the United Presbyterian Church, and attended services regularly as long as his health permitted.

In 1910, Mr. Maxwell was married to Elizabeth Taylor in Chicago, Ill. He is survived by his widow and a daughter, Jean Elinor.

Mr. Maxwell was elected an Associate Member of the American Society of Civil Engineers on November 12, 1913, and a Member on December 4, 1922.

THOMAS MERO McCLURE, M. ASCE[1]

Died November 5, 1946

Thomas Mero McClure, the son of John T. and Clara (Webster) McClure, was born on July 21, 1895, at Beaver City, Nebr. The family moved to Roswell, N. Mex., in 1908, where they established a permanent home. His father was a leading lawyer of that city, holding the office of district judge for many years.

Mr. McClure completed his preliminary education in Roswell and attended the New Mexico Military Institute there; he was graduated in 1914. He entered Iowa State College in Ames as an engineering student and later transferred to the University of Kansas at Lawrence. His education was interrupted in 1917 when he entered the army as a Second Lieutenant and served with the 91st and 89th divisions; he spent a year in France with the 342d Machine Gun Battalion, engaging in the Meuse-Argonne and St. Mihiel offensives.

After his discharge, he went to work for the Saint Louis and San Francisco Railroad Company in Texas as an instrumentman and chief of party. In 1922 he was appointed project engineer for the State Highway Department of New Mexico. Returning to Texas in 1926, he worked for five years with the Missouri Pacific Railroad Company as assistant division engineer. From 1931 to 1933 he again worked with the New Mexico highway department as location engineer and assistant district engineer.

In 1925 the State of New Mexico entered into a cooperative agreement with the United States Geological Survey to make a comprehensive investigation of the Roswell artesian basin, whose water supply for irrigation uses was seriously threatened by overdeveloped and extensive losses from the uncontrolled flows of leaking, abandoned wells. During 1925 and 1926 Mr. McClure participated in the basin study and it was during this time that he first became actively interested in the conservation and utilization of ground waters.

---

[1] Memoir prepared by a Committee of the New Mexico Section consisting of John H. Bliss, M. ASCE, Chairman, Berkeley Johnson, M. ASCE, and Rufus H. Carter, Jr., Assoc. M. ASCE.

On September 7, 1933, Mr. McClure was appointed state engineer of New Mexico and served continuously in that position until his death. As state engineer he had jurisdiction of the public waters of the state; in this capacity he proved himself a thorough and capable administrator. He spent considerable time in the administration of the state underground water law which became effective in 1931. His pioneer work in the administration of this law and the promulgation of rules and regulations for the equitable application of water right principles in this relatively new and untried field stands as a monument to his keen insight and thorough understanding of the problems involved. The New Mexico underground water code has become a standard which several western states have consulted liberally in drafting their ground-water laws.

In 1936 he served as president of the Association of Western State Engineers. Becoming an active member of the association in 1933, Mr. McClure worked consistently toward a better understanding between states and a coordinated approach to the solution of their mutual water problems. In 1934 and 1935 he served as vice-president for New Mexico in the National Rivers and Harbors Congress. He was secretary of the State Planning Board and a member of the State Flood Commission as well as the National Reclamation Association. Mr. McClure was the first secretary of the State Board of Registration for Professional Engineers and Land Surveyors, a position he held at his death.

The legislature created in 1935 the Interstate Stream Commission of which Mr. McClure, as state engineer, was ex officio secretary. The commission was formed for the purpose of negotiating interstate stream compacts, matching congressional appropriations for cooperative investigations, instituting legal proceedings in interstate stream controversies, and doing everything necessary in the conservation and development of these waters. In connection with his duties as secretary of the commission Mr. McClure took an active part in the supreme court suit brought by the State of Texas against the State of New Mexico over the use of the waters of the Rio Grande within the Middle Rio Grande Conservancy District. This suit was not settled in the courts, but led directly to negotiations between the states of Colorado, New Mexico, and Texas, looking toward an equitable allocation of the waters of the Rio Grande among the three states. Mr. McClure served as New Mexico's commissioner on these negotiations which culminated in the drafting and final adoption of the Rio Grande Compact on May 31, 1939.

He served as commissioner on the Costilla Creek Compact negotiations, a compact agreement being approved by the states of Colorado and New Mexico, which was signed in 1946 by the Hon. Harry S. Truman, President of the United States. Mr. McClure was also commissioner for New Mexico on the Pecos River negotiations, which were interrupted by his untimely death. As secretary of the Interstate Stream Commission he was intimately connected with the Colorado River problems and assisted in the negotiations leading to the Boulder Canyon Adjustment Act, as well as the drafting of the treaty with Mexico. He was appointed by the Hon. John J. Dempsey, Governor of New Mexico, in August, 1946, to represent the state in discussions looking toward an equitable allocation of the waters of the Colorado River Basin above Lee Ferry (Ariz.) among the upper basin states.

During the last days of October, 1946, Mr. McClure was attending a four-day series of basin meetings of the Upper Colorado River Compact Commission. The party had driven to Farmington, N. Mex., the afternoon of November 1, where the last of the meetings was to be held the following day. Mr. McClure suffered a heart attack that evening and succumbed the morning of November 5.

As a past-president and prominent member of the New Mexico Section of the Society, Mr. McClure was being sponsored as a candidate for Director of the national organization at his death. He was one of the leading figures in the local and state organizations of the American Legion and the Forty and Eight, holding a number of posts in those organizations: Post Commander of the Montoya y Montoya, Post No. 1, in 1942; Grande Chef de Gare of the state organization of the Forty and Eight (1944–1945); and a member of the National Executive Committee in 1946. He was a member of the Theta Xi fraternity. In addition to these activities Mr. McClure found time to make stamps his hobby, specializing in United States issues; a stranger needed no better introduction than an expressed interest in philately.

Mr. McClure possessed a high degree of ability as an engineer and was a loyal, faithful advocate of protecting and conserving the rights of New Mexico in its waters. He possessed the character, courage, integrity, and tenacity of purpose which inspired respect and confidence in all with whom he came in contact. He has long been regarded as one of the outstanding engineers and reclamation authorities in the west. He has been truly a faithful servant of the people of New Mexico.

The following editorial, appearing in the November 6, 1946, edition of the *Santa Fe New Mexican,* aptly describes the feelings he inspired among his co-workers:

> "With the death of Thomas M. McClure, New Mexico has lost an able public servant and many a person has lost a valued friend. Tom McClure was a man of courage, integrity and intelligence. He would never hedge on a question; everyone always knew precisely where he stood and why. He was a respected antagonist in an argument, but never let a mere argument interfere with a friendship.
>
> "His State Engineer's office was remarkably free from politics, because Tom McClure placed the welfare of the state before that of his party or himself. Even the knowledge of his precarious health for several years could not diminish his energy and his interest in his work. He died with his boots on, doing the work he loved and knew best. There are never many men in the world like Tom McClure. He will be missed."

Mr. McClure was married on May 22, 1926, in Santa Fe, to Margaret L. Murphy of Waterloo, Iowa. He is survived by his widow, a daughter, Margaret Jean, and a sister, Gretchen, of Long Beach, Calif.

Mr. McClure was elected an Associate Member of the American Society of Civil Engineers on May 13, 1935, and a Member on November 14, 1938.

ROBERT LEE McCORMICK, M. ASCE[1]

Died April 10, 1947

Robert Lee McCormick, the son of Leander C. and Katherine (Gwynne) McCormick, was born at Charlestown, Clark County, Ind., on January 12, 1867. His boyhood was spent on a small Indiana farm. After he was graduated from the local high school, he entered Franklin College at Franklin, Ind., where his interest in mathematics was awakened.

Before completing work for a degree at Franklin, he transferred first to Indiana University at Bloomington, and then to Rose Polytechnic Institute in Terre Haute, Ind., to study civil engineering. At Rose Mr. McCormick came under the influence of Malverd A. Howe,[2] M. ASCE, and developed a major interest in structural engineering. He was graduated in June, 1891, with the highest academic record in his class, for which he received the Hemingway Medal.

On being graduated, Mr. McCormick accepted an appointment to the staff at Rose as instructor in mathematics and civil engineering. He remained at Rose for forty-six years, being, successively, instructor and assistant professor of mathematics and civil engineering and, finally, professor of civil engineering. He retired in 1937 at the age of seventy. During his long term at Rose, he contributed to the development of the character of many outstanding engineers and left a lasting impression on those who passed through his classes as students. He was popular with the Rose alumni as well; this was evidenced by the fact that they elected him president of the alumni association for several terms.

Professor McCormick engaged in numerous professional undertakings in addition to his teaching. At the turn of this century he assisted Professor Howe in the design and construction of the Wabash Avenue Bridge across the Wabash River at Terre Haute. For many years, too, he engaged in mine surveying for the numerous coal mine operations in the vicinity of Terre Haute. After his retirement, he moved to Brazil, Ind., and served as county surveyor for several terms. He had refused to run again for this office shortly before his death.

He was a member of several professional and scientific societies; among these were the American Railway Engineering Association, the American Association of University Professors, the American Society for Engineering Education, the American Association of Professional Engineers, the Indiana Engineering Society, and the Tau Beta Pi fraternity. Also, he was a member of the Student Chapter Committee of the Society in 1933 and a member of the first Indiana Board of Registration for Professional Engineers and Land Surveyors in 1921, serving as its first chairman. Professor McCormick was a member of the Terre Haute Lodge No. 86 of the Benevolent and Protective Order of Elks until his retirement from Rose in 1937, after which he transferred his membership to the Brazil lodge.

---

[1] Memoir prepared by R. E. Hutchins, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 106, 1941, p. 1599.

He was married to Floy Maguire of Kansas on December 24, 1894. His widow and two sons, Bruce R. and Francis, survive him.

Professor McCormick was elected a Member of the American Society of Civil Engineers on December 14, 1925.

WILLIAM NAYLOR McDONALD, M. ASCE[1]

Died January 6, 1947

William Naylor McDonald was born at Cool Springs, Clarke County, Va., on May 27, 1868. He was a nephew of the late Hunter McDonald, Past-President and Hon. M. ASCE, who was for many years chief engineer of the Nashville, Chattanooga and St. Louis Railway in Nashville, Tenn. As a young man, William McDonald had considerable experience in railroad work in and near Nashville.

His first experience, when he was in his "teens," was office work in Louisville, Ky., in 1887. For a year, in 1888, he was with the maintenance of way department of the Louisville and Nashville Railroad Company at Hopkinsville, Ky. Feeling the need of further training, he spent a year as a student at the University of Virginia in Charlottesville, after which he was reemployed by the railroad company as a draftsman and inspector of masonry. For a few months in 1890 he was assistant engineer on bridge masonry for the Pine Mountain Iron and Coal Company in Pineville, Ky. Beginning in May, 1890, and for eight years, he served on the engineering staff of the Nashville, Chattanooga and St. Louis Railway on surveying and construction work which included depots and yards with shop buildings. Much of the work was in or near the Clay Street yard in Nashville.

Responding to the patriotic call for service during the Spanish-American War, he joined the Second Regiment, Louisiana Volunteer Infantry, in June, 1898. Within five months he was promoted to Second Lieutenant, in which capacity he served until he was mustered out in April, 1899. After an introduction to Cuba, he spent the next few years in the government engineering service on the island. Until the end of 1902 he was assistant engineer and superintendent in the Department of Streets at Havana. This government service placed him in charge of all street work, including some surveys and the establishment of street grades. He supervised the building of the celebrated Malecon sea wall and drive. Under his plans and specifications about $7,000,000 worth of work was laid out—$4,000,000 worth of which was finished. The new paving system was started after the United States government relinquished control.

---

[1] **Memoir prepared by Robert M. Angas, M. ASCE.**

Mr. McDonald then returned to Nashville and in 1903 and 1904 served as chief engineer of the Tennessee Central Railroad Company. Feeling the urge to undertake construction work as a business, however, he left Nashville, and spent the remainder of his life in Florida. For twenty-one years, from 1905 to 1925, inclusive, he was continuously in the contracting business, except for a period of service in World War I. Prior to the war this work consisted largely of erection of concrete and reinforced concrete buildings, bridges, and dams. His war service comprised the latter half of 1918, following receipt of a commission as Captain of Engineers in the United States Army. Continuing his contracting work during the years from 1919 to 1925, he was engaged largely on construction of concrete highways and bridges at a total cost of about $2,000,000.

The development of real estate in Florida then attracted Mr. McDonald's attention. During 1926 and 1927, he was chief engineer for the D. P. Davis Properties—including Davis Shores in St. Augustine, Fla. The work consisted of design and construction at an estimated cost of $3,000,000. Then for two years, 1928–1929, he was city manager of St. Augustine. In 1930–1931 he served as engineer in charge of drainage work for J. L. Ketterlinus. His next engagement was at the close of 1933 and during most of 1934 when he was engineer in charge of the design and construction of the sea wall at Jacksonville Beach, Fla. This was a Works Progress Administration project, costing approximately $130,000, and he designed and constructed a reinforced concrete sheet pile bulkhead to protect the waterfront.

With the approach of ill health, Mr. McDonald went into virtual retirement. He purchased a small farm near the village of Hogan, Fla., where he devoted his time to raising Satsuma oranges and gladiolus bulbs.

During his residence in Nashville, Mr. McDonald was married to Emma Hicks on December 10, 1900. They had one daughter, Catherine, who was born in October, 1901; she died on December 6, 1927. Mrs. McDonald died in 1946 and from that time until his death Mr. McDonald lived with his sister, Mrs. Nannie Eustaphieve, in Jacksonville. He is survived by Mrs. Eustaphieve and three other sisters—Mrs. Bayard Stevens and Catherine Powell McDonald, both of Washington, D. C., and Mrs. W. E. Suddath, of Warrenburg, Mo.; also, by a brother, Hugh M. McDonald, of Gloversville, N. Y.

Besides the Society, Mr. McDonald was a member of the Society of American Military Engineers and the Florida Engineering Society. He also was a member of St. Marks Episcopal Church in Jacksonville.

Mr. McDonald was elected a Member of the American Society of Civil Engineers on September 3, 1902.

BENJAMIN McKEEN, M. ASCE[1]

DIED DECEMBER 16, 1947

Benjamin McKeen was born at Terre Haute, Ind., on Jauary 29, 1864. He was the son of William Riley and Ann (Crawford) McKeen.

His father was a prominent financier and railroad executive, who was head of the McKeen National Bank and directed the affairs of the Vandalia Railroad Company before and after it became a part of the Pennsylvania Railroad System.

Mr. McKeen enrolled at Worcester Polytechnic Institute (Worcester, Mass.) and when Rose Polytechnic Institute (Terre Haute) opened its doors, he entered as a junior and completed his technical education; he was graduated with a degree in mechanical engineering in 1885, with the first class.

In September, 1885, he entered railroad service as draftsman in the office of the superintendent of motive power and machinery of the Terre Haute and Indianapolis Railroad Company (later included in the Pennsylvania System). He later served as rodman in the engineering department and in April, 1886, was appointed resident engineer on the work of cutting down the Rockville grade on the Logansport (Ind.) division of that railroad. On January 1, 1887, he was appointed engineer, maintenance of way, of the Logansport division, and in 1889 was chief engineer on completion of the Indiana and Lake Michigan Railroad Company lines, in addition to being engineer, maintenance of way, of the Logansport division.

On August 1, 1892, Mr. McKeen was transferred to the Peoria (Ill.) division as engineer, maintenance of way, and, on January 5, 1894, he was advanced to the position of superintendent of that division.

Mr. McKeen was appointed superintendent of the main line division of the Vandalia Railroad on June 10, 1901, and, on April 1, 1902, he became superintendent of the Chicago (Ill.) terminal division of the Pennsylvania Lines West of Pittsburgh (Pa.). This transferred his residence to Chicago. He was further advanced on December 15, 1903, to the position of general manager of the Vandalia line with an office at St. Louis, Mo. Ten years later he was appointed general manager of the Pennsylvania Lines West of Pittsburgh, and was vice-president of this railroad from 1917 to 1920 and vice-president of the southwestern region from 1920 to June 1, 1925, when he was made a vice-president of the Pennsylvania Railroad System. He retired as vice-president on February 1, 1934, on reaching the age of seventy.

All railroad officers and employees who served with Mr. McKeen held the highest respect and esteem for him. He was a man who, even under the most trying conditions, always maintained his equanimity, and was an inspiration to all the men who served under him.

Mr. McKeen was the first president of the alumni association of Rose Polytechnic Institute. He was a director of the Mississippi Valley Trust

---

[1] Memoir prepared by W. S. Hanley, Assoc. M. ASCE.

Company and was a member of the St. Louis Country Club and the Noonday Club. He belonged to the Episcopal Church, and in politics was a Republican.

On October 20, 1891, he was married to Anna Strong, daughter of Joseph Strong of Terre Haute. Surviving are an only daughter, Mary Josephine (Mrs. Neal Creighton) of La Jolla, Calif.; a grandson, Thomas Niedringhaus of St. Louis, who made his home with Mr. McKeen; and a granddaughter, Mrs. Mary Kaiser, and a nephew, William R. McKeen—both of Terre Haute.

Mr. McKeen was elected a Member of the American Society of Civil Engineers on November 6, 1895. He became a Life Member in January, 1930.

JOHN THOMAS LAMAR McNEW, M. ASCE[1]

Died December 21, 1946

John Thomas Lamar McNew, known affectionately as "Mac" by his many close friends and respectfully as "Mr. Mac" by all his students, was called to his final reward as he neared the peak of his profession as an educator. When stricken with his last illness, he was filling the newly created office of Vice-President of Engineering at the Agricultural and Mechanical College of Texas at College Station.

He was born in Belcherville, Tex., on January 20, 1895. He was the only son and the older of two children of Edgar O. and Sarah E. (Taylor) McNew. John Thomas Lamar and his sister, Vera, each elected to become teachers, a profession in which both parents served.

The McNew ancestors were Scots, descendants of that part of the ancient clan of McNew which had migrated from Scotland to Northern Ireland several generations before the colonial McNews settled in the United States in Washington County, Virginia. The McNew family was well established in Virginia by 1879 and was called "Scotch-Irish" by the other residents of the area, a term used to indicate that its members were Scots from Ireland instead of people of mixed Scotch and Irish heritage.

Edgar O. McNew had a long career as an educator in Texas. His professional life included many years as a classroom teacher in several public school systems in the state and twenty-three years as superintendent of the Independent School District of Mineral Wells, Tex. He loved children and was in turn beloved by all his pupils. He taught for the love of teaching and appreciated his responsibility in guiding young lives. Young Lamar, as John Thomas Lamar was called in his youth, was his father's most ardent admirer and he adopted as his own the wise and canny philosophy of life and rules of personal conduct so ably taught and exemplified by his dad.

Lamar received his high school education and training in Mineral Wells. He was graduated from high school in 1912 and in the fall of that year entered the University of Texas at Austin where he enrolled for the civil engineering course. He spent two school years as a student; then he decided that he wanted to work. During the fourteen months spent in the service of the Wells Fargo Express Company as an express trainman his desire to become a civil engineer crystallized and he acquired the ambition to attend Texas A. and M. With this in mind he announced his wish to become a student again and his father told him that he might return to college if he could save fifty dollars in the very short time remaining before the opening of the fall semester. Lamar's determination plus his native Scotch thrift and business acumen in a quick sale of some of his wearing apparel combined to produce the stipulated amount, so he matriculated in the class of 1918 at A. and M.

---

[1] Memoir prepared by O. H. Koch and J. H. Bringhurst, Members, ASCE.

Mr. McNew spent the two years prior to the entry of the United States into World War I in school and worked at his profession during the summer months. His education was interrupted when he was drafted into the Army in October, 1917. However, he returned to A. and M. after his discharge in 1919 and received the degree of Bachelor of Science in Civil Engineering in 1920, and that of Master of Science in Civil Engineering in 1926. The Iowa State College of Agriculture and Mechanical Arts at Ames conferred upon him the degree of Civil Engineer in 1925.

One of his professors on the civil engineering faculty at A. and M. wrote the following description of him, as a college student:

> "I had Lamar as a student in practically every class I taught. I learned to hold him in very high esteem for his sincerity, his enthusiasm as a student, depth of thinking, high personal and professional idealism, deep sense of fairness, inherent friendliness, intellectual curiosity and well balanced sense of humor.
>
> "Mac was a quiet young man who evidently believed in thinking through a proposition before explaining his opinion.
>
> "In short, J. T. L. McNew was the kind of student that a teacher wishes he might have in every class. He was always responsive to intellectual stimulation, cheerful in attitude, vigorous in effort, analytical in thought, kind in sprit and gentlemanly in conduct."

Mr. McNew's first actual contact with engineering work in the field occurred during the summer vacation of 1917, at which time he accepted a position with the Strawn Coal Mining Company of Strawn, Tex., as engineer in charge of surveying, mapping, and layout for two mines.

When he was inducted into the United States Army in the fall of 1917, he spent seven months at Camp Travis in San Antonio, Tex., before he was admitted to the Fourth Officer Candidates' Training School at Camp Lee in Petersburg, Va. He was commissioned a Second Lieutenant on May 25, 1918, and was assigned to Company A, 113th Engineers at Camp Shelby in Hattiesburg, Miss. In September, 1918, Lieutenant McNew was sent overseas and was placed in charge of road construction and maintenance in France until the armistice. After hostilities ceased, he was charged with the operation and maintenance of 540 miles of highway in his division area in the Army of Occupation in Germany.

On his honorable discharge from the armed service in July, 1919, he accepted a position as foreman on construction of concrete road paving and structures. In September, 1919, he resigned this position in order to return to college for his last year's work toward his undergraduate degree.

During the Christmas vacation of his junior year at Texas A. and M. Mr. McNew met and fell in love with Edna E. Murphy who was teaching at Graford, Tex., a town near Mineral Wells. This romance had developed to the engagement stage, duly sealed with the solitaire, by the time he resumed his civilian status in 1919. On May 27, 1920, the day after commencement, the two were married and went to Beaumont, Tex., where Mr. McNew had accepted his first assignment as a graduate engineer, a position with the City of Beaumont as assistant city engineer on paving work.

In the fall of 1920 Mr. McNew joined the staff of the civil engineering department of his alma mater, beginning his career as an educator with the title of instructor. On December 1, 1921, he was appointed assistant professor in civil engineering; on September 1, 1924, he was made associate professor in civil engineering; on September 1, 1925, he was named professor of highway engineering; and on June 1, 1940, Professor McNew, after four months as acting head, became head of the civil engineering department. He held this title until February 1, 1945, when he was appointed to the newly created position and title of Vice-President of Engineering. On July 12, 1945, he was given, in addition to his other duties, the work as director of Engineering Extension Service.

During his period of service on the faculty at A. and M., Professor McNew had many opportunities for intimate contact with his students. His humane and sincere personality instilled genuine confidence in his students and attracted them to him for consultation and advice. "Mr. Mac" was the students' real friend who sought and found many ways to help those who were helping themselves secure their education. He gave them jobs in his testing laboratory, in his professional practices, and in his home. One of the very needy boys, who used to earn money taking care of the two McNew children while the parents were out in the evenings, avowed that the stipend paid for his services was negligible compared to the cost of replenishing the larder after he and "Mr. Mac" had finished their customary raid, and that "Mr. Mac" insisted that the position of "sitter" carried with it unlimited access to and enjoyment of anything eatable that could be found.

Professor McNew was primarily interested in highway construction and was a recognized authority on this subject. He realized the importance of the teacher having personal contact with the actual work in the field. He used most of his summer vacations in getting actual experience with the various phases of highway engineering construction. He spent one summer as assistant city engineer for the City of Beaumont, another summer with the county engineer of Dallas County, Texas, and other vacation periods with contractors on highway bridge and highway pavement projects throughout the state. He was district engineer for Works Project Administration

(W.P.A) of the Dallas District and state field engineer for the W.P.A. at San Antonio during parts of 1935 and 1936.

His record in Society activities reveals a genuine interest and active participation from the very beginning. In less than three years after he became a corporate member of the Society he was elected Secretary of the Texas Section. He served in this post with great credit for a period of ten years. During this time he was the spark plug of the Texas Section. His interest and aggressiveness is given credit for the unusual growth and progress of the section during that period. One of the important institutions of the Texas Section is the regular publication, *The Texas Engineer,* which was developed and edited by Secretary McNew. It became, under his regime, a real house organ with genuine personality typical of the Texas Section. His tremendous interest in the affairs of the section and his efficient method of looking after the details and arrangements of the semiannual meetings were in a great measure responsible for the continued interest of the members in the Texas Section. In recognition of his excellent services and because he had the proven qualifications of leadership, he was elected President of the Texas Section in 1938. In 1941 he was chosen to represent District No. 15 as the National Director and then was returned to the National Board in 1946 as Vice-President of Zone No. 4.

He served as a member of the Society's committees on Juniors and Local Sections and, while Vice-President, as Chairman of the Committee on Engineering Education. This last committee undertook an aggressive program working toward a plan of sponsoring the young engineering student from the beginning of his college work on through his entry into the profession. The enthusiasm, the possibilities, and the objectives of the committee's program are a reflection of his keen, sympathetic interest in the student engineers. He wrote two technical bulletins [2, 3] and miscellaneous discussions in *Proceedings* and *Transactions.*

In civic affairs Professor McNew was quite active in the work of building his home city and community. He took the lead in getting the City of College Station incorporated; he was a member of the City Planning Committee, and served for three years as city engineer. In negotiating with the city commission for this professional assignment, he suggested and received an annual fee of fifty cents claiming that his code of professional practice demanded that he receive compensation.

When the United States entered World War II officers were badly needed and the cadet corps at A. and M. was called upon to supply officer material. Many of the faculty also entered the armed forces, on leave of absence from the college. Professor McNew, although quite busy in the essential work of conducting the war training program with a reduced faculty, knew he had experience and ability in paving and roadwork that was demanded at the

[3] "Proceedings of the Fourth Annual Short Course in Highway Engineering," by J. T. L. McNew, *Technical Bulletin No. 36,* Eng. Experiment Station, Agri. and Mech. College of Texas, College Station, Tex., 1928.

front, so he presented himself to the Officer Procurement Division of the U. S. Army as a candidate for a commissioned overseas assignment. He was commissioned a Major in the Corps of Engineers in the summer of 1943 and sent first to Ft. Belvoir, Virginia, and then to Orlando, Fla., for training before going overseas.

Major McNew was forty-eight years old at this time. He had served in one world war and to him there was no glamour in the wearing of a uniform and brass buttons; no spirit of adventure called him from an honored and respected position as head of the civil engineering department and from a happy home life with a devoted wife and two fine children to seek the hardships and rigors of warfare on foreign soil. His was the deepest sense of patriotism that sent him, smiling, by plane from Houston, Tex., to the China-Burma-India (CBI) front on October 25, 1943. His wife, no less valiant a soldier than he, waved him farewell in the same assumed spirit of cheerfulness, knowing full well that long lonely months, or years, or maybe eternity, might elapse before they should meet again.

How well he served his country may be understood from the words of a fellow officer and former student:

> "I had served with Mr. Mac at Belvoir, Richmond, and again at Orlando, Florida. On my way overseas I was sitting on a bench outside the ATC operations office at Accra on the Gold Coast of Africa, when a plane landed and Mr. Mac was the first man off the plane. On arriving in India, we found ourselves together again and I was in close contact with him until his return home. General Stuart Godfrey [4 M. ASCE] (who has since been killed) leaned on the Colonel for nearly every decision that he made. Colonel McNew had accomplished wonders before his return to College."

On February 1, 1945, Professor McNew returned to A. and M. from active army duty with the rank of Lieutenant Colonel which commission he had won in the CBI area planning and supervising roads and air bases, among which were some of the first B-29 bases in China and Burma. He was immediately given the duties and title of Vice-President of Engineering, a position just created.

The teaching of good citizenship and the work of character building among his students were emphasized on every appropriate occasion, as is shown in his summary of a few of the responsibilities of an educated citizen given in Vice-President McNew's commencement address to the graduating class at A. and M. on May 25, 1945. In this category he included:

> "1. A continuing acquaintance with the current events of government.
> "2. An obligation to express a considered opinion on matters of public concern.
> "3. An obligation to vote at elections—National, State, County, City, and School.
> "4. An obligation to serve the public with your talents in an ethical way.
> "5 An obligation to make your technological skill contribute to the better living of your fellow man.

---

[4] For memoir, see *Transactions*, ASCE, Vol. 112, 1947, p. 1449.

> "6. An obligation to be an example as an all around honest, straightforward and useful part of your community and to take from it less than you contribute."

Professor McNew was a great lover of the outdoors, and he enjoyed and participated in most of the outdoor sports. He earned the coveted athletic "T" on the track team at A. and M. and in 1917 broke the state record in javelin throwing. He was also an ardent golfer, hunter, and fisherman. One of his most prized trophies was the mounted head of a marvelous specimen of white tail buck which he killed in the brush country of south Texas while hunting on the ranch of one of his college students. This buck was so large that he had to send his student host back to the ranch house for a team while he built a fire and guarded his kill for many hours.

"Mac" was a keen observer of nature and possessed a marked literary ability in describing the scenes and people encountered in his travels. The descriptions in his letters from the CBI theater of the customs and modes of living of the natives and their construction methods and equipment show not only an unusual capacity for the understanding of their problems, crude analyses, and solutions, but also a mastery of the art of writing seldom equaled by an engineer and surpassed only by the great authors.

His life work represented many and varied fields of activity. Whatever the work at hand he did it with enthusiasm and with marked success. He shone equally as a student, a teacher, a consultant, a soldier, a Society member and officer, a citizen, and finally, a husband and father. The profession needs more men like Professor McNew. In Society affairs and especially in its Texas activities he will be sorely missed.

He is survived by his widow and by two children, Elizabeth (Mrs. Don Dale Little) and J. T. L. McNew, Jr.

Professor McNew was elected an Associate Member of the American Society of Civil Engineers on February 25, 1924, and a Member on October 7, 1929.

RUDOLPH PHILIP MILLER, M. ASCE[1]

DIED JANUARY 18, 1947

At this time of uncurbed condemnation of building codes, it is significantly pertinent to record the accomplishments of a long and faithful professional career devoted to the improvement and administration of progressive and equitable building laws. With the death of Rudolph P. Miller the building industry and the profession lost an outstanding engineer who gave his time and ability unreservedly to the promotion of fire-safe and economical building. As a staunch advocate of freedom in the application of new developments and methods of construction, without sacrifice of safety to life and property, he won the fitting title of "dean of building codes." His unswerving conviction of right and his resolute will power, which were tempered by an innate modesty and charm of manner, won for him the admiration and the esteem of his associates. His integrity and professional accomplishments well deserved the high honors which were conferred upon him by the public and the profession.

---

[1] **Memoir prepared by George E. Strehan, M. ASCE.**

Rudolph Philip Miller was born in New York, N. Y., on July 5, 1866, the seventh of thirteen children. His parents were Anton William and Matilda (Schmahl) Miller. The door of the hospitable Miller home on Madison Street was always open, and it gave entry to the wholesome family surroundings in which he grew to manhood. A love and an appreciation of music were fostered in the frequent home gatherings of family and friends who spent evenings in good cheer and fellowship. This early training in art was supplemented by a deep interest in the natural sciences, which subsequently led to an application, with four other friends, for membership and eventual admission into the Agassiz Association as Chapter No. 87.

After initial private schooling, at ten years of age he entered Public School No. 34 from which he was graduated in 1880. In 1885 he received the degree of Bachelor of Science from the College of the City of New York. His postgraduate studies were pursued in the School of Mines at Columbia University in New York, leading to the degree of Civil Engineer in 1888, and later to the honorary degree of Master of Science.

After graduation Mr. Miller was engaged for six years in railroad construction and operation. First, he was connected with the Richmond and Danville Railroad (later the Southern Railway Company) as assistant engineer and supervisor of track, laying out and superintending the erection of bridges, culverts, station buildings, and shops, including the replacement of fourteen Howe trusses with new steel bridges. Later, he became supervisor in charge of maintenance of one hundred and nineteen miles of main line and three terminal railroad yards. Subsequently, he served as engineer on the location and construction of the Montauk Extension of the Long Island Railroad Company. In 1895 he undertook public service work for the City of New York, successively, holding the positions of special inspector, plan examiner, and assistant engineer in the department of buildings; and from 1901 to 1905 he held the post of chief engineer, supervising methods of construction and planning and directing tests for new materials, in addition to developing new forms of building construction.

As chief engineer of the department of buildings, Mr. Miller collaborated with Prof. Ira H. Woolson of the Columbia University School of Engineering, undertaking an extensive investigation of fireproof building construction. The test standards and practices developed by them in the first decade of the century established the basis for fire-resistive requirements and procedures which later became standard practice. This work led, in 1912, to the printing of a report and graphical tabulation of test results of various types of fireproof floor systems.[2] Those records are an important and rare contribution to the literature concerning fire-resistive materials and assemblies for building construction. In 1905 he also promulgated for New York the first rules governing reinforced concrete construction which established the basis for design of that material and which became a model for similar regulations throughout the country.

---

[2] *Proceedings*, International Soc. of Testing Materials, Sixth Cong., New York, N. Y., 1912.

Beginning in 1905 Mr. Miller engaged in private practice, designing and supervising all types of building construction with special emphasis on the early development of reinforced concrete structures. He was also consulted as an expert in analyzing safety of buildings from the standpoint of fire hazard, unusual stress conditions, and adequacy of exit facilities; in the investigation of structural and fire failures; in development and testing of new materials and forms of construction; in arbitration of disputes in the building industry; and in expert testimony in court procedures. In 1907 he became a member of the General Society of Mechanics and Tradesmen of the City of New York, giving unreservedly of his time to the educational program of that institution; he served on the finance, library, and pension committees, and subsequently became president of the society in 1920.

In 1910 George McAneny, President of the Borough of Manhattan, appointed Mr. Miller superintendent of the Bureau of Buildings of the Borough of Manhattan, an office he held until March, 1914. In addition to his official duties much of his time was devoted to the formulation of progressive building legislation, the development of material standards for the American Society for Testing Materials (ASTM) of Philadelphia, Pa., and in work for the National Fire Prevention Association in the improvement of building codes and practices to insure structural, fire, and sanitary safety of buildings.

He relinquished the position of building superintendent in 1914 to accept a commission with the Board of Aldermen for the revision of the building code of New York. Two years of intensive work and close cooperation with all branches of the building industry accomplished the adoption of a new building code, which remained in force until 1938. Mr. Miller's code succeeded where thirteen prior attempts at a cost of $200,000 to the city had failed. This code was acclaimed and is still recognized as a model building regulation noted for clarity, simplicity, and efficiency. On February 8, 1916, he was tendered a testimonial dinner by the joint committee on city departments of New York and was presented with an engraved scroll and watch, certifying the honor, esteem, and respect in which he was held by the city administrative officials and representatives of the building industry.

When a group of building officials having jurisdiction over the administration of building laws in various localities throughout the United States met in New York in May, 1914, to discuss their common problems, Mr. Miller served as temporary chairman of the conference. He proposed and became the founder of the Building Officials Conference of America which was subsequently incorporated under the laws of the State of Connecticut. The objective of that organization was to strengthen the principles and practices underlying laws and ordinances for public safety and health through effective building regulations and their administration, to improve the status and civic standing of the building official, and to enable that official to do his work as it should be done. To Mr. Miller is ascribed the success of this pioneering group, which he guided through ten successive terms as president of the conference. On his retirement as president, he was elected an honorary member of the conference. At its annual convention in Detroit, Mich., in 1939, the twenty-fifth year of its existence, the conference, dedicated that meeting to "Mr. Rudolph P. Miller as a token of respect, esteem and appreciation for the invaluable counsel and guidance which he so generously and unselfishly contributed." To him is due the interest and enthusiasm which kept the organization alive through its formative years and which later culminated in the expanded scope of the Building Officials Foundation for the promulgation of a national basic building code.

In July, 1916, Mr. Miller was appointed chairman of the newly created Board of Standards and Appeals by the Hon. John Purroy Mitchell, then Mayor of New York, with the task of organizing and establishing the board's methods of procedure. The functions of that board involved the interpretation of all statutes governing building construction in New York, including the use and occupancy of buildings when difference of opinion arose between applicants and administrative officials concerning building permits, the formulation of rules to interpret and supplement the legal provisions of the building code and other statutes, the granting of variations of the provisions of the zoning ordinances, and the testing and approval of new materials. He laid the groundwork so efficiently that there has been no essential change in procedure to this day, and these practices have been followed as a guide by similar boards throughout the United States in the testing of building materials and in the administration and application of zoning laws.

In his book,[3] John P. Comer gives the following appraisal of Mr. Miller's accomplishments as chairman of the Board of Standards and Appeals:

> "The chairmanship went to Rudolph P. Miller, the able professionally-trained engineer, brought up in the Manhattan building bureau, unselfish in sharing his broad knowledge of building conditions with official superiors and laymen alike, experienced as head of the most important local building agency, and a nonpartisan servant of the people through the application of scientific principles."

This tribute is further amplified by the 1947 chairman of the Board of Standards and Appeals in its official bulletin.[4]

During World War I, Mr. Miller acted as chairman of a draft board in New York resigning to accept the appointment as consultant to the United States Housing Corporation of the War Department in Washington, D. C. In the latter capacity, he was called upon to negotiate with legislative and administrative authorities of municipalities throughout the United States for temporary suspension of building code restrictions in the interest of conservation of critical construction materials required for the war effort. With the end of hostilities, he re-entered private practice.

---

[3] "New York City Building Control—1800–1941," by John Preston Comer, Columbia Univ. Press, New York, N. Y., 1942.

[4] Bulletin of Board of Standards and Appeals-City of New York, January 28, 1947, Vol. 32, No. 4, p. 81.

In 1920, Borough President Henry Curran again appointed Mr. Miller superintendent of buildings of the Borough of Manhattan of New York, and on completion of his second incumbency, he resumed private practice in general consultation. Much of his work was devoted to the preparation and study of building codes, zoning ordinances, and fire prevention laws. New building codes were written by him for Rochester, Niagara Falls, and Pelham Manor, in New York; Stamford, Conn.; Cumberland, Md.; and Richmond, Va.; as well as the original draft of the model code for the State of Connecticut. Prentice White, administrator of the Connecticut State Housing Authority, in connection with the adoption of the state model code in 1946, writes: "It would have been very difficult if not impossible to have compiled the code without the very fine work that he did for our Authority." Mr. Miller also was the author of the 1931 Recommended Building Code of the National Board of Fire Underwriters (New York). He served in a consulting capacity on the revision of building codes for Springfield, Mass.; Ossining, Bronxville, and Scarsdale, in New York; and prepared many other municipal and state building regulations.

From 1919 until 1928 Mr. Miller represented the engineering profession on the National Board of Jurisdictional Awards in the Building Industry, serving as chairman for five years. The function of that board was to adjudicate disputes arising between unions operating in the building industry. The board, by its decisions, is accredited with untold savings in time and money through the prevention of strikes. Ernest John Russell, the architect, said:

> "Rudolph P. Miller was a worthy representative of the engineering profession on the Board. It was a feeling of confidence to me and a great pleasure to be fortunate enough to serve with him for about four years."

Ferdinand John Conrad Dresser, M. ASCE, who also served with him throughout the entire life of the National Board of Jurisdictional Awards wrote:

> "I soon became aware that because of his experience in public affairs and their relation to the building industry, Mr. Miller had acquired an understanding and a grasp of the problems in the building industry such as few men in industry possessed. This service was always given without any thought of himself and with the only consideration that these problems must be reconciled for the benefit and common good of the industry as a whole."

Herbert Hoover, Hon. M. ASCE, former President of the United States, who was then Secretary of Commerce, appointed Mr. Miller a member of the Building Code Committee of the United States Department of Commerce in 1921. He served in this capacity throughout the life of the committee and was active in urging the continuance of the work under the procedure of the American Standards Association when the committee was discontinued in 1934 and the work was transferred to the Building Code Correlating Committee of that organization. Mr. Miller represented the Society in that body;

and in 1935 he was elected chairman of the committee, a position which he held until his resignation in 1944.

Because of his unfailing interest in civic improvements, his acknowledged judgment in all matters pertaining to building laws, and his willingness to share the results of his experience, Mr. Miller's services were continually in demand and they were freely donated, without thought of pecuniary reward, to committee work of technical organizations and to the solution of all building and planning problems in the public interest. In this connection he was a member of the gypsum and other committees of the ASTM throughout his professional life. Many of the standard test specifications governing fire-resistive constructions were prepared and adopted by Committee C5 (later E5 of the ASTM) under his chairmanship. This activity was one in which he took great pride and which resulted in a widely recognized standard.[5]

In 1914 he was a member of the advisory committee for New York on the proposed recodification of the labor law, then recommended by the New York State Factory Investigating Commission. In 1919 Mr. Miller occupied the post of chairman of the Advisory Committee on Mercantile Establishments at the request of Frances Perkins, former Secretary of Labor, then Commissioner of the New York State Labor Department. From 1930 to 1940 he served on the labor departments Advisory Committee on Fireproof Construction and Fire-Resisting Materials for the Division of Industrial Codes, acting as the representative of the ASTM.

Mr. Miller in 1923 become a member of the committee on seasonal operation in the construction industries by appointment of Herbert Hoover, who was Secretary of Commerce when that committee was formed, in conjunction with the president's conference on unemployment, to study the causes of, and remedies for, ungainful seasonal employment. In 1924 he was chairman of the committee on better building of the American Construction Council by appointment of the late Franklin D. Roosevelt, and ten years afterward was elected a member of the board of governors of that body. Secretary of Commerce Robert P. Lamont appointed him in 1931 to the committee on construction of the president's conference on home building and home ownership. In 1941, the seventy-fifth anniversary of the National Board of Fire Underwriters, Mr. Miller received the award of the New York Safety Council with the citation, "For forty-five years of service in the cause of fire prevention through intelligent engineering."

Associated with numerous building industry organizations, he took an active part in the deliberations of their technical committees. Among them he served on the committee to draft specifications for fireproofing of structural steel of the American Institute of Steel Construction; the Planning Committee of the National Conference on Construction; The Fire Waste Conservation Committee of the National Federation of Construction Industries; the Charter Revision Committee and the Safety Committee of the New York Building Congress; and as chairman of the Building Laws Committee of the City of New York on the Proposed Uniform Certificate of Occupancy.

---

[5] **"Standard Methods of Fire Tests of Building Construction and Materials," A.S.T.M.** Designation C-14-41, revised 1941.

Numerous articles and papers by Mr. Miller were contributed to the technical press and he was associate editor of several handbooks.[6, 7] He frequently lectured on building codes and their application before technical gatherings and as a member of the staff of the extension school of New York University (New York).

Mr. Miller's membership in the Society dated from 1889 and in recognition of his long association the Society made him a Life Member in 1931. He was indentified with its Steel Column Committee, Reinforced Concrete Committee, and the Committee on Docks, Wharves, and Piers; he represented the Society on the Standards Council of the American Standards Association, and was chairman of the Committee on Professional Relations of the Metropolitan Section of the Society in 1924.

He was a charter member of the American Institute of Consulting Engineers (New York) and served a term as vice-president. At his death, he was an honorary member of the National Fire Protection Association, having served as vice-president from 1922 to 1924, and as president from 1924 to 1926. He helped to shape the policies of that organization as a member of the executive committee from 1913 through 1922, as president of the New York chapter of the association for three years, and as a member of the committees on building construction, city planning, zoning, and safety to life, at various times.

In 1892, Mr. Miller was married to Agnes Robinson Nelson of Stafford, Va., and through that alliance he became interested in the history of colonial Virginia and the families that played important roles in the life of those pioneer times. His genealogical studies and research in colonial history proved a source of unending pleasure and interest to him throughout life. He is survived by three children, Rudolph Nelson Miller (village engineer of Bronxville), Mary Moncure Miller, and Tillie Miller of White Plains, N. Y.

As a public official, Mr. Miller will long be remembered for his freedom from undue influence of any kind in the performance of duty. Stanley Macomber, M. ASCE, then president of the Steel Joist Institute (Washington, D. C.), in a letter written a few years ago, said, "You always stood out in my mind as the best example of a building official that we had in the United States."

A practicing builder on chance meeting remarked to him, "You were hard-boiled, but everybody got a square deal." Ernest John Russell, past-president of the American Institute of Architects (Washington, D. C.), who served with Mr. Miller on the National Board for Jurisdictional Award in the Building Industry, stated, in tribute,

> "His knowledge and experience in building problems earned the respect of the contending parties who appeared before the Board; and his opinions were of great value in formulating the decisions that were rendered by the Board."

---

[6] "Architects' and Builders' Handbook," by Thomas Nolan, Editor in Chief, 16th Ed., John Wiley & Sons, Inc., New York, N. Y.

[7] "American Civil Engineers' Pocketbook," by Mansfield Merriman, Editor in Chief, 1st Ed., John Wiley & Sons, Inc., New York, N. Y.

In bestowing the honorary degree of Master of Science in 1914, Dr. Nicholas Murray Butler of Columbia University cited Mr. Miller as "exercising a strong influence in drafting and codifying building laws." It is by such estimates that he will always be remembered as an engineer and a public servant.

Rudolph P. Miller was modest and unassuming by nature, a man who traveled quietly through life serving the community through his profession without thought of financial return or public recognition. A man of moderate means, he contributed liberally to a variety of charitable enterprises. His record of public and professional accomplishment is an enviable one.

There is no more fitting tribute to Mr. Miller than the following quotation from Mr. Comer's book:

> "If an objective appraisal of building officialdom could be presented in terms of a hero, Mr. Miller would certainly be that man, for he served in one capacity or another for over thirty years and introduced practices that tended to increase the efficiency of the bureau of buildings in its administration of the laws and regulations."

Mr. Miller was elected a Junior of the American Society of Civil Engineers on January 2, 1890; an Associate Member on April 7, 1897; and a Member on January 5, 1904. He became a Life Member in January, 1931.

CHARLES ADAM MIXER, M. ASCE[1]

DIED OCTOBER 24, 1947

Charles Adam Mixer, the son of Alfred A. and Martha (Hinkle) Mixer, was born in Hamilton, Ohio, on June 9, 1859.

Mr. Mixer obtained his first engineering job in 1883 as assistant to the city engineer of Hamilton, engaging in municipal and hydraulic work. He next turned to the field of transportation which included work on both steam and street railways. From 1883 to 1886 he was affiliated with various railroad companies as assistant engineer on location and construction. During the period from 1886 to 1888 he was employed as principal assistant engineer on the design and construction of cable roads in Cincinnati, Ohio, and in Denver, Colo., and from 1889 to 1890 he was engaged in the same capacity during the construction of the Providence (R. I.) Cable Trainway. In 1890–1891 Mr. Mixer served as assistant to the city engineer and the commissioner of public works in Providence.

With this preliminary training, he was prepared for what was to become his life work. In 1892 he was employed by the Power Company and Rumford Falls (Me.) Light and Water Company and with these companies he spent his succeeding, active professional life—covering almost half a century.

---

[1] Memoir prepared by P. W. Thomas, Engr., Rumford Falls Power Co., Rumford, Me.

After a ten-year service as resident engineer, he was advanced to the position of engineer in 1902. In 1902 the Rumford Falls Realty Company commenced a housing development, part of which is known as "Strathglass Park" and Mr. Mixer was very active in the layout and construction of these properties. In November, 1919, his title was chief engineer.

As of March, 1931, he was retired from active duty but continued his association as consulting engineer. This unusually long connection with a single organization was commemorated on the occasion of his eightieth birthday (1939) when he was the recipient of a bronze plaque signalizing his forty-seven years with the Rumford Falls Power Company.

During this long period of service Mr. Mixer had a major share in the considerable engineering, civic, and industrial progress in Rumford. He completed the accepted plans for developing Rumford Falls, an important source of power on the Androscoggin River. His subsequent work included the making of surveys and working plans for the construction, operation, and maintenance of the dams, canals, water supply system, pumping station, power station, electrical systems, and paper mills. In all instances, he supervised the construction. He was also instrumental in developing public schools, libraries, churches, and parks, particularly Chisholm Park.

One of his engineering interests had more than local importance. He originated a method of estimating the water content of snow cover, which made possible long-range forecasting of water storage probabilities and flood hazards.

In Rumford Mr. Mixer was prominent in religious and community activities. He was a charter member of the Rumford Cosmos Club, deacon of the First Baptist Church, organist for the church for forty years, and one of a committee of three to lay the cornerstone of the new church. He also served as park commissioner of Rumford. Among the national organizations he was an associate (later life member) of the American Institute of Electrical Engineers and a member of the New England Water Works Association as well as of the Franklin Institute (Philadelphia, Pa.).

After a lingering illness, Mr. Mixer died in a nursing home on October 24, 1947. He was buried from the First Baptist Church of Rumford and interred at Sunnyside Cemetery in East Rumford.

He was married twice. His first wife, Nellie M. Naughton, died in 1934. On September 24, 1942, he was married to Emma Richardson, who survives him. Also surviving are two sons, Charles N., of Livermore Falls, Me., and Alfred L., of Belmont, Mass.; two daughters, Martha L., of Newark, N. J., and Alice (Mrs. Richard Rouillard), of North Hinsdale, N. H.; five grandchildren; and two great grandchildren.

Mr. Mixer was elected a Member of the American Society of Civil Engineers on November 1, 1893. He became a Life Member in January, 1928.

ROBERT REGNAULT NACE, M. ASCE[1]

Died May 19, 1947

Robert Regnault Nace was born in Philadelphia, Pa., on August 27, 1882. His parents were Joseph R. and Eliza (Davis) Nace. He was graduated from the Northeast Manual Training School in Philadelphia in June, 1900, supplementing his studies with work at Drexel Institute of Technology, also in Philadelphia. Throughout his studies his evident interest in railroad work brought him to the early attention of his instructors and to his initial employment as rodman in the Jersey City (N. J.) office of the Pennsylvania Railroad Company. This was to form an association which lasted until his death.

His work and promotions followed the usual pattern of supervisory maintenance on the lines east of Pittsburgh, Pa., until 1914, when he was appointed supervising pilot to head and develop the field and office work of the valuation department. In 1917 his assignment was that of special duty work on the South Philadelphia improvements, a major grade crossing elimination project; and in 1919 Mr. Nace was appointed assistant engineer in the general office at Philadelphia. With the system reorganization in 1920, Mr. Nace was made engineer, maintenance of way, on the Eastern Ohio Division, later entering the transportation department as superintendent on the Schuylkill and Indianapolis divisions. He returned to the maintenance of way department as chief engineer, maintenance of way, of the New York Zone, in 1928, holding that position until his death in 1947.

Mr. Nace was a member of the Society, the Engineers' Club of Philadelphia, the Society of American Military Engineers, the Roadmasters and Maintenance of Way Association, the Metropolitan Roamers, and the Miles River Yacht Club. He held a commission as Lieutenant Commander in the United States Naval Reserve. He was a member of the F. and A. M., and an enthusiastic sportsman, spending his brief vacations boating and fishing with extended trips on the water.

To those who worked with him, the factual data of his life leave much unsaid. "Bob" Nace was an able engineer and an outstanding leader with a personality both forceful and pleasing. A tireless worker, his approach to the many problems in his professional life of forty-six years showed a prophetic insight into the field of modern railroad practice. He pioneered in roadway drainage of major proportions, in mechanized work equipment, and in heavy rail that anticipated the later higher speeds and loadings.

He was forceful in speech with a dry wit often expressed in unusual terms that will long be remembered. Even more, his capacity for enduring friendships left his memory stamped indelibly on those who were his friends. Throughout a full life in his chosen field, he always found time to be sympathetic and helpful, and his passing leaves many who will remember him always.

---

[1] **Memoir prepared by Henry D. Stowe, Assoc. M. ASCE.**

On June 15, 1909, in Philadelphia, he was married to Elsie May Porr. He is survived by his widow; a daughter, Mildred R. (Mrs. William G. Hart); and two sons, Robert Porr, and Charles Derick.

Mr. Nace was elected a Member of the American Society of Civil Engineers on July 6, 1920.

CHARLES EDWARD PARRY, M. ASCE[1]

DIED JULY 7, 1946

Charles Edward Parry was born in Newcastle upon Tyne, Northumberland County, England, on February 4, 1877. His parents were Henry and Sarah Jane (Newbold) Parry. He was educated in England at the Portsmouth Grammer School (Portsmouth), Eton College (Eton), and Cambridge University (Cambridge), being graduated from the latter with the degrees of Master of Arts and Bachelor of Science in 1897.

In 1898 he became associated with the business of his father, a consulting engineer in Newcastle upon Tyne. At the outbreak of the Boer War, Mr. Parry entered the British Army as a First Lieutenant; he served throughout the war, receiving the South African War Medal. During Mr. Parry's army service his father died and his practice was closed. Mr. Parry then left for Canada where he entered the service of the Northwest Mounted Police.

Beginning in 1906 he was employed by the Minneapolis, Saint Paul and Sault Sainte Marie Railway Company in Minneapolis as assistant chief draftsman in the office of the superintendent of motive power and served in that capacity until 1912. In that year he was engaged by the Minnesota and Ontario Power Company as assistant chief draftsman on the plans of a 110-ton capacity newsprint paper mill for Fort Frances, Ont., Canada. At intervals he also acted as construction engineer for the company.

In 1913 he accepted the position of city engineer of Fort Frances, with the privilege of conducting a private practice. While he was city engineer, he designed, complete in all details, an eight-room schoolhouse and sanitary sewers and designed and built a 2,300-volt substation for the city power supply.

On the outbreak of World War I in 1914 he was commissioned in the Canadian Army and was quartermaster of the garrison barracks. He applied to England for active service in the British Royal Engineers and was duly commissioned as a First Lieutenant. In the First Battle of the Marne he was gassed, recovered in three weeks, and received a field commission as Captain. Gassed again in the Marne sector and invalided out of service, he returned to America in 1915, taking up residence in West Palm Beach, Fla.

---

[1] Memoir prepared by Charles H. Parry, Philadelphia, Pa.

In the latter part of that year, he was employed by Palm Beach County as resident engineer on the construction of eleven miles of penetration asphalt roadbed on the Dixie highway. Upon the completion of this work he was employed by the Pebble Phosphate mines at Brewster, Fla., designing and constructing phosphate washers and storage bins and making monthly computations of output for one year. In 1917 Mr. Parry was chief draftsman for the Tampa Dock Company on the building of four Ferris-type wooden ships.

Following the war, in 1918 he was offered the position of assistant city engineer in the City of Allentown, Pa., which he accepted and held for three years. During this period, Mr. Parry designed and wrote the specifications for a $40,000 public comfort station, a $300,000 sewage disposal plant, a steel highway bridge of four spans, concrete roadways, and street crossings.

Because of a change in administration, he resigned in 1920 and joined the Municipal Disposal Company of Philadelphia, Pa., as chief engineer in charge of construction and design. The work involved the completion of construction of the Philipsburg, N. J., and the Allentown sewage treatment works, and making complete designs and writing specifications for a large amount of prospective work. This company specialized in sewage disposal plants but failed two years later. He then entered the service of the Public Service Commission of the State of Pennsylvania and, as transit engineer, assisted in the valuations of the Philadelphia Suburban Gas and Electric Company and also those of the Philadelphia Rapid Transit Company. Six months later the Municipal Disposal Company was reorganized and refinanced under the name of the Direct Oxidation Corporation and Mr. Parry was recalled as chief engineer. This company constructed, or redesigned for efficiency, sewage disposal plants in all parts of the United States before being dissolved in 1927.

For the next twelve years he was again employed by the Public Service Commission as street railway engineer, being dismissed in 1939 because of a reduction in budget and personnel. After a lapse in employment he became chief engineer for the Pennsylvania Utility Consumers Service. His work consisted of the acquisition of privately-owned utilities and their purchase by municipalities. Rate studies were also made with a view to reductions for the consumers. This company became defunct in 1940. In the latter part of 1940 Mr. Parry was employed by the Public Works Department of the Philadelphia Navy Yard as assistant engineer checking contracts.

In the early part of 1941 he was recalled by the Public Utilities Commission (formerly the Public Service Commission) and employed as a railroad engineer in the Bureau of Engineering on highway and railroad crossings. In 1944 he was made chief gas engineer on matters pertaining to natural and manufactured gas utilities, and in 1946 was given complete charge of the investigation of all informal complaints to the Public Utilities Commission against public utilities (gas, electric, water, etc.) in the State of Pennsylvania, continuing in this capacity until his death on July 7, 1946.

Mr. Parry's life was a full one because of his many different types of employment all over the world, his experiences in two wars, and his service on the Northwest Mounted Police of Canada. Incidently, it has been stated that some of Mr. Parry's experiences were used by James Oliver Curwood in his book "The Sunset Trail."

He belonged to the American Association of Engineers, American Concrete Institute, Engineers Society of Pennsylvania, and the Society of American Military Engineers. He was a Thirty-Second Degree Mason in the Trimble Lodge of New Jersey. He was a member of the Episcopalian Church. Mr. Parry became a citizen of the United States in Philadelphia in 1921.

His two brothers served in the British Navy: His brother, Harry, on the Chief Surgeon's staff and his other brother, Reginald, served on the flagship as an electrical engineer. Both were knighted by the King of England and decorated for bravery in battle.

On September 3, 1903, he was married to Carrie Leonora Kaiser in the Church of the Holy Trinity in Toronto, Ont., Canada. Mr. Parry lost his wife on July 6, 1946, after she was operated on for gangrene poisoning of the leg. He suffered a heart attack forty-six hours later due to grief. He is survived by his only son, Charles H. Parry, of Philadelphia. Mr. Parry was highly respected and loved by the friends and co-workers he left behind, some of whom felt his passing almost as much as his son. He and his wife were cremated and laid to rest in the Whitemarsh Cemetery in Whitemarsh, Pa.

Mr. Parry was elected a Member of the American Society of Civil Engineers on May 19, 1924.

HARRY NELSON PHARR, M. ASCE[1]

Died November 3, 1947

Harry Nelson Pharr, the son of Capt. Henry Newton and Stella Houghton (Scott) Pharr, was born in LaGrange, Lee County, Ark., on May 8, 1875. His father, of Scotch-Irish ancestry, was a Presbyterian, originally from the Rocky River settlement of North Carolina; he moved to Shelby County, Tennessee, in 1838, and built his home near Raleigh (Tenn.), which was then the county seat of Shelby County. Following the termination of the Civil War, in which he took an active part in the Confederate Army, Captain Pharr moved to LaGrange, where he acquired considerable farm property. At LaGrange, three sons and one daughter were born.

Harry Pharr, his second child, attended the Lee High School at LaGrange, and the University of Arkansas at Fayetteville, from which he was graduated in 1893 with the degree of Bachelor of Science in Civil Engineering. In 1900, after several years of experience as assistant engineer and then chief engineer of the St. Francis (Ark.) Levee District, he did research work and submitted a thesis on the "Theory, Practice and Economy of Embanking Lands of the

---

[1] Memoir prepared by Herbert S. Gladfelter, M. ASCE.

Mississippi Valley Against Floods," for which his alma mater conferred on him the degree of Master of Civil Engineering.

He grew up in an engineering environment and it was natural for him to devote his life to this work—especially to flood control projects. After the Civil War, his father, a civil engineer, resumed his work and, after engaging in railroad location and construction until 1883, became interested in the reclamation of the overflowed lands and swamplands of his adopted state—Arkansas. In 1893, he initiated the organization of the St. Francis Levee District of Arkansas and Missouri and served as chief engineer of the levee boards of both states until his death in 1897. This man pioneered the work in the organization of the levee district and in the development of the lands within it. The northeastern part of Arkansas, known as the Arkansas Delta, was at that time largely overflowed land and swampland, sparsely settled with few roads; it is now one of the most productive agricultural sections of the United States, and contains numerous cities with populations ranging from 2,000 to 10,000.

Harry Pharr's first engineering employment after being graduated from the University of Arkansas was as assistant engineer under his father. In 1897, following his father's death, he was made chief engineer of the St. Francis Levee District of Arkansas.

In 1907 he resigned as chief engineer to engage in the private practice of general engineering, and for eight years was engaged as chief engineer of the newly organized Crawford County (Arkansas) Levee District in locating and constructing a levee along the north bank of the Arkansas River. This was followed by surveys and reports on flood control for the Obion River in Tennessee, the Kansas River in Missouri and Kansas, the Wabash River in Indiana, and the White River in Arkansas. In addition to flood control work, he also acted as consultant for numerous counties, corporations, and individuals in the design and construction of highway bridges over the St. Francis River. He was also consultant on flood control and drainage problems for the Mobile and Ohio Railroad Company; the Nashville, Chattanooga and St. Louis Railway Company in Tennessee; the Big Four Railroad Company in Indiana; for various municipalities in the design and construction of streets, sidewalks, sewers, and layout of subdivisions.

In 1915, following the great floods of 1912 and 1913, when the existing levee system proved inadequate in protecting the St. Francis Basin, he again was appointed chief engineer of the St. Francis Levee District, and during the next two years planned and constructed extensive enlargements of the levee system. Two years later Mr. Pharr left the levee district to engage in private business, largely devoted to the improvement and development of a large tract of land he owned in Lee County, Arkansas.

He returned again to the St. Francis Levee District in 1918 as chief engineer, remaining in that position until 1935. During this period, in cooperation with the federal government, he planned and constructed extensive works of levee enlargement and strengthening of the entire levee system within the district. Also he engaged in the relocation and rebuilding of part of the levee. During this time he was responsible to a large extent for the interpretation of the laws and rules for assessing benefits to land and property resulting from the construction of levees.

In June, 1935, he resigned as chief engineer of the St. Francis Levee District to accept the appointment by the Hon. Franklin D. Roosevelt, then President of the United States, as member of the Mississippi River Commission on which he served as a valued member until his death in November, 1947. The Mississippi River Commission has charge of the design and construction of flood control projects, including levees, revetments, dikes, spillways, floodways, cutoffs, and outlets on the Mississippi River from Cairo, Ill., to the Gulf of Mexico and, in addition, of dredging for the improvement of navigation.

In accepting his resignation as chief engineer of the St. Francis Levee District, the board of directors of that district adopted the following resolution:

> "In the course of worldly affairs it so happens that men are called upon to perform a vast and intricate multitude of duties, some in humble pursuits, others in pursuits more exalted. Men qualify for higher position by the quality of effort put forth in lower position. Thus, there comes promotion for those to whom promotion is due;
>
> "And Whereas, Harry N. Pharr, for a long number of years, spanning a good portion of his active life, has occupied by the free will, choice and selection of this Board, elected over and over again by its membership, the office of its Chief Engineer, and, as such has linked his name and fame eternally with the successful prosecution of the gigantic work for which the St. Francis Levee District was created and now exists; having throughout the years borne himself in the highest traditions of his profession, a true Knight of Old, buttressed in the bright and shining armor of honest resolve and consecrated purpose; and
>
> "Whereas, the President of the United States, Honorable Franklin D. Roosevelt, conscious of the importance of choosing for membership on the Mississippi River Commission talent of the highest order, has tendered appointment to that body to Mr. Pharr, who has accepted, and has resigned his position as Chief Engineer;
>
> "NOW, THEREFORE, BE IT RESOLVED, by the Board of Directors of St. Francis Levee District assembled in annual meeting at the domicile of the same, West Memphis, Arkansas, that we express to Mr. Pharr our late Chief Engineer, and now member of the Mississippi River Commission, our profound regret occasioned by his departure from us, and along with the same express our gratification that his ability and other qualifications have received this high recognition; that the Levee Board has undoubtedly sustained a great loss which we should be unwilling and loath to take were it not so patently to his great advantage, and also, to the advantage of the whole country which has so large an interest in the development to a state of nearer completion of the public works program proceeding on the Mississippi River and its tributaries under the supervision and control of the Commission of which he is now a member.
>
> "BE IT FURTHER RESOLVED, that we express our unbounded appreciation of Mr. Pharr's services; of his character as a man and true gentleman; of his uncompromising fidelity to principle and his fearless discharge of duty; of his professional skill, which is of high order, and commend him to his future associates in the responsible field of public duty to which he has been called by our honored Chief Executive."

Following Mr. Pharr's death in November, 1947, Maj.-Gen. R. W. Crawford, United States Army, President of the Mississippi River Commission, in announcing the death of a member of the Commission, stated:

> "Mr. Pharr was appointed to the Commission in 1935. Connected in earlier years with the St. Francis Levee District of Arkansas, his knowledge of flood control in the Alluvial Valley became a valuable asset to the Commission. As a member he was actively connected with all phases of the Commission's work, and his close and industrious application, his judgment and his understanding were of great assistance to the Commission in its deliberations.
>
> "He will be missed both as a valued professional associate and a most cordial and pleasant fellow member."

Mr. Pharr was a member of the Board of Trustees of the University of Arkansas from 1900 until 1902; a Colonel and chief of engineers of the Arkansas National Guard from 1907 until 1908; past-president of the Memphis Engineering Society, which was disbanded about 1900 and later revived in the Engineers' Club of Memphis of which he was a charter member; and he was active in the formation of the Mid-South Section of the Society of which he was a charter member. In addition, he also belonged to the University Club of Memphis.

The demands of his work precluded Mr. Pharr's indulgence in hobbies; however, in later life he did devote much of his spare time, in cooperation with the director of the proposed William R. Moore School of Technology in Memphis, to the planning, construction, and fitting out of this industrial trade school for boys. This school was built and completed in 1938 from a trust fund established in 1912 by the late William R. Moore. Mr. Pharr was appointed a trustee of the then-proposed school in 1936 and took a great deal of interest in its building in 1938, and in its development and operation until his death.

He was a member of the Idlewild Presbyterian Church of Memphis, taking an active part in its operation as a member of the Board of Elders. Always an enthusiastic worker in the church, the spirit of the church permeated his home and his work. He was known as an engineer of the highest integrity, soft spoken, but firm in his convictions—one who believed in doing his work thoroughly and well.

About 1900, Mr. Pharr transferred his residence from Arkansas to Tennessee, establishing a home in Memphis. In 1908 he was married to Creola Strong, and they had one son, Samuel Strong, who later became an attorney-at-law in Memphis. Mr. Pharr was married a second time in 1923 to Rose Scott Coleman of Uniontown, Ala., who survives him; they had two children, Kitty Grey (Mrs. Thomas R. Long) of Uniontown, and Stella Scott, who also survive.

Mr. Pharr was elected an Associate Member of the American Society of Civil Engineers on October 3, 1900, and a Member on June 6, 1905. He became a Life Member in January, 1935.

HENRY CYRUS PORTER, M. ASCE[1]

DIED MAY 31, 1946

Henry Cyrus Porter was born in Rockdale, Tex., on September 3, 1886. His parents were Louis Henry and Mary Catherine (Hamblen) Porter.

In 1904 he was graduated from the Rockdale High School and later attended the Engineering Department of the University of Texas, at Austin, from 1906 to 1912. At the university he was a member of the Phi Gamma Delta fraternity. Because of insecure finances he was unable to attend college continuously; he would work for a year or two and then go to school until his funds were exhausted. During his college career he took selected courses in electrical and civil engineering, preparing himself for municipal administration work, or what is now called the position of city manager.

From October, 1909, to October, 1910, Mr. Porter worked as chainman, draftsman, and computer for the Fred A. Jones Engineering Company on surveys for railroad and interurban railways in Oklahoma and Texas. He was resident engineer for the Fred A. Jones Engineering Company, from October, 1910, to October, 1911, on the construction of White Rock Dam for the City of Dallas, Tex.

On leaving the University of Texas in June, 1912, he was office engineer and assistant to the chief engineer of the San Benito and Rio Grande Valley Railway Company. In July, 1913, he became city engineer of Kingsville, Tex., and was in charge of the design and construction of a water system, sanitary sewage system, and street improvements.

Mr. Porter resigned this position in May, 1917, to attend the first Officers' Training Camp at Leon Springs, Tex. In August, 1917, he was commissioned a First Lieutenant in the Corps of Engineers, United States Army, and was assigned to the 315th Engineers, 90th Division, which was activated in September, 1917. His first duty was that of training troops. In February, 1918, he was made regimental supply officer and was promoted to Captain in June, 1918. He served overseas in France and Germany from June, 1918, to August, 1919, as regimental supply officer and regimental adjutant, and was in charge of the operations of the railroads in the 90th Division area while the division was part of the Army of Occupation in Germany. He was discharged in August, 1919, and immediately returned to Kingsville, where he was appointed county engineer of Kleberg County, responsible for the design and construction of a highway system.

In June, 1922, Mr. Porter resigned to become a division engineer for the Texas Highway Department, and he served in divisions No. 3, No. 4, and No. 9, supervising construction and maintenance of state highways. Then, in January, 1926, he became field engineer for Nagle, Witt, Rollins, and Gilchrist, Consulting Engineers, in charge of highway construction. The following year, in November, 1927, he was appointed resident engineer for the

---

[1] Memoir prepared by John A. Focht, M. ASCE.

Texas Highway Department in Goliad and Victoria counties, where he served until December, 1929. Then, he moved to Austin and was in charge of the Division of Specifications in the Austin office until May, 1930. During this time he advocated many improvements in the designs of highways, including the wide, flat type of cross section which is used very widely today.

One of his important publications at this time was a manual on roadway construction.[2] He became special resident engineer in McLennan and adjoining counties, in May, 1930, designing and constructing highways. In June, 1932, he returned to Austin as engineer of soils and research, which position he held until his death.

Mr. Porter did much research and wrote extensively on many of his findings. He contributed materially to the development of the cotton mat for curing concrete pavements, and was connected very closely with the Guadalupe County (Texas) Research Project, observing it over a long period of years; he compiled four large volumes of data collected on this project, from which he drew many conclusions which have been incorporated beneficially in design and construction of highways in Texas. He also developed the use of an electrical resistivity instrument to locate base materials.

In the last four or five years of his life Mr. Porter devoted his attention to soil foundations for pavements, and he wrote widely on the results of these findings. He was insistent that more attention should be given to drainage, soil selection, densification, and stabilization of the soil foundation for highways. His publications are found in the *Texas Highway Department Information Exchange,* the *Texas Parade,* the *Texas Engineer,* the *Manufacturers' Record, Roads and Streets, Engineering News-Record;* also, *Proceedings* of the National Research Council, *Proceedings* of the International Conference on Soil Mechanics, and *Foundation Engineering* of Harvard University, at Cambridge, Mass.

The culmination of his research and publications is found in a series of eleven bulletins.[3] It was his burning desire to present this information, along with many of his other findings, in a textbook on soil mechanics to be used in engineering colleges. He had prepared much of this manuscript, and had collected many cuts and illustrations, when a fatal illness prevented its completion.

Mr. Porter was quiet and cheerful—a friendly, unassuming individual who never sought publicity. He was most industrious, staying at the office or laboratory early and late; even his spare time was devoted to initiating new experiments and approaches. Tireless and meticulous in every detail, he did not object to the great precision required to eliminate all but one variable, or to check his results by other approaches. His office was always kept in neat order, and at his passing his personal affairs were complete, with his books ready to be closed. Mr. Porter was most enthusiastic about his work, and he was always happy to have an opportunity to discuss new developments with interested colleagues. When given an office in the penthouse of the Highway Building in Austin, he was delighted, for here he could work without interruption by the casual visitor; only those who had business with him would climb the extra flight of stairs. He welcomed the opportunity of passing on the information he had collected to others.

---

[2] "Manual for Surveys, Plans and Specifications for Construction of Roadways," by Henry C. Porter, January, 1930.

[3] "Roadway and Runway Soil Mechanics Data," by Henry C. Porter, Texas Eng. Improvement Experiment Station, College Station, Tex., 1942.

Mr. Porter was a registered professional engineer in the State of Texas, a member of the Texas Society of Professional Engineers, and the Church of Christ, and was a Thirty-Second Degree Mason.

On September 4, 1920, Mr. Porter was married to Grace Ellen Bludworth. He is survived by his widow and one son, Louis Henry Porter.

Mr. Porter was elected an Associate Member of the American Society of Civil Engineers on November 21, 1921, and a Member on October 1, 1926.

DE WITT PAWLING PUGH, M. ASCE[1]

DIED FEBRUARY 27, 1947

De Witt Pawling Pugh was born at King of Prussia, Pa., on April 19, 1872. He was the son of John Ramsey and Emily (Knight) Pugh. His early education was received in the vicinity of Philadelphia, Pa., and he was graduated from Ohio Northern University at Ada, in 1894, with the degree of Bachelor of Civil Engineering.

In the fall of 1894 Mr. Pugh joined the engineer corps of the Borough of Norristown, Pennsylvania, after which he became affiliated with the Pennsylvania Railroad Company. For this company he specialized in reconnaissance, location, construction, foundations, elimination of grade crossings, and estimates on economic railroad work. In the words of an associate, he was an outstanding locating engineer, who had a natural eye for line and grade. His life's work was spent in the service of the Pennsylvania Railroad Company.

He was a member of the following orders: Charity Lodge No. 190, Norristown Chapter No. 190, Hutchinson Commandery No. 32, the Scottish Rite, and the Nobles of the Mystic Shrine—all of Pennsylvania. Also, he was a member of the vestry of Washington Memorial Chapel at Valley Forge, Pa., from 1923 until 1946. During his association with the patriotic shrine, he was interested in augmenting the finances and activities of the chapel and especially in developing the churchyard, which flourished under his leadership.

His ancestors were Episcopalians and because of this early association with the church, he cherished a close relationship with the Episcopal Academy —a preparatory school for boys in Overbrook, Pa., where four of his sons were graduated. He was vitally interested in its development during his life.

Mr. Pugh, of Welsh descent, was an American of outstanding integrity, ingenuousness, and sincerity of purpose. He died on February 27, 1947, and was buried in the Washington Memorial Chapel churchyard.

---

[1] Memoir prepared by Mrs. De Witt Pawling Pugh, Wayne, Pa.

On October 7, 1908, he was married to Anna Elizabeth Ramsey. He is survived by his widow and three sons, Lt. Col. John R. Pugh (Fort Leavenworth, Kans.), Edward Pugh (Baltimore, Md.), and Capt. Theodore R. Pugh (Fort Riley, Kans.).

Mr. Pugh was elected a Member of the American Society of Civil Engineers on May 6, 1908. He became a Life Member in January, 1943.

REINALDO RAMIREZ, M. ASCE[1]

DIED JANUARY 19, 1947

Reinaldo Ramirez, the son of Severiano and Isolina (Marini) Ramirez, was born at Cabo Rojo, Puerto Rico, on December 28, 1892. A few years later this island of the Greater Antilles became a possession of the United States as a consequence of the Spanish-American War. He was, therefore, born a citizen of Spain, but, like most Puerto Ricans, became an American citizen in 1917 when Congress passed the Jones Act.

Mr. Ramirez received his early education in the public schools of the island. Later he attended the Baltimore Polytechnic Institute at Baltimore, Md., and was graduated in 1912. He then entered Cornell University at Ithaca, N. Y., from which he received the degree of Civil Engineer in 1916. His record as an outstanding student won the admiration of his Latin American classmates, friends, and students, some of whom offered him attractive positions to work in Cuba and South America.

He preferred to work for his native land, however, and returned to Puerto Rico to become assistant engineer and, later, chief assistant engineer for the South Puerto Rico Sugar Company, the largest cane sugar corporation in the island and, at the time, one of the largest in the world. His work was of varied character, covering land surveys, mapping, and the design and construction of irrigation works, which included pumping stations to supply cane plantations, houses, warehouses, piers, and the miscellaneous type of construction which is ordinarily required by a large sugar company. On the death of his father, having been appointed by the court administrator of the Ramirez estate, he was obliged to leave this position to take care of family business. At the same time he was able to engage in some engineering work.

In June, 1921, he was appointed assistant engineer in the newly organized Isabela Irrigation Service, a government institution created for the purpose of designing, constructing, and operating an irrigation system to water 15,000 acres in the northwest part of the island, and, incidentally, to develop hydroelectric power. At first he was in charge of surveys and subsoil investigations for an earth dam that was to have a maximum height of 123 feet and a 38,000 acre-foot reservoir, and later he assisted in the design of the dam and appurtenant structures, as well as of other features of the project. When construction work was started early in 1924, he was appointed assistant resident engineer.

---

[1] Memoir prepared by Rafael A. González, M. ASCE.

Mr. Ramirez resigned that position in January, 1926, to become chief assistant engineer in the Maintenance of Ways and Structures Department of the American Railroad Company, a corporation owning most of the public railroads on the island. Besides maintenance, his work involved design and construction of bridges, buildings, and miscellaneous structures. In May, 1943, he was promoted to chief engineer of that department and held this position until his death.

Mr. Ramirez was always interested in, and devoted much time to, the activities of the engineering profession. He was one of the founders of the Puerto Rico Section of the Society and was its first secretary-treasurer, a position he held from 1929 until 1935, when he was elected president. He was also a member of the local society, Sociedad de Ingenieros de Puerto Rico, of which he was president in 1940. Frequently, he was a member or chairman of committees dealing with some problem or phase of the engineering profession. His memberships also included the social club, Casino de Puerto Rico, and the Cabo Rojo Lodge of the F. and A.M.

The principal attributes of Mr. Ramirez were his integrity, modesty, and industriousness. The last is demonstrated by the fact that, while engaged with the American Railroad Company, he found time to do some private engineering work, which included contracting in the building industry. He possessed winning manners which earned him willing cooperators in all his undertakings. High moral principles always guided his actions. He was an excellent husband and father, a reliable friend, and a faithful citizen.

On January 18, 1919, Mr. Ramirez was married to Eulalia Irizarry Ramirez of Yauco, Puerto Rico. He is survived by his widow; three sons—Reinaldo Elliot, a graduate (Bachelor of Science in Agriculture) of Southwestern Louisiana Institute of Liberal and Technical Learning at Lafayette; Rene Octavio, an architect, graduate of Cornell University; and the youngest, Hernan Rolando; and two grandchildren.

Mr. Ramirez was elected an Associate Member of the American Society of Civil Engineers on September 10, 1923 and a Member on March 27, 1933.

ALLAN APPLETON ROBBINS, M. ASCE[1]

DIED FEBRUARY 17, 1947

Allan Appleton Robbins, the son of George Appleton and Susan (Morris) Robbins, was born at Scarsdale, N. Y., August 25, 1872. His early education was received at Eversons and Halsey's School, and he was graduated with the degree of Bachelor of Philosophy from the Sheffield Scientific School, Yale University, at New Haven, Conn., in 1893.

---

[1] Memoir prepared by R. T. Betts, M. ASCE.

Mr. Robbins did not enter an active engineering career until the autumn of 1896 at which time he became a draftsman for William Barclay Parsons,[2] Hon. M. ASCE, in connection with rapid transit work. Later, in the autumn of 1897, he joined the late F. Stuart Williamson, M. ASCE, as engineer in charge of piling, foundation, and masonry on the Manhattan Valley viaduct (extension of Riverside Drive, New York, N. Y.). This assignment was interrupted in the summer of 1898 by his service in Puerto Rico, as a First Lieutenant with the First United States Volunteer Engineers. On his discharge from the Army, he returned to Mr. Williamson and served with him until 1900.

It was during his work on the viaduct that he met John W. Ripley,[3] M. ASCE, who also was employed by Mr. Williamson as engineer in charge of the steelwork. From this friendship came the formation of The Robbins-Ripley Company in New York, in October, 1909.

From 1899 to 1901 Mr. Robbins was assistant general manager and director during the erection and operation of the plant of the Pinkney Mining Company at Pinkney, Tenn. He was resident engineer from May, 1901, to May, 1904, with the Rapid Transit Subway Construction Company, in charge of the fourth division, including the terminal yard and shops, 148th to 150th streets, New York, and the construction of substations No. 16 and No. 18 for the Interborough Rapid Transit Company. From May, 1904, to October, 1909, Mr. Robbins served as resident engineer, then as principal assistant engineer, with the New York and Long Island Railroad Company for a proposed tunnel under the East River (later used as a part of New York's subway system).

Mr. Robbins was president of The Robbins-Ripley Company, from the time of its organization in October, 1909, until his death in February, 1947. During his incumbency as president, The Robbins-Ripley Company rebuilt considerable stretches of the New York Dock Company's waterfront in Brooklyn, N. Y., involving the removal of approximately ten old piers, and the building of ten new piers, as well as rebuilding approximately 3,000 linear feet of bulkhead. Other projects include the waterfront improvements for Carl Fisher in his development of Montauk Point, Long Island, N. Y.; the rebuilding of pier No. 54 in the North River, after its destruction by fire in May, 1932, for the Board of Fire Underwriters, and the Cunard Steamship Company; and the design and construction of the Eastern Steamship Lines terminal at piers No. 25 and No. 26 (North River).

On his mother's side (Susan Morris Robbins), he was a descendant of Lewis Morris, first governor of New Jersey as a separate province (from 1738 to 1746), for whom Morristown, N. J., was named. He also was related to Robert Hunter Morris, one-time mayor of New York, and to Gouveneur Morris, signer of the Declaration of Independence.

He was a member of the Society of Colonial Wars, and of the University, Piping Rock, and Turf and Field clubs.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 98, 1933, p. 1485.
[3] *Ibid.*, Vol. 109, 1944, p. 1517.

Mr. Robbins was elected an Associate Member of the American Society of Civil Engineers on October 2, 1901, and a Member on September 6, 1904.

WILLIAM JOSEPH ROWLAND, M. ASCE[1]

Died May 21, 1947

William Joseph Rowland, the son of William Joseph and Bobbie (Roberts) Rowland, was born in Vicksburg, Miss., on September 29, 1902. His education tion was received at the Saint Aloysius High School (Vicksburg), the Georgia Military Academy (Millidgeville, Ga.), the University of Alabama (Tuscaloosa), and the United States Military Academy (West Point, N. Y.). The death of his father forced his resignation from West Point after completing only two years study.

The early years of Mr. Rowland's professional life (from 1922 to 1931) were spent with various lumber companies in the south supervising plant construction and mechanical installations. When the United States Waterways Experiment Station was established at Vicksburg in 1931, Mr. Rowland was placed in charge of the soils testing section as chief technician; he served in that capacity until 1938, when he was placed in charge of all field operations of the soils division of the experiment station. He also served as consultant to various engineer districts on problems relative to field explorations and the installations of new soils laboratories.

Mr. Rowland was in the Reserve Officers' Corps, United States Army, and in 1942 was called to active duty with the rank of Captain in the Corps of Engineers. He served on the construction of the Alaska Highway until 1945 when he was discharged for disability. After his discharge, Mr. Rowland operated his own engineering and construction business in Vicksburg and handled a number of construction projects, including the widening of the east approach to the Vicksburg Bridge.

He was a member of the Engineers' Club of Vicksburg, the American Legion, and the F. and A. M. Mr. Rowland was of sterling character and strong personality He was always true to his ideals and to his friends, and his sound judgment and will for work commanded the respect of his associates and fellow workers.

He is survived by his mother, Mrs. Bobbie E. Rowland; three sisters, Juliette Rowland, Mrs. W. J. Melsheimer, and Mrs. R. B. Hutchinson; and several nieces and nephews.

Mr. Rowland was elected an Associate Member of the American Society of Civil Engineers on March 14, 1938, and a Member on January 11, 1943.

---

[1] Memoir prepared by W. L. Wells, Assoc. M. ASCE.

JOSHUA STEWART SAWYER, M. ASCE[1]

DIED APRIL 6, 1947

Joshua Stewart Sawyer was born in Montrose, Colo., to the former Mary Edlen Peters of Cincinnati, Ohio, and Edward Bertrand Sawyer, of Hyde Park, Vt., on March 20, 1883. His father, a civil engineer, had emigrated to the northwest, where he engaged in mining and railroad construction, and the son's indoctrination into the profession began at an early age. Some of Mr. Sawyer's earliest recollections were of construction sites and survey camps in the great plains and mountains of the northwest, of pack horses, and of fishing and hunting—experiences that bred in him a love of the outdoors which remained with him and colored his entire life.

He attended the Colorado School of Mines, in Golden, working during the summer periods with his father and, in 1910, was appointed assistant city engineer of the City of Medford, Ore. There followed various work as locating engineer on railroads and highways and a term as city engineer of Brandon, Ore. These experiences perhaps assisted in determining the particular field in which he was most interested, for in 1917 he joined the Oregon State Highway Department as locating engineer. From that time on Mr. Sawyer was identified with highway design and construction and with the development of materials.

After about six years of service as division engineer in charge of Division No. 2 of the Oregon Highway Department, Mr. Sawyer joined the Shell Oil Company in San Francisco, Calif., in 1929 as manager of the Asphalt Department and in that capacity organized and directed the department. In 1932 he came to New York, N. Y., to organize the Asphalt Department on the East Coast for the Shell Oil Company and remained as head of the department until his death.

Interested in highway construction and, in particular, in asphalt construction, he assisted in developing asphaltic materials for that purpose, and was well known for his work with emulsified asphalts.

An ardent fisherman and hunter, he spent most of his leisure in the field, and was particularly skilful in building fishing rods and gear. With a huge capacity for friendship, he had the respect and affection of all who knew him.

Mr. Sawyer was married to Minne P. McIntyre. He is survived by his widow and their two children, Irma (Mrs. W. C. Wells) and Joshua Stewart Sawyer, II, an engineer with the Oregon State Highway Department.

Mr. Sawyer was elected a Member of the American Society of Civil Engineers on January 13, 1930.

---

[1] Memoir prepared by James P. Williams, Assoc. M. ASCE.

FRANCIS JOSEPH SEERY, M. ASCE[1]

Died July 27, 1947

Francis Joseph Seery, the son of Thomas H. and Mary (Seery) Seery, was born on May 24, 1874, in Waterbury, Conn. Thomas Seery was a mill superintendent and a grandson of Gregory Delacy Seery, the leader of the United Irishmen in 1798.

Francis Seery received his secondary education in Waterbury High School, and then went to work. For seven years, from 1893 to 1900, he served his home city as engineering assistant on construction for additional water supply including Wigwam Dam. In 1900 he was transitman for the Isthmian Canal Commission exploring possible canal routes in Darien, Panama.

With this background of practical experience he decided to continue his education. In 1901, at the age of twenty seven, he entered Tufts College in Medford, Mass., and in 1905 received the degree of Bachelor of Science in Civil Engineering. During his summer vacations he was employed by the cities of Waterbury and Fulton, N. Y., and also by the United States Geological Survey on topographic work in Kentucky.

After being graduated from Tufts he served, during the summers from 1905 to 1908, as assistant engineer in Department D of the New York State Engineers' Office on construction of the Barge Canal.

In September, 1905, Mr. Seery was appointed instructor in hydraulic engineering in what was then the College of Civil Engineering at Cornell University in Ithaca, N. Y. This was the beginning of a teaching career at this institution which continued until his retirement as professor emeritus of civil engineering in 1942. In 1907 he was promoted to the grade of assistant professor, and in 1918 to a full professorship of hydraulic engineering, serving in the latter position for twenty-four years.

Professor Seery organized and taught courses in water supply, hydraulic construction, hydraulic engineering, water power (devoted to characteristics, hydrology, and operating conditions), water power and pumping plants (a design course), and conservancy and reclamation problems.

He was not idle during the summers of this long teaching career. Besides spending much time on very careful preparation of the practical engineering problems (on which he later had his students present reports), he undertook numerous jobs for which his assistance was requested. He prepared a report on hydroelectric development on Geneganslet Creek, and Oswegatchie River in New York in 1909 and also a design of the Potters Falls Dam on Six Mile Creek in Ithaca. In 1910 he made a valuation appraisal of the water plant at Lyons, N. Y., and in 1913, a similar appraisal for Watertown, N. Y.

With the participation of the United States in World War I, during the summer of 1917, Professor Seery was superintendent of water supply and sewers at Camp Dix, N. J.; and, during the summer of 1918, he served as hydraulic engineer for the United States Geological Survey assigned to investigate and make a confidential report to the Capital Issues Commission, United States War Board, on a proposed water plant at Watertown.

---

[1] Memoir prepared by a Committee of the Ithaca Section consisting of Charles L. Walker and Ernest W. Schoder, Members, ASCE.

His activities also included: A design survey and estimate for extensions to the water supply of Moravia, N. Y. (in 1919); a report on five proposed water power developments on Jacques Cartier River in Quebec, Canada, for the Donnaconna Paper Company (in 1921); a report on proposed alterations of Hoffman Hill Reservoir in Elmira, N. Y. (in 1922); a report to Congress as a member of the board of consulting engineers appointed to review the "Jadwin Plan" for flood protection of the Mississippi River (in 1925–1926); a report on the sufficiency of Hemlock Lake for the water supply of Rochester, N. Y. (in 1935); testimony as expert witness on hydraulics for the State of New York on the Montezuma, Oneida Lake, and Ley Creek cases (in 1936); a report on the extension of water works for Hammondsport, N. Y. (in 1937); work as expert on hydraulic meters for the New York State attorney general's department on water supply in Rochester (in 1937–1938); and expert witness in the Harrington Farms case (in 1938).

Professor Seery served the City of Ithaca as a member of the Board of Public Works for six years, from 1919 to 1925, being vice-chairman for the last three years; also, from 1943 to 1946, he was a member of the Ithaca Civil Service Commission.

The varied practical experience of Professor Seery in the field of hydraulic engineering had convinced him of the value of such experience to the teacher and to the student of engineering. Design problems of considerable scope, length, and suggestiveness were made a part of the courses which he taught. The educational worth of these problems is attested by the fact that almost all his students valued them highly, preserving their reports when returned at the end of the course, and frequently benefiting by them in their professional careers after graduation. By spending much time and energy in the composition of these problems Professor Seery asserted his conviction of the basic truth in the words of Aristotle: "For the things we have to learn before we can do them, we learn by doing them." This feature of the teaching methods of Professor Seery has become incorporated in other fields in the curriculum of the School of Civil Engineering at Cornell. His work thus will extend an influence toward the better training of students in the future.

Since he always had available in his memory much interesting and supporting extraneous material gleaned from his own practical experience and from extensive reading, his classes were far from dull. He made much direct use of current engineering literature, both to fortify the textbook and to orient the student toward the actual living world of engineering. He did not, however, neglect basic theory in developing the student's grasp of subject matter. In his work as a teacher he stressed conception, design, construction, and maintenance as elements in the structure of an engineering education and as activities that would be required of the engineer in his varied experience after graduation.

Professor Seery was married to Elnora C. McElligot of Waterbury, in 1909. He is survived by three daughters: Miriam, with whom he resided in Dover, Del., after leaving Ithaca; Virginia, of New York; and Francesca (Mrs. J. Theodore Chamberlain), of Tarrytown, N. Y.; and a grandson, Teddy Chamberlain.

Professor Seery was elected an Associate Member of the American Society of Civil Engineers on April 3, 1907, and a Member on June 6, 1921. He became a Life Member in January, 1942.

VALENTINE BERNARD SIEMS, M. ASCE[1]

DIED FEBRUARY 15, 1946

Valentine Bernard Siems, the son of A. G. John and Anna K. B. (Kohlhepp) Siems, was born in Baltimore, Md., on October 30, 1887. After being graduated from a Baltimore public school in 1903, he attended and was graduated from the following schools: The Maryland Institute (Baltimore) in 1906; the Baltimore Polytechnic Institute (Baltimore) in 1907; and Milton University (Baltimore), receiving the degree of Bachelor of Science in 1909. In 1941 Milton University honored him with the degree of Doctor of Engineering.

Subsequently, he was awarded the degree of Master of Science from Washington College (Chestertown, Md.) in 1919. Later he studied business administration and finance at the Alexander Hamilton Institute (New York, N. Y.) from 1919 to 1922 and law at the University of Maryland (Baltimore) during the same period. In 1923 he received the degree of Civil Engineer from Gettysburg College (Gettysburg, Pa.).

In March, 1909, Mr. Siems became a member of the engineering staff of the Baltimore city water department and was engaged in design and construction of various parts of that system, including two years as resident engineer on the construction of the Montebello filtration plant in that city. In 1918–1919 he was supervising and construction engineer in the construction division of the United States Army for the water systems at Camp Meade and Camp Franklin in Maryland. He was also assistant water engineer for the Baltimore water department (from 1918 to 1923) and president of the water board and water engineer for Baltimore (from 1923 to 1927).

Mr. Siems became interested in the North American Waterworks Corporation in New York, which was one of the large holding companies in 1926, and served as vice-president, general manager, and director until 1928. In addition, he was president and director of some of the subsidiaries of this corporation. For the next two years he was vice-president and chief engineer of the National Waterworks Corporation of New York and also president and director of subsidiary companies.

---

[1] Memoir prepared by William W. Brush, M. ASCE.

In 1931 Mr. Siems formed V. Bernard Siems and Company, an organization of consulting engineers specializing in management work and at the same time had an interest in the firm of George H. Siems and Company, contractors.

Mr. Siems was the author of numerous articles on the operation and management of utilities and of reports on water works for municipalities. After leaving the Baltimore water department he became interested in financial as well as engineering work and served as trustee of the St. James Savings Bank in Baltimore, and as director of the North Bond Street Permanent Building and Savings Society also in Baltimore. He was a member of the American Water Works Association and the American Association of Engineers.

For a number of years before his death, Mr. Siems gave a great deal of time to church activities and was an honorary trustee of the Bethany Lutheran Church in Elmhurst, N. Y., and of the Evangelical Lutheran Church of Our Savior in Baltimore.

On June 6, 1911, he was married to Mary Fens, who, together with their son, V. Bernard, Jr., Jun. ASCE, survives him.

Mr. Siems was elected an Associate Member of the American Society of Civil Engineers on November 25, 1919, and a Member on December 3, 1926.

SIDNEY MONTEFIORE SIESEL, M. ASCE[1]

Died September 15, 1946

Sidney Montefiore Siesel was born in Macon, Ga., on August 20, 1889. He was the son of Jacob and Clementine (Wolf) Siesel, who were natives of Germany and had been married in Macon. In 1891 the family moved to Pittsburgh, Pa., where they continued to live until Mr. and Mrs. Siesel's passing in 1906 and 1933, respectively.

In acquiring an education, Mr. Siesel attended the public schools of Pittsburgh, and in due time entered the Carnegie Institute of Technology there. He was graduated in 1908 with the degree of Bachelor of Science. Following his graduation he studied reinforced concrete for thirteen months at the Technical School in Charlottenburg, Germany. In 1932 he was awarded the degree of Civil Engineer from the Carnegie Institute of Technology after submitting a thesis on reinforced concrete piling.

Mr. Siesel became affiliated with the Pittsburgh Testing Laboratory in 1910 as inspector and served in this capacity on various classes of work in Pittsburgh and Milwaukee, Wis., for a period of two years. This was followed by a position in Pittsburgh where he became associated with James L. Stewart as construction engineer, estimator, and expediter, continuing until 1914. At that time he returned to Milwaukee as president of the O. H. Bossert Company, Contractors, with headquarters in Milwaukee, and continued as chief executive of this company for four years.

---

[1] Memoir prepared by Lebrecht J. Klug, Assoc. M. ASCE.

In September, 1918, he entered business as S. M. Siesel, Contractor, and continued to operate in this way until 1922 when he incorporated under the name of S. M. Siesel Company. Later it was changed to Siesel Construction Company, of Milwaukee and Pittsburgh, with Mr. Siesel as president and general manager. He was very active in this capacity until December, 1945, when illness prevented further work and resulted in his death in 1946.

Mr. Siesel was widely known, both professionally and socially. He was an active member of the Engineers' Society of Milwaukee, the Wisconsin Society of Professional Engineers, the Associated General Contractors of America, and the Master Builders Association of Pittsburgh.

In addition, he served as a member of the Milwaukee Building Code Committee and as president of the Milwaukee Employers' Building Trades Association, which he was instrumental in founding. He was influential in bringing about the enactment of the Tehan Slum Clearance Law by the Wisconsin State Legislature in 1945. This law granted to municipalities the power to condemn and claim land for slum clearance and to eliminate blighted areas.

He was a Thirty-Second Degree Mason and maintained memberships in the Milwaukee Association of Commerce, the Milwaukee Athletic Club, the Elks Club, the Woodmount Country Club, and the Westmoreland Country Club in Pittsburgh. He also served as treasurer of the Milwaukee Urban League and as president of the Mount Sinai Hospital Association of Milwaukee.

The work of Mr. Siesel was characterized by an ability, determination, and thoroughness which commanded the respect and praise of clients, fellow engineers, and contractors. Among the many engineering and construction accomplishments in which he was engaged during his lifetime, the following are particularly deserving of mention:

The Milwaukee County Court House, perhaps the largest and most beautiful building in Milwaukee County, the Mariner Tower, the Shorecrest Hotel, and the Mount Sinai Hospital—all in Milwaukee; the German Evangelical Protestant Smithfield Church and the Allegheny County Office Building in Pittsburgh; the Scottish Rite Cathedral in Newcastle, Pa.; the Department of Justice Building foundations in Washington, D. C.; and the twenty-seven-story Exchange National Bank Building in Tulsa, Okla.; and the Robert E. Lee Bridge in Richmond, Va.

During World War II, under the administration of the Defense Plant Corporation, Mr. Siesel's work was most outstanding in the construction of the Allis-Chalmers supercharger plants No. 1 and No. 2 in West Allis, Wis., the addition to the Ford Motor Company plant in Milwaukee, and the new forge shop for the Continental Can Company in McKees Rocks, Pa.

In 1944 he was chosen as a member of a special committee by the Society to complete an exhaustive study and to prepare a report on classifications and salaries for engineering employment in the Milwaukee area. His diligence and untiring efforts while serving on this committee were invaluable as he was intimately familiar with the local situation, and, at the same time, was able to maintain the objective point of view which, in itself, was a noteworthy achievement. The results of the study and the subsequent report as prepared by this committee were valuable contributions to the engineering profession.

On June 24, 1915, Mr. Siesel was married, in Pittsburgh, to Dorothea Jacobs, a native of England. Shortly thereafter he moved his family to Milwaukee. He is survived by his widow and three daughters, Barbara, Ruth Peggy, and Claude Sally.

Mr. Siesel was elected a Member of the American Society of Civil Engineers on February 24, 1931.

JOSEPH EMORY SIRRINE, M. ASCE[1]

Died August 7, 1947

Joseph Emory Sirrine was born in Americus, Ga., on December 9, 1872. He was the son of George William and Sarah Euodias (Rylander) Sirrine. Both his father and grandfather were Confederate soldiers, although the family was originally from Connecticut.

The family of George William Sirrine moved to Greenville, S. C., in 1876, and Joseph was educated in the Greenville Military Institute (1883–1886); then, he received the degree of Bachelor of Science from Furman University in Greenville in 1890. Mr. Sirrine received the degree of Honorary Mechanical Engineer from Clemson College (Clemson, S. C.), in 1928, and a degree of Doctor of Laws from the Presbyterian College (Clinton, S. C.), in 1941.

Mr. Sirrine engaged in private practice as a civil engineer from 1890 to 1895. He then worked (from 1895 to 1902) with Lockwood, Greene and Company of Boston, Mass., and from 1898 to 1902 served as southern manager for that company. In 1902 he went into business for himself and in 1921 formed a partnership with eight of his associates in the name of J. E. Sirrine and Company, Engineers. The business now continues under the name of J. E. Sirrine Company with eleven partners.

The scope of the company's work is illustrated by its activities during World War II. Among other projects were included the erection of four shipyards for the United States Maritime Commission, two major camps for the War Department, together with many smaller projects for the War Department, such as air bases, ammunition depots, and so on. The firm also did major construction work for the Charleston (S. C.) navy yard and the Parris Island (S. C.) marine barracks. Also, for the Defense Plant Corporation they built aluminum plants, and two plants for the manufacture of rayon tire cord, as well as doing a good deal of work for the Reconstruction Finance Corporation.

Mr. Sirrine belonged to the following organizations: The American Society of Mechanical Engineers; the American Institute of Electrical Engineers; the Newcomen Society of England; Greenville Elks Lodge, No 858 (honorary member); the A. F. and A. M. Recovery Lodge, No. 31; the Knights Templar; and Hejaz Temple. He was also a life trustee of Clemson College, past-president of the Greenville Chamber of Commerce, head of the Greenville Community Chest, past-president of the Young Men's Christian Association, and past-president of the Greenville Rotary Club (one of the international organization's few honorary members). Mr. Sirrine was an Episcopalian, being a former member of the vestry of Christ Episcopal Church in Greenville. In politics he was an independent Democrat. His clubs were the Greenville Country Club, the Poinsett Club, the Cotillion Club, the Biltmore Forest Country Club, and the Merchants Club of New York.

---

[1] Memoir prepared by H. L. Hagerman, M. ASCE.

He was chairman of the board of the Brandon Corporation, vice-president of four South Carolina textile concerns, and a director of nineteen other textile companies throughout the southeast. He was also a director of the First National Bank of Greenville, the Liberty Life Insurance Company, and the *Greenville News-Piedmont* (morning and afternoon papers in Greenville).

Mr. Sirrine was a member of the Cotton Mill Industry Advisory Committee for the War Production Board during World War II. During World War I he was chairman of the Price Fixing Committee for Cotton Textiles.

The following words speak so well of Mr. Sirrine, as the world knew him, that they can well be repeated herein:

> "The value of his counsel and assistance so freely given, and the value of his sound and experienced judgment can be visualized but it cannot be measured.
>
> "His ability in solving difficult problems and in clarifying difficult situations was one of his many great characteristics.
>
> "His willingness to give of his time, his thought and his substance for the benefit of others was known by all who knew him, and by many who only knew of him.
>
> "His was a life based upon studious practical learning, sound thinking, fair dealing, honest ambition for others as for himself, faith in honest undertakings, and a belief in his fellow men. He was tolerant with men's failures and intolerant only with dishonesty and greed.
>
> "In his heart there was love of thousands and hate for no one. His life, his vision and his encouragement have been an inspiration to an untold number of people."

His death marked the close of a colorful career.

On November 8, 1898, Mr. Sirrine was married to Jane Pinckney Henry of Greenville. She died on July 31, 1938. They had no children.

Mr. Sirrine was elected a Junior of the American Society of Civil Engineers on June 20, 1893; an Associate Member on May 4, 1898; and a Member on May 6, 1903.

LEONARD SEWALL SMITH, M. ASCE[1]

DIED JULY 1, 1947

Leonard Sewall Smith was born in East Troy, Wis., on February 14, 1864. His father, Charles Warren Smith, a merchant, who had migrated from Vermont to Wisconsin in 1840, was married to Mary Buell Edwards. Their family consisted of four daughters and two sons.

Young Leonard matriculated at the University of Wisconsin in Madison, entering from the Whitewater Normal School (Whitewater, Wis.) as a special freshman in 1886. In college he was a member of Beta Theta Pi fraternity and of the college band. The university conferred on him the degree of Bachelor of Science in Civil Engineering in 1890.

His first job as a young engineer was with the Union Pacific Railroad Company at Omaha, Nebr., where he worked as a draftsman in the office of the chief engineer from June to December, 1890. In the spring of 1891, he went to upper Michigan to do some topographic surveying for Prof. Charles R. Van Hise (later president) of the University of Wisconsin. He continued there until the spring of 1892 when he began work as transitman on the international boundary survey.

Mr. Smith began his teaching career as an instructor in engineering at the University of Wisconsin in January, 1894. He taught surveying and established a reputation as an effective teacher in that field. When the "good roads" movement began to attract wide attention, he introduced in 1905, the university's first course in roads and payments. This course expanded and, in 1925, became the course in highway engineering. As interest in housing and city planning developed in the more advanced nations, Professor Smith introduced a course in city planning in 1915 that proved popular. In 1920, Professor Smith was appointed professor of highway engineering and city planning, which title he held until his retirement.

Professor Smith was not an academic recluse; he felt the urge to put his professional knowledge to practical application. As a young teacher of surveying, he frequently pulled on the high boots that distinguished the young engineer of the period, and took to the field to lay out a new subdivision for the growing little city of Madison. He designed and platted many of its well-known sections. These contacts led to business connections that made him director for both the Royal Securities Company and the Madison Realty Company. From 1897 to 1905, Professor Smith was hydrographer for the Wisconsin Geological and Natural History Survey and from 1901 to 1905 was engineer for the Wisconsin Levee Commission. During the summer of 1918 he worked for the United States Housing Corporation of the Department of Labor.

In the early part of the century the records show that a number of the members of the engineering faculty engaged in local political activity. Professor Smith was one of this group and served as alderman from the Fifth Ward in 1905–1906. He introduced the ordinance that established the famous "Half-mile Dry Zone" around the university and created a desert that existed until the repeal of the prohibition amendment. After he had been appointed professor of city planning, Professor Smith was called upon by various Wisconsin cities to assist with the preparation of city plans and zoning ordinances—Appleton, Eau Claire, Madison, Manitowoc, Oshkosh, Racine, Waukesha, and Wausau all benefiting from his professional assistance and advice.

---

[1] Memoir prepared by Ray S. Owen, Prof. Civ. Eng., Univ. of Wisconsin, Madison, Wis., based on resolutions adopted by the faculty of the Univ. of Wisconsin, dated October 6, 1947.

A paper on surveying was the result of his experience as surveyman on the international boundary survey between the United States and Mexico.[2] This paper, written in 1895, was accepted as a thesis for the professional degree of Civil Engineer and was also printed as a United States Senate document. A "Field Manual of Engineering Instruments" appeared in 1900. A hydrographic map of Lake Mendota and the adjacent topography, published by the Wisconsin Geological and Natural History Survey, was based upon surveys made by civil engineering students under his direction, and, in 1908, the same survey published Professor Smith's report on the water powers of Wisconsin. In 1910, he revised an earlier textbook[3] by J. B. Johnson,[4] M. ASCE.

Professor Smith made a number of trips abroad. In 1912–1913, he took his family on a journey through England, France, Germany, and Switzerland and in 1920, he was an American delegate to the World Congress on Housing and Town Planning held in London, England. Accompanied by Mrs. Smith, in 1923, he attended the Fourth International Good Roads Congress in Seville, Spain, where he presented a paper on the "The Relation of Modern Traffic to the Planning of Streets." Following the meeting, he and Mrs. Smith toured Spain, France, Italy, Norway, and Sweden. He spent the month of October, 1926, in Japan, inspecting the work of reconstruction that followed the great earthquake of September 1, 1923. The Japanese government extended many courtesies to him and he lectured at the universities at Osaka, Kobe, and Tokyo.

The Engineering Society of Wisconsin was one of Professor Smith's hobbies. He served the society as secretary from 1915 to 1926, during which time the membership quadrupled and the society resumed and continued publication of its *Proceedings.* At a joint meeting of the society and the Technical Club of Madison, on February 18, 1927, he was presented with a watch in recognition of his eleven years of service.

He retired from teaching in February, 1929, and went to California, where some of his children had established themselves. He joined the Los Angeles City Planning Association and engaged actively in city planning. In addition to other work, he assisted with the preparation of plans for San Clemente and laid out that subdivision. He also made plans for National City and for Hollywood Rivera. (All those communities are in Southern California.)

---

[2] "An Experimental Study of Field Methods Which Will Insure to Stadia Measurements Greatly Increased Accuracy," by Leonard S. Smith, *Bulletin No. 5,* Univ. of Wisconsin, Madison, Wis., 1895.

[3] "The Theory and Practice of Surveying Designed for the Use of Surveyors and Engineers Generally, But Especially for the Use of Students in Engineering," by J. B. Johnson, 17 Ed., rewritten by Leonard S. Smith, John Wiley & Sons, Inc., New York, N. Y., 1910.

[4] For memoir, see *Transactions,* ASCE, Vol. LI, December, 1903, p. 454.

For the few years prior to his death Professor and Mrs. Smith lived in Stockton, Calif., at the home of their daughter, Ruth. To the last, he maintained his interest in educational activities, attending classes in German and other subjects, and occasionally lecturing to the students of the College of the Pacific (Stockton) on city planning.

His death removed one of the most colorful of the early teachers who created the College of Engineering at the University of Wisconsin. Through a long career, he retained, undimmed by the passing years, an energy that drove him from one accomplishment to another, and an enthusiasm that made all work seem worthy of his best effort. He was devoted to his family, of which he had reason to be proud, and was a good citizen who took his duties seriously, both in private life and in public office. Professor Smith was a conscientious and effective teacher. There developed through the years a "Lenny Smith" tradition as he was enthusiastic and colorful; it is held in fond remembrance by hundreds of engineers who, as students, sat in his classes and worked in the field under his guidance. From their contacts with him, they acquired, along with professional competence, a fund of anecdotes that will, for many years, keep alive his memory.

Besides serving the Engineering Society of Wisconsin, Professor Smith was a member of the American Institute of City Planning, the American Civic Association, the City Planning Commission of Madison, the Los Angeles City Planning Association, the University Club of Madison, and the Los Angeles City Club.

In 1893, Leonard Smith was married to Lucy Fowler Austin in his home town of East Troy. In the course of time, the family circle was increased to six by the arrival of four children. He is survived by his children: Maxwell Austin, dean at the University of Chattanooga (Chatanooga, Tenn.); Helen (Mrs. Robert Postgate) of Maracaibo, Venezuela; Ruth, professor of French at the College of the Pacific; and Lucy (Mrs. Alfred E. Ellerby) of Lander, Wyo. There are seven grandchildren. Two sisters, Grace (Mrs. White Jones), of Madison, and Marie (Mrs. E. S. Park), of Fond du Lac, Wis., also survive.

Professor Smith was elected an Associate Member of the American Society of Civil Engineers on June 2, 1897, and a Member on February 28, 1911. He became a Life Member in January, 1932.

JESSE BAKER SNOW, M. ASCE[1]

DIED JUNE 16, 1947

Jesse Baker Snow was born on May 26, 1868, at Nantucket, Mass., on the Island of the same name off the south coast of Cape Cod. He was one of five children born to Charles E. and Emily Jane (Carpenter) Snow.

---

[1] Memoir prepared by Louis E. Robbe, M. ASCE.

An ancestor landed at Plymouth, Mass., in 1623, from the historic *Mayflower* on one of her trips from England and in 1823 his paternal grandfather moved from Cape Cod to Nantucket where he later became the father of fourteen children. Emily Carpenter's grandfather was a Macy, of the family which started the department store of R. H. Macy and Company in New York, N. Y. Both sides of Mr. Snow's family had sons in the early wars of colonial days and in the later wars of the United States. Two of his grandsons served in World War II.

His father was in the packet trade, operating a schooner for many years and later became a Nantucket merchant. It was in this environment that Jesse Snow grew up, knowing something about transportation by sea and observing some of the lack of proper transportation by land. Perhaps he was influenced by the then popular era of street railway construction in choosing engineering as a career. He passed through the common and high schools at Nantucket and was graduated from Union College in Schenectady, N. Y., with the degree of Civil Engineer in 1889.

Immediately after graduation Mr. Snow held for four months a field position on surveys and cost estimates for sewer and drainage works at Goshen, N. Y., and at Long Island City, N. Y., after which he returned to his home town and entered private practice. There he laid out and built the first horse drawn streetcar line and made plans for extending it seven miles to Siasconset. He also assisted with plans and layouts for a sanitary system for Nantucket which then (1890) was only partly constructed. It is interesting to note that thirty-eight years later another engineering firm made a new design which was almost identical with Mr. Snow's, showing that sound principles and good judgment produce engineering designs which are unaffected by years.

In 1891 he followed Horace Greeley's advice and went west as far as West Superior, Wis., where he engaged in the private practice of land surveying and general engineering. About a year later he contracted typhoid fever and was forced to go home to recuperate. When restored to health he went to North Tonawanda, N. Y., engaging in the construction of street railways and land subdivisions.

After a year of this work Mr. Snow formed a partnership with another engineer, T. W. Barrally, in 1893 and together they engaged in municipal engineering. As city engineers for Tonawanda and North Tonawanda they designed and constructed sewers; brick and macadam pavements; extensions to the water supply and pumping plant, including new intake piers in the Niagara River; and bridges and culverts—construction totaling about $550,000. They also made assessors' maps, railroad property valuations, and constructed eight miles of electric street railway. After five years he terminated this partnership and became resident engineer on the constructions of water works and sewers in five towns in New York, Pennsylvania, and Ohio, totaling $100,000. Shortly afterward he built ten miles of single-track steam railroad for the Jamestown, Chautauqua and Lake Erie Railroad Company ($350,000) at Westfield, N. Y.

In 1902, after gaining thirteen years of field experience, Mr. Snow was ready to accept a more responsible assignment. He became chief engineer, first, of the Jersey Central Traction Company and, later, of the West Chester, Kennett and Wilmington Electric Railway (in Pennsylvania and Delaware). He secured the rights of way and the various local franchises and constructed about forty miles of street railway from South Amboy to Red Bank, in New Jersey, from Avondale, Pa., to Brandywine Springs, Del.

After two years of this work Mr. Snow decided to broaden his construction experience by working for a contractor. Thus, he became a superintendent on railroad construction at Occoquan, Va., and on water works improvements at Bellaire and Portsmouth, Ohio. Five months later he returned to engineering, undertaking surveys and estimates for a power development project at Walling, Tenn., for the Tennessee Power Company and, later, made surveys in New York City.

In November, 1905, he started on work which he learned to like so well that it became his specialty—compressed air subaqueous river tunneling. At first he was in a minor position on the engineering staff of the Pennsylvania Tunnel and Terminal Railroad Company of which Alfred Noble,[2] Past-President, ASCE, was chief engineer. At that time the company was constructing the four tunnels under the East River (New York) to be used by the Long Island Railroad. He was quickly promoted to first assistant to the resident engineer in charge of the two southerly tunnels, and was placed in charge of the alinement and inspection forces. Later, this was extended to include the cross-town tunnels extending from the East River back to the Pennsylvania Station on Manhattan Island.

On completion of this work in 1910 and because of his experience with construction under compressed air and water works construction, he was sent to Hauser Lake Dam, in Montana, by the Foundation Company. On this project he was engineer and assistant superintendent on the foundation work and also on the design and construction of the caissons and cofferdams, two of which had failed prior to his going there. After eight months his work was completed and he returned to New York where he was busy for about three years on various projects. These included a proposed large hydroelectric development near Port Jervis, N. Y. ($40,000,000), for which he was field engineer making surveys and reports for Canada Syndicate, Limited, of Montreal. He also prepared reports and cost estimates on other proposed hydroelectric developments for Charles Cooke, consulting engineer.

In 1914 he succeeded in returning to work of his primary interest, becoming resident engineer on the construction of compressed air subaqueous tunnels for the New York Public Service Commission. At that time the commission was undertaking a great subway construction program in New York with four pairs of tunnels planned under the East River. Mr. Snow was, simultaneously, in charge, on the Manhattan side, for both the Old Slip-Clark Street ($7,300,000) and the Whitehall Street-Montague Street ($6,300,000) tunnels for about one year; and then he supervised the Fourteenth Street-North Seventh Street tunnels ($6,800,000) for about three years. Here he came in contact with Clifford M. Holland,[3] M. ASCE, then in charge of all the commission's tunneling operations.

---

[2] For memoir, see *Transactions*, ASCE, Vol. LXXIX, 1915, p. 1352.

In 1919 he and Mr. Holland joined the New York, New Jersey (Interstate) Tunnel Commission, then undertaking the construction of the now famous Holland vehicular tunnels under the Hudson River. He became principal assistant to Mr. Holland, who was chief engineer and greatly assisted in the organization of the force and in the actual construction of the two tunnels.

In 1921 combined railroad and rapid transit tunnels were proposed under the Narrows between Staten Island and Brooklyn by the Board of Estimate and Apportionment of New York City, of which Arthur S. Tuttle, Past-President and Hon. M. ASCE, was then chief engineer. Mr. Snow, now gaining prestige and renown in the construction of subaqueous tunnels, was thus the logical selection as tunnel engineer. He set up an organization; two steel pneumatic caisson shafts were sunk to grade; and he had the designs well advanced for the entire project ($60,000,000) and was advertising for bids for the construction of the two tunnels when the work was stopped in 1925 by the state legislature.

Mr. Snow was then appointed division engineer in the Board of Transportation of New York City (successor to the Public Service Commission), in charge of the subaqueous tunnels to be built in another great expansion of subway construction. Under his direction the following rapid transit tunnels were built under the East River using compressed air: Fifty-third Street, Manhattan-Nott Avenue, Queens (two tunnels); Fulton Street, Manhattan-Cranberry Street, Brooklyn (two tunnels); and Rutgers Street, Manhattan-Jay Street, Brooklyn (two tunnels). In addition, three tunnels were built from 157th Street in Manhattan under the Harlem River to the Bronx and two tunnels, under Newtown Creek in Queens. The contracts for this work totaled about $71,000,000.

In December, 1933, Mr. Snow became acting chief engineer and, in February, 1934, chief engineer of the Board of Transportation. During his incumbency the Sixth Avenue (Manhattan) subway ($50,000,000) was designed and constructed. This was the most intricate and most difficult subway yet built because of the presence, at the time of construction, of the Sixth Avenue elevated railroad and the street surface transportation throughout its length and the Hudson and Manhattan Railroad tunnels and stations along part of its length, as well as the several subsurface transit facilities crossing Sixth Avenue. Between Thirty-second and Thirty-fifth streets are the Long Island Railroad tunnels, the Hudson and Manhattan Railroad station, and the Brooklyn-Manhattan Transit (B.M.T.) subway and station. It was necessary to remove and rebuild the Hudson and Manhattan Railroad station and to alter the other conflicting structures to provide sufficient clearance to build the new subway and station in that area.

---

[3] For memoir, see *Transactions*, ASCE, Vol. 89, 1926, p. 1625.

The Fulton Street subway line in Brooklyn was extended ($25,000,000) and the Hillside Avenue connection in Queens ($7,500,000) was built. In addition, nearly nine hundred new subway cars ($36,000,000) were designed and added to the operation equipment of the subway besides making an extension to the subway to reach the World's Fair grounds, in Flushing Meadows, in Queens ($2,000,000). The existing elevated railroads became outmoded and the Sixth Avenue line, the Ninth Avenue line, and a large part of the Second Avenue line (all in Manhattan) and the Fulton Street line (in Brooklyn) were removed.

In June, 1940, the B. M. T., the Interborough Rapid Transit (I. R. T.), and the Eighth Avenue (Independent System) subway lines were consolidated and Mr. Snow then became chief engineer of the entire system. The consolidation greatly enlarged his duties and responsibilities, and about doubled the engineering employees under his authority.

His plans for future subways and extensions were extensive; among these were the Second Avenue (Manhattan) line estimated at $400,000,000 and the Concourse (Bronx) line extension at an estimated cost of $30,000,000, as well as many others of lesser importance.

Because of his knowledge of compressed air tunnel construction, the New York City Tunnel Authority arranged for his services as consulting engineer on the Queens-Midtown East River vehicular tunnels, then being constructed. This was in addition to his duties with the Board of Transportation. He served in this dual capacity from 1936 to 1939 and again from 1940 to 1943 when the Brooklyn-Battery tunnel was started. (In 1933 he presented a paper bofore the Metropolitan Section of the Society on the "Fulton Street-Cranberry Street East River Tunnels.")

After reaching the mandatory retirement age of seventy the Board of Estimate, on four occasions, extended his employment by the city. However, on May 31, 1945, he finally retired after a period of fifty-six years of engineering activity including twenty-nine years service with the city. His extensive experience and great ability brought him to the forefront in his profession and he was regarded as the outstanding compressed air tunnel engineer and one of the foremost subway engineers in the United States. He had an active part in the construction of twenty-three rapid transit, railroad, and vehicular tunnels of a total of forty one constructed along the periphery of Manhattan, besides the two additional rapid transit tunnels under Newtown Creek in Queens. No other engineer has had such a direct hand in the design and construction of so many subaqueous tunnels by the use of compressed air.

Through his ingenuity the junctioning of the river shields in earth, instead of rock, was first accomplished on the Fulton Street tunnels. He also raised the river bottom of the East River, between Welfare Island and Manhattan, sufficiently to embed the two Fifty-third Street tunnels and provide them with earth and riprap cover for protection. Improvements in the design of the cast-iron tunnel rings by the insertion of a third and intermediate flange lengthwise (which provided greater stiffness and thus enabled wider tunnel rings to be used) were also credited to Mr. Snow. In addition to great ability, Mr. Snow had a keen mind, a very retentive memory, and was attentive to details. He was noted for his generosity and his loyalty to all those who served under him. Outstanding was his great capacity for hard labor, his only hobby was taking work home at night.

Civil engineering fitted him well for he loved the life that it gave, and it brought him happiness and satisfaction, not only through the details of under-river tunnel and subway construction but also in the making of estimates of quantities and costs. He was very retiring by nature and refrained from making many friends; his love of home and of family was his main comfort in life. Mr. Snow's great contribution to the life in which he lived was to provide better, faster, and more extensive transportation for the people of New York City.

Because of his renown as a tunnel and construction engineer Mr. Snow was honored by his alma mater, Union College, with the degree of Doctor of Science in 1930. He was a member of the Railroad Club and the Engineers' Club and was a licensed professional engineer in New York State. In college he had been a member of Delta Upsilon fraternity and of the honorary society of Sigma Xi.

Honoring his memory at his funeral were many of the leading engineers and representatives of large contracting organizations besides many intimate friends and former employees.

He was first married to Eleanor Curtis Harman of Schenectady. To this happy union, two children were born, Annette W. (Mrs. Earl Allington) and Charles G. Snow. His wife died a few years after they were married, but he maintained his home and kept his little family together. In 1903 he was married to May Purdy whom he had met while working in New Jersey. They enjoyed a very happy companionship for many years, broken only by her death a few months after his retirement. They had one son, Edgar P. Snow. Surviving him are the three children, seven grandchildren, and one great-grandchild.

Mr. Snow was elected a Member of the American Society of Civil Engineers on October 2, 1907. He became a Life Member in January, 1939.

ISAAC JOSHUA STANDER, M. ASCE[1]

DIED FEBRUARY 13, 1947

Isaac Joshua Stander was born on January 26, 1872, in Riga, Latvia. His parents were Lazarus Joseph Stander, a gifted musician with a beautiful lyric tenor voice, and Rose (Soloway) Stander. His father died at the age of forty-four as the result of an accident when "Ike" was sixteen years old. Three years later he came to the United States, the "land of promise."

---

[1] Memoir prepared by William Goldsmith, M. ASCE.

In the "land of promise" he followed the usual Horatio Alger pattern. Within one year he had prepared himself by his own efforts for entrance into the School of Engineering of Columbia University in New York, N. Y., in 1893. Mr. Stander belonged to the "Forty-Niners," a group of men who studied when Columbia University held sessions at Forty-Ninth Street and Madison Avenue. In 1897 he was graduated from Columbia University with the degree of Civil Engineer, and immediately entered the engineering field as a draftsman for the City of New York and later for the Purdy and Henderson Company. For sixteen years (from 1900) he specialized in the design and construction of docks, bulkheads, piers, and all phases of water front construction for the Department of Docks of New York. The ten years that followed found him busy as a contracting engineer on water front, building, and underpinning work also in New York.

From 1925 to 1935, when subway construction was active in that city, Mr. Stander became, successively, chief engineer for the Hyman and Goodman Company, chief engineer for the Clementi Contracting Company, and consultant on subway work for other large contractors. In 1935 he went back to his "first love"—water front construction—remaining in this type of work until his death; and, successively, he was associated with the Triborough Bridge Authority, superintending the construction of the East River and Harlem River drives, and with the president of the Borough of Manhattan on the design and construction of the lower section of the East River Drive. In 1942 Mr. Stander was retired on a pension by the City of New York. However, he was not content to be idle, and he became a private consultant, specializing in New York water front construction for local contractors.

His splendid accomplishments in engineering do not tell the complete story of his well-filled life. He was a devoted husband to his wife, Lena Smith, one of his childhood friends, to whom he was married on November 15, 1892. Mrs. Stander died on January 27, 1936, after forty-four years of happy married life. He was a cherished and respected father of three daughters and one son: Thamara, an outstanding physician; Elizabeth (Mrs. Harold Pimblett) of Alvinston, Ont., Canada; Ruth (Mrs. Meyer M. Harris), who was married to a physician; and Joseph L., who followed in his father's footsteps in construction work. There are also four grandchildren of whom Ike was very proud. In March, 1939, he was married to Mrs. Ray W. Sundelson who survives him.

However, Ike's home duties did not prevent him from being of both financial and professional assistance to his many friends. No matter who requested aid, Mr. Stander would always offer a helping hand. The writer can vouch for this wonderful trait in Ike, for it was through Ike's efforts that his first engineering position was received, after graduation from school. That fine deed to a comparative stranger has never been forgotten.

One of Mr. Stander's outstanding characteristics was his unshakable belief that a man's word was as good as his bond, and he persisted in that behavior pattern as long as he lived. Possessed with an excellent sense of humor, it carried him over rough experiences and showed in his good nature. His zest for living remained undiminished, even when his physical condition limited his activities to a minimum. His plans were always cheerful and hopeful. During his last days he was strongly advised against climbing stairs, yet, each morning at the nursing home in Florida where he passed his last days, he climbed the stairs to make the rounds of those who were bedridden—brightening them by reading the newspapers, telling humorous stories, and generally spreading cheer. It was especially fortunate for those who loved him that his last and only illness was of short duration.

It can be said of Isaac Stander, an outstanding engineer, that his principal characteristic was a sense of human values. He recognized that these values were more important than material accomplishments and, when he passed on, his friends and associates realized and appreciated that the world was better, both spiritually and materially, for his having "passed this way."

Mr. Stander was elected a Member of the American Society of Civil Engineers on October 10, 1921. He became a Life Member in January, 1946.

HOMER REED STANFORD, M. ASCE[1]

Died April 7, 1947

Homer Reed Stanford was born on June 26, 1865, in Alton, Ill. His parents were Homer Stanford of Alton and Evalyn Clark of Boston, Mass.

In 1820 Joshua Reed Stanford, whose ancestors came from England to Massachusetts in about 1650, faced the hardships of the westward migration of that time with his wife Elizabeth. They settled in Griggsville, Ill., and later moved to Alton, where a son, Homer Stanford (father of Homer Reed Stanford), was born in 1835. The present city hall of Alton is located on the site of the Stanford family homestead.

Young Stanford attended the local public schools, being graduated from the Alton High School in 1881. He then took a course in the St. Louis (Mo.) Manual Training School and in 1884 entered Washington University in St. Louis. At the university his scholarship won him election to the Sigma Xi society and he was graduated in 1888 with the degree of Bachelor of Engineering, magna cum laude.

During the ten years following graduation he had varied engineering experiences. These included surveys for the design of sewer and irrigation works, shop inspection and erection supervision of steel bridges, supervision of a metallurgical laboratory, and superintendence of a bridge company.

In 1898 the war with Spain created a demand for a material enlargement of the shore facilities of the United States Navy. The existing strength of the Civil Engineer Corps of the Navy was insufficient to handle the expanded requirements and a considerable increase in the corps was authorized by Congress. Additional officers were selected from applicants whose records of education and experience were satisfactory and who attained a high mark in a comprehensive examination. Mr. Stanford met these requirements and in May, 1898, was commissioned a Civil Engineer in the Navy with the rank of Lieutenant (jg).

---

[1] Memoir prepared by DeWitt C. Webb, M. ASCE.

After a short period of indoctrination at the Bureau of Yards and Docks of the Navy in Washington, D. C., he was ordered to the navy yard at Boston. From there he was sent to the Philippines where he made subsurface investigations and prepared plans and specifications for a large coaling plant. Returning to the United States he was assigned, successively, to the navy yards at Mare Island, Calif., Pensacola, Fla., and Philadelphia, Pa., and was promoted, first, to the rank of Lieutenant and then to that of Lieutenant Commander. His efficient and economical handling of day labor construction work at Philadelphia was noted by the Secretary of the Navy. Doubtless this was a material factor in bringing about his appointment, in January, 1912, as chief of the Bureau of Yards and Docks with the rank of Rear Admiral.

As chief of the bureau Admiral Stanford was responsible for the solution of many complex engineering problems, the most difficult of which was the completion, after an initial failure, of a large masonry dry dock at Pearl Harbor, Hawaii. This work was fully described in a paper[2] by Admiral Stanford, and in 1917 he received the Society's James Laurie Prize for this paper.

After the completion of his four-year term as chief of the Bureau of Yards and Docks he was assigned to duty at the Philadelphia Navy Yard and, later, at the Boston Navy Yard. While in Boston the State of Massachusetts was constructing the large Commonwealth dry dock in South Boston. Admiral Stanford was designated naval representative on this work, advising in its design and construction to insure that, when completed, the dry dock would be suitable for use by naval vessels.

After leaving Boston Admiral Stanford was for several years a special adviser to the chief of the Bureau of Yards and Docks. Among other tasks during this period he was ordered to Manila, Philippine Islands, to investigate and report on the location of a large floating dry dock. He was also a member of a board charged with the settlement of claims for damages to fishing rights in Naval waters at Pearl Harbor.

On June 26, 1929, Admiral Stanford was placed on the retired list, in accordance with law, at the age of sixty four. The occasion was marked by a dinner given by his associates in Washington and vicinity. After his retirement he continued to live in Washington, and, later, in Chevy Chase, Md.

Admiral Stanford was awarded the Navy Cross for his work in World War I, and also received the Spanish American War and Philippine Insurrection medals. In 1937 he was awarded the honorary degree of Doctor of Science by Rensselaer Polytechnic Institute in Troy, N. Y. He was a member of the Metropolitan and Chevy Chase clubs, and of the Boston Society of Civil Engineers, the Franklin Institute, and the Newcomen Society. He was an expert contract bridge player and an enthusiastic golfer. Weather permitting, a round of golf was a vital part of his daily routine up to the commencement of his last illness.

---

[2] "Pearl Harbor Dry Dock," by Homer Reed Stanford, *Transactions*, ASCE, Vol. LXXX, December, 1916, p. 223.

Admiral Stanford loved his family, his friends, and his work. He had a keen business sense and was energetic and impulsive. True to Navy tradition he was critical of delays, errors, and inefficiency.

In 1896 he was married to Maidie Mason, the daughter of Carrington and Maria Bodie Mason, of Memphis, Tenn. Mrs. Stanford died on November 10, 1923. Admiral Stanford is survived by a son, Carrington Stanford of Wayne, Me., and a daughter, Elizabeth (the wife of Rear Admiral Earl LeRoy Sackett, U. S. Navy, Retired).

Funeral services were held at the Fort Myer, Va., chapel and interment was in Arlington Cemetery in Virginia with the honors accorded to his rank.

Admiral Stanford was elected a Junior of the American Society of Civil Engineers on October 1, 1890; an Associate Member on November 7, 1894; and a Member on September 4, 1901. He became a Life Member in January, 1929.

HENRY ARTHUR VAN ALSTYNE, M. ASCE[1]

DIED JANUARY 23, 1947

Henry Arthur Van Alstyne was born at North Chatham, N. Y., on October 9, 1869. He attended the Nassau (N. Y.) Academy and Marshall Seminary at Easton, N. Y. He then worked about three years at the Schenectady (N. Y.) plant of the General Electric Company to earn money to pay for a college education. He was graduated from Union College at Schenectady in the class of 1893 with the degree of Civil Engineer. In college he was a member of the Psi Upsilon fraternity and in his senior year was elected a member of the scientific society of the Sigma Xi.

After graduation Mr. Van Alstyne worked about a year as assistant city engineer of Schenectady and another year constructing a system of sewers in the Village of Fort Plain, N. Y. He then spent about three years, 1894 to 1897, as leveler and assistant engineer in the Rochester (N. Y.) office of the state engineer and surveyor. He left this office for about two years to do special work for other employers and re-entered state service in 1899 as first assistant engineer in the Eastern Division office. In that same year he was promoted to resident engineer, and in 1901 division engineer, Eastern Division.

In 1903 the people of the State of New York had approved the Barge Canal Law appropriating $101,000,000 for the construction of the Barge Canal. An Advisory Board of Consulting Engineers was appointed to pass upon the design of the canal. The late Edward A. Bond, M. ASCE, resigned as state engineer to accept the chairmanship of that board. Benjamin B.

---

[1] Memoir prepared by Frederick W. Newton, Assoc. M. ASCE.

Odell, Jr., then Governor of New York State, appointed Mr. Van Alstyne to succeed Mr. Bond as state engineer and surveyor. In November of that year Mr. Van Alstyne was elected to the office for a full term. Eleven years after graduation from college, it became his job to create the organization which was to design and supervise the building of the Barge Canal. He was in charge of one of the greatest engineering projects of all time.

That was not all. The state engineer was also responsible for the highway work in the state. When Mr. Van Alstyne entered office there were no state highways, and in the preceding seven years, from 1898 to 1904, the state had appropriated only $3,273,000 as its share of the cost of building and maintaining "state-aid" roads. Mr. Van Alstyne was not satisfied; he worked and lectured in support of the "good-roads" movement, and for greater participation by the state. In 1905 the people amended the constitution to authorize the state to borrow $50,000,000 for highway work, and in 1906 the state spent more than $5,000,000 on its roads—all designed and supervised by the state engineer's office.

Road building in 1905 was not the science that it later became. Mr. Van Alstyne explained in a lecture given at Cornell University at Ithaca, N. Y., in May, 1905, that under the law he had a choice of a telford or a macadam or a gravel surface and he might in a proper case use brick or a steel rail track. He ordered a series of experiments with the use of road oil and he particularly recommended the use of oils with an asphalt base. Such experiments had already been conducted in California, and Mr. Van Alstyne remarked particularly that Nassau County had taken the lead in similar experiments in the east. The use of concrete in road work was not considered—concrete being mentioned only as a substitute for stone masonry in structures. However, the State Testing Laboratory reported in both 1904 and 1905 that Portland cement had not yet reached the required standards and that many of the samples submitted were rejected. There was so much public distrust of the durability of concrete structures that a special committee was appointed to determine whether concrete was sufficiently reliable to be used in the structures for the Barge Canal.

In his search for suitable materials for road surfaces Mr. Van Alstyne in 1904 retained Prof. William H. Burr,[2] M. ASCE, to test all the rocks of the state for resistance to abrasion and for a stone dust which would make a suitable binder for water-bound macadam. One of the recommendations in Mr. Van Alstyne's report for 1904 is interesting in that it undoubtedly represents the first gun in an ever-continuing battle—the assessment of an automobile license tax, the proceeds to be used exclusively for the maintenance of roads.

The Barge Canal Law, as approved by the voters, contemplated the use of one thousand-ton barges about twenty-seven feet wide by one hundred and fifty feet long with ten-foot draft. The law specified that the locks should be twenty-eight feet wide and eleven feet deep. Mr. Van Alstyne insisted that the locks should be at least as large as those on the Canadian canals—namely, forty-five feet wide by fourteen feet deep. He succeeded in obtaining authority to increase the width of the locks to forty-five feet, and the depth to twelve feet.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 100, 1935, p.1617.

The use of the canal, particularly during World War I and World War II, demonstrated the advantages of the larger locks, and after the canal was completed to the twelve-foot depth large sums of money were expended in deepening it to the fourteen feet which Mr. Van Alstyne had originally recommended.

Why was so young a man given so much responsibility? The answer is that Mr. Van Alstyne had already attracted attention to himself for his initiative and ability. He was in charge of some work on grade crossings over the Erie Railroad on what later became route No. 17 through Suffern and Tuxedo, N. Y., and to the north. Instead of building bridges he relocated the highway to eliminate the bridges. Edward H. Harriman, the railroad builder, and the owner of the land from the Hudson River to the New Jersey state line (which his widow gave to New York State and which later became part of Bear Mountain Park), was so impressed that he personally urged Mr. Van Alstyne's promotion. Mr. Harriman's support had two results: (1) A personal friendship and business association which lasted throughout Mr. Harriman's life; and (2) an order issued by Mr. Van Alstyne when he became state engineer, and which became a part of the permanent policy of the state engineer's office that, in rebuilding a highway, the engineer should change the route whenever such change would materially reduce the cost of future maintenance.

After he became state engineer, Mr. Van Alstyne found that progress in the improvement of highways was impeded by the many, and sometimes conflicting, laws under which highways were built and maintained. He urged amendments and finally, in his report for 1906, he urged that all existing laws relating to highways be repealed and that there should be one act, to be known as the "Highway Law." This recommendation was adopted in 1909 when the "Highway Law" was enacted.

Mr. Van Alstyne was personally responsible for another innovation which is of particular interest to contractors. The memory of the legal battles and the charges of fraud in connection with the so-called "$9,000,000 Improvement" of the canals was still fresh in the minds of the people. Most of that difficulty had resulted from differences of opinion as to the classification of excavated materials. To avoid a repetition Mr. Van Alstyne introduced two new features in state construction work. He required a single bid at a single bid price for "unclassified excavation" including all materials of every nature. However, to make this system practical and to secure bids which would not be excessive, he directed that very complete borings be made and that the record of borings, including samples, should be shown to all bidders. There were no substantial charges of fraud or misconduct in the entire construction of the Barge Canal. If there is any one person who deserves credit for this accomplishment it is the man who built up the organization and who established the policies under which the canal was constructed.

In 1906 Mr. Van Alstyne ran for re-election against Frederick Skene, a Democrat and also the candidate of the William Randolph Hearst Independent League. Charles Evans Hughes was elected Governor of New York State on the Republican ticket. Mr. Van Alstyne ran well ahead of the rest of the Republican ticket but all except the Governor lost to the combination of the Democrats and the Independent League.

Early in 1907 Mr. Van Alstyne was retained as consulting engineer by the Atlantic Gulf and Pacific Company, contractors building a section of the Champlain Canal. In the following year Mr. Harriman organized the Acme Engineering and Contracting Company. He intended that this should be a construction company to build the railroads necessary to complete his transcontinental road from Boston, Mass., to Seattle, Wash. He made Mr. Van Alstyne president and directed that the company take Barge Canal and highway contracts to train the organization for its future railroad work. That company operated under Mr. Van Alstyne's direction from 1908 to 1925 and built several sections of the Barge Canal and of the new state highway system.

During the period from 1925 until Mr. Van Alstyne's retirement in 1935, he was president and chief engineer of the Mohawk Dredge and Dock Company and the New York State Dredging Corporation, and was in charge of the construction of many sections of the Barge Canal, the deepening of the Hudson River below Albany (N. Y.), dredging in Boston harbor, and work for the New York Central and Delaware and Hudson railroads.

An illness from which he never fully recovered forced Mr. Van Alstyne's early retirement from active engineering work. He maintained a very keen interest in public affairs. He read a great deal, particularly history and biography, and was a great lover of music. He maintained contact with many of the younger engineers who had started their professional work under him. He was intensely proud of their achievements and always ready to advise and to give material aid to those who brought their problems to him.

On October 11, 1899, Mr. Van Alstyne was married to Bertha Stone Neher of Nassau. Mrs. Van Alstyne and Mr. Van Alstyne's two sisters, Mabel V. A. (Mrs. F. D. Marsh) and Edith V. A. (Mrs. C. J. Sheldon, Jr.), survive him.

Mr. Van Alstyne was elected an Associate Member of the American Society of Civil Engineers on June 6, 1900, and a Member on December 3, 1907. He became a Life Member in January, 1935.

ALBION NOYES VAN VLECK, M. ASCE[1]

DIED AUGUST 22, 1945

Albion Noyes Van Vleck, the son of Eugene A. and Florence M. (Noyes) Van Vleck, was born on June 6, 1886, at Sligo, Md. His home was just outside the District of Columbia. He attended both grade and high schools in Washington, D. C., being graduated from Central High School in June, 1904. Mr. Van Vleck won a scholarship to Lehigh University in Bethlehem, Pa., and, after completing the regular four-year course at Lehigh, he was graduated in June, 1908, with the degree of Civil Engineer. While at college he composed (and won first prize for) a football song which to this day is always played at its games. In later years he again won first prize for an alumni song.

For a few years, until 1911, he was employed in a number of structural steel offices, including those of the J. B. and J. M. Cornell Company; Post and McCord, Incorporated; Milliken Brothers, Incorporated; the Baltimore Bridge Company; and the American Bridge Company. This work was a fine preparation for his career in structural engineering, giving him experience as detailer, checker, and squad boss. During the following two years Mr. Van Vleck held the position of assistant chief engineer for F. M. Andrews, an architect of New York, N. Y. Beginning in April, 1913, and for four years, he served as chief engineer and construction manager for Guy Lowell, an architect with offices in New York and Boston, Mass.

On the entry of the United States into World War I, he offered his services to the Army and received a commission as Captain. While commanding Battery C, Sixtieth Artillery, Coast Artillery Corps, he participated in the St. Mihiel and Meuse-Argonne offensives in France in 1918. He came through with no injuries but was gassed. This left him with a bronchial weakness which, although it did not incapacitate him, made him susceptible to bronchial ailments. His military services were recognized by promotion, and he received his discharge in January, 1919, as a Major.

Following this Army experience, he held two positions briefly—first, as district plant engineer and secretary of the District Claims Board of the United States Shipping Board for the Great Lakes District, centering in Cleveland, Ohio. After a year of this work he served for two years as assistant general manager of the Saginaw Shipbuilding Company in Saginaw, Mich. From Michigan he moved to Pittsburgh, where he served in an engineering capacity for the Dravo Contracting Corporation for about a year. Mr. Van Vleck's next employment lasted for almost six years, when he returned to New York as chief engineer and construction manager for J. E. R. Carpenter, an architect and builder.

With all this experience and background, he felt qualified to enter the structural engineering field as a principal. In November, 1927, he formed a partnership with the writer under the firm name of Hurlbut and Van Vleck and opened an office as consulting engineer in New York. The firm had an office in the Architects Building at 101 Park Avenue, and later moved to 370 Lexington Avenue, a building on which the firm had executed the engineering design.

---

[1] **Memoir prepared by Charles C. Hurlbut, M. ASCE.**

Although not as colorful, perhaps, as some of his other assignments, this chapter in Mr. Van Vleck's life was one of the most productive of his career. The firm of Hurlbut and Van Vleck not only took over the structural work in connection with Mr. Carpenter's office, but also carried on a general consulting practice in structural engineering—specializing in buildings and foundations in steel and reinforced concrete. Among other assignments from Mr. Carpenter's firm were the fifty-three-story Lincoln Building on Forty-second Street; the Madison Avenue-Fifty-second Street Building (twenty-seven stories); and the forty-five-story office building at 515 Madison Avenue—all in New York. Notable structures were also designed for other clients, including the Marine Hospital at Stapleton, Staten Island, in New York; the National Democratic Convention Hall at Houston, Tex.; and the building at 370 Lexington Avenue in New York (twenty-seven stories). For the International Telephone and Telegraph Company the firm designed an addition to its New York building (twenty-seven stories), as well as the headquarters building in Bucharest, Rumania. The latter building subsequently went through a severe earthquake without a single crack.

In spite of these notable accomplishments, the path of this consulting engineering office, with the onset of the depression, was not an easy one. After struggling against insuperable conditions, the partners decided to give up a losing venture. The office was closed and both took positions with the Public Works Administration. Mr. Van Vleck's work was in the regional office in New York under M. E. Gilmore, M. ASCE, regional director. He continued as senior engineer in charge of work in the State of New York for more than four years, from November, 1933, to January, 1938. In this office he had charge of more than $250,000,000 worth of major projects, such as buildings, bridges, sanitary systems, grade crossing eliminations, docks, highways, hospitals, and schools.

Accepting appointment with the New York City administration, he served for almost two years, until November, 1939, as first deputy commissioner of the Department of Housing and Buildings. Here his wide technical experience served him in good stead, and he maintained his excellent reputation among engineers and architects. He rendered a particularly fine service in organizing six city departments into one combined department under the new city charter. Under his executive charge were 1,100 employees of the department, including engineers and inspectors.

In dealing with the political phases of this position, Mr. Van Vleck did not feel at home; and, as a result, he returned shortly to his former activity as consulting engineer, maintaining an office in New York, from November, 1939, to June, 1941. Among other commissions, he was retained as consultant by the Mortgage Conference of New York, having charge of inspection and rating of all apartment buildings under erection in New York and Bronx counties in New York City. Then, for a year, until April, 1942, he was employed as senior construction engineer (civilian) in the Army Quartermaster Corps, engaged in engineering work covering design and construction of cantonments, and ordnance and chemical warfare plants for World War II. A major assignment in this connection was the construction of Camp Wheeler, Ga.

All his life, Mr. Van Vleck had the gift of making friends. This faculty, plus his long-standing interest in matters of the Masonic Order, led to his next and final business association. Always an ardent member of the F. and A. M., he had held many offices and trusts of responsibility in that fraternal organization. Starting in April, 1942, he devoted the remaining years of his life to looking after the interests of Masons in the government services. His title was Executive Director of the Grand Lodge Committee on Military and Naval Service (New York State) and his duties covered such varied activities as the establishment and continuance of contact with more than thirty-five thousand men serving in the Armed Forces; the establishment and operation of twelve service centers for service men in the State of New York, in total catering to about seven thousand men per week; hospital visitations; and extension of aid to wounded service men. The last function required special emphasis on bridging the financial gap between discharge from the service and reestablishment in civilian life. This social service work, with its emphasis on the welfare of veterans, made a fitting conclusion to his lifetime of service.

Mr. Van Vleck's Masonic activities included the following offices: Past Master, Roome Lodge No. 746, New York; Past Master (First Master), Lodge of the United Services No. 1118, New York; Past Assistant Grand Lecturer, New York; Past High Priest, Jerusalem Chapter No. 8, Royal Arch Masons, New York; Past Commander, Coeur de Lion Commandery No. 23, Knights Templar, New York; Past Master of the United Services Lodge, and also of the Manhattan Chapter of the National Sojourners. He was also a member of the Structural Engineers Society of New York, of which he was a past president; the New York Society of Professional Engineers; the Society of American Military Engineers; the Architectural League of New York (an Associate Member); and the Holland Society of New York.

Possessed of a warmhearted personality, Mr. Van Vleck made a host of loyal friends. Among his recreations, he was an accomplished pianist, organist, and composer (an odd accomplishment for an engineer) and found pleasure in many outdoor sports. In particular, he was adept at hunting, fishing, and golf. His greatest pleasure in later years was gardening and his yard was quite the showplace of the neighborhood. Roses of all types and rare species were his pride.

On August 24, 1907, he was married to Anna L. Magee in Bethlehem, Pa. He is survived by his widow; two daughters, Florence (Mrs. O. Johnson, Jr.) and Anna (Mrs. F. H. Gibbs); three sisters; one grandson, Gerald M. Gibbs; and two granddaughters, Carole A. Gibbs and Anne Marie Johnson.

Mr. Van Vleck was elected a Member of the American Society of Civil Engineers on August 27, 1928.

WILLIAM BERNARD WARD, M. ASCE[1]

DIED JUNE 6, 1947

When the sand of time runs out on a man like "Bill" Ward, in its wake follow reminiscences that reach beyond the mere technicalities of an engineer's life—not just the slide rule, the tee square, and the structures created, but the intimate bits of his life remembered by those who were associated with him. The closer the associations, the finer and the more enduring are those memories.

William Bernard Ward, the son of John and Sarah (Curtiss) Ward, was born in Cincinnati, Ohio, on December 16, 1890. Educated in the public and parochial schools, Mr. Ward began his career in architecture and structural engineering in 1906 as a cub in the office of Samuel Hannaford and Sons, Architects. The priest in charge of young Ward's education must have foreseen in him the superb draftsman and clear thinking engineer of the future when he recommended to Harvey Hannaford that the boy, Bill, be taken in charge by that firm for mutual benefits. During this engagement of some six years, and in the following three years with Krucker and Deckbar, Architects (Los Angeles, Calif.), periods of study in various technical school and college courses built up his engineering foundation.

Returning to Cincinnati in 1915, a short engagement with Garber and Woodward, Architects, and a few months with Tietig and Lee, Architects, intervened before Mr. Ward entered military service. Enlisting on June 27, 1918, he was assigned to the 309th Engineers, United States Army, and was sent to France on base hospital construction and road maintenance. Returning to the United States as a Master Engineer, Junior Grade, of Headquarters Company, he was discharged from the service on July 12, 1919, having taken advantage meanwhile of the opportunity to attend lectures at the Sorbonne in Paris.

Rejoining Tietig and Lee as a structural engineer in 1919, he remained in charge of that department, and was superintendent of construction until 1942, except for two short engagements in Los Angeles. In 1943 Mr. Ward established his own office for the practice of structural engineering, continuing in the wide range of school, office, hospital, and industrial buildings which had been his interest in years past, and with the same simplicity, directness, and orderliness of solution which had formerly characterized his work.

Representative of Mr. Ward's operations are the following buildings, for which he designed the structures, often having a part in the architectural planning and in the supervision of construction: The Cincinnati Chemical Works building, the William S. Merrell Company Pharmaceutical Products plant, the J. and F. Schroth Packing Company buildings, the Knox Presbyterian Church, the Christ Hospital and Nurses' Home, the Parkside Hotel, the Atlas Bank Building, the City Garage and Testing Lane, Shillito's Garage at 7th and Elm Streets—all in Cincinnati—the Medical Arts Building (Memphis, Tenn.), and the Mengel Company war plant (Louisville, Ky.).

---

[1] Memoir prepared by F. W. Morrill and Hunter W. Hanly, Members, ASCE.

Mr. Ward was a modest and retiring man with a keen sense of humor, and it was natural that he should be an avid reader of select current literature. He played a good game of bridge and was proficient at golf. For many years, he was a member of the Advent Canoe Club at Tower Hill in Cincinnati, and, in 1912, he was roller skating champion of Ohio. His family treasures the many trophies Mr. Ward won in tournaments at the Hyde Park Tennis Club in Cincinnati.

He continued his interest in Army associations by holding membership in the Bentley Post of the American Legion and its Voiture of the Forty and Eight. Mr. Ward was an early member of the Cincinnati Architectural Society, an organization of draftsmen and younger architects for social and cultural purposes. Later, he conducted classes in engineering for the club. He was an officer of the Cincinnati section of the Architects' Society of Ohio, and he was admitted to corporate membership in the American Institute of Architects in 1943. In addition, he had been a member of the structural provisions subcommittee of the Building Code Revision Committee for the City of Cincinnati for several years.

In 1927 Mr. Ward was married to Marie Oberschmidt; they had two children, William B., II, and Sally Jo, who survive one of Cincinnati's most amiable and able men in the architectural and engineering professions.

Mr. Ward was elected an Associate Member of the American Society of Civil Engineers on December 15, 1924, and a Member on June 30, 1935.

WILLIAM GODFREY WEGNER, M. ASCE[1]

DIED AUGUST 25, 1947

William Godfrey Wegner, the son of Edward J. Wegner and Emelie (Schmidt) Wegner, was born on October 9, 1897, in New York, N. Y., but his family moved to a German community in the Polish part of Russia before he was a year old. The family lived there until William was about nine years old, when they returned to the United States and took up residence at Niagara Falls, N. Y. He developed a liking for mechanical things and educated himself for the engineering profession by attending night schools and studying with the International Correspondence School.

Mr. Wegner worked as a tracer and draftsman at the United States Light and Heat Company and also at the Titanium Bronze Company, both in Niagara Falls, for a short period. The family then moved to Tacoma, Wash., where he spent the remainder of his life.

---

[1] Memoir prepared by John S. Abel, M. ASCE.

On January 28, 1920, he entered the employ of the Weyerhaeuser Timber Company at Tacoma. With the exception of a few months at Snoqualmie Falls (Wash.) in 1920, he spent twenty-seven years continuously in the service of the Tacoma engineering office of the Weyerhaeuser Timber Company. During this time he worked on plans and improvements for all the manufacturing branches of the company. Starting as a draftsman, he advanced to the position of designing engineer for the company, and contributed much to the progress of new developments in the mills.

His memberships included those of the Zion Lutheran Church, the Society, and the Tacoma Engineers' Club.

He was married to Pearl V. Wilson on April 22, 1924; they had two children—a son, Harvey Edward (born on August 12, 1925) and a daughter, Martha Ann (born on October 4, 1932). He died from a heart ailment, and is survived by his widow and two children, in addition to one brother and four sisters.

Mr. Wegner was elected a Member of the American Society of Civil Engineers on August 13, 1945.

GEORGE GROVER WICKLINE, M. ASCE[1]

DIED NOVEMBER 27, 1943

George Grover Wickline was born on January 5, 1883, near Stephenville, in Erath County, Tex. He was the son of Lloyd Edward and Arie Elizabeth (Ramage) Wickline.

He came of pioneer stock. His father was born in Monroe County, West Virginia. When he was six years old, the family moved to Miami County, Kansas, and later, as a young man, he moved to Erath County, where he became a rancher and a schoolteacher, and where he lived until his death in 1926. His mother, the daughter of Josiah and Margaret Ramage, was born in McCool, Miss. The family moved to Texas in 1873 and settled in Erath County, and there Elizabeth Ramage was married to Lloyd Edward Wickline in 1880.

George Wickline attended the public schools of Stephenville and John Tarlton College at Stephenville. In 1901 he entered the University of Texas in Austin, from which he was graduated in 1904 with the degree of Civil Engineer.

After graduation, Mr. Wickline's first engineering job was that of instrumentman and bridge inspector in the construction of the St. Louis, Brownsville and Mexico Railroad between Corpus Christi, Tex., and Bay City, Tex. Then he was, successively, engineer for the North Texas Traction Company and assistant engineer of Dallas County, Texas, in the expenditure of a large bond issue on the first county-wide highway improvement program in north Texas.

---

[1] Memoir prepared by Banks McLaurin, Assoc. M. ASCE.

On the completion of the highway building program in Dallas County, Mr. Wickline took the advice of Horace Greeley and went west to seek adventure and fortune in California. He obtained employment as assistant engineer in the preliminary location survey, in the preliminary plans, and in the estimates for the first great aqueduct to be built in Southern California; this was known as the Owens River Aqueduct, which was to bring water from the region of Owens Lake on the western edge of Death Valley, to the City of Los Angeles. For the early years of the twentieth century this was a great engineering project and attracted world-wide attention. Mr. Wickline spent three years in the mountains, the desert, and Los Angeles on this great engineering project.

After three years in the west, Mr. Wickline returned to his native state, Texas, working for the El Paso and Southwestern Railroad Company at El Paso, and for the engineering department of that city. He then returned to Dallas in 1910 and was employed by Dallas County as bridge engineer for three years. From 1912 to 1914 he was engineer of bridges and buildings for the Southern Engineering Construction Company in Dallas, later a part of the Texas Electric Railway Company.

After completing this work, he was again employed by Dallas County as engineer in the preparation of the designs and as supervising engineer in the construction of the Commerce Street viaduct. Years later, in 1936, this viaduct was replaced by the Triple Underpass, which was also designed and constructed under Mr. Wickline's supervision as bridge engineer of the Texas Highway Department. When the viaduct was completed, he was employed by the City of Dallas as bridge engineer.

In January, 1918, Mr. Wickline accepted the position of bridge engineer of the Texas Highway Department. This department was created by legislative action in 1917, and Mr. Wickline was its first bridge engineer. He held this position until his death, with the exception of a three-year period (from 1936 to 1939) when he was given a leave of absence to serve as supervising engineer for construction of the Neches River bridge near Port Arthur, Tex.

The Neches River bridge spans the Neches River on the highway between Port Arthur, and Orange, Tex. It has long approaches rising on a 5 per cent grade from the level marshes on both sides of the river to a 680-foot main cantilever span affording 176-foot vertical clearance for ocean-going ships. The over-all length is 7,815 feet. The cost of the project was $2,750,000, and was provided by a Public Works Administration grant, a Texas Highway Department allotment, and a local bond issue of Jefferson County, Texas.

From the minutes of the Texas Highway Commission of December 16, 1943, the following is quoted:

> "Mr. Wickline has served as bridge engineer for the Texas Highway Department since 1918, and in point of service was the oldest member of the engineering staff. The outstanding accomplishment of his long, successful career was the Neches River Bridge between Port Arthur and

Orange, the largest bridge ever built by the Department. This, and many other bridges throughout the state, designed and constructed under his supervision, will stand as a lasting monument to his ability."

Mr. Wickline's pastor, Dr. Edmund Heinsohn, said of him:

> "Men are known by their works. Ye shall know them by their fruits. The work of George Wickline has been characterized by faith, intelligence and action. The great bridges in this state conceived in the faith of George Wickline were born out of his knowledge and understanding, and under his guiding hand were made into concrete actuality. No wonder he had a quiet and an abiding joy in the work of his faith, his mind and his hand."

Mr. Wickline was a registered professional engineer of the State of Texas. He was a member of the Society of American Military Engineers, the Society of Professional Engineers, the American Road Builders' Association, and the American Association of Highway Officials. Mr. Wickline was also a member of the Bridge Committee of the American Association of Highway Officials, and as such he took part in the development of the specifications and standards of the organization.

Death came to Mr. Wickline while en route from Austin to Chicago, Ill., to attend a meeting of the American Association of Highway Officials (A.A.H.O.). In resolutions passed by the Committee on Bridges and Structures of the A.A.H.O. are these words:

> "It is significant that the end came as he was en route to Chicago to attend the meeting. He was a charter member of our Committee. For years we have worked together. There was ever wisdom in his counsel, warmth in the depth of his human sympathy and understanding. Truly down the years we learned to love him greatly."

Mr. Wickline's activities extended beyond the engineering field. He was a member of Austin Lodge No. 12, A. F. and A. M., in Austin, and the Rotary Club of Port Arthur. In religion, he belonged to the University Methodist Church at Austin, serving very efficiently on the Board of Stewards of this church. Mr. Wickline's hours of relaxation were devoted to photography, to collecting historical books, and to gathering the folklore of Texas.

In 1913 Mr. Wickline was married to Hattie Belle Coffman, daughter of William Amos and Margaret (Barbour) Coffman, at Dallas. He is survived by his widow; one daughter, Joyce (Mrs. Robert Darling); and two granddaughters, Ruth and Joyce Darling.

Of modest and dignified bearing, Mr. Wickline was quiet and considerate, as well as painstaking, logical, and thorough. His opinions were formed slowly, but surely and soundly and he was a conscientious and an untiring worker. Mr. Wickline's death removed a fine Christian gentleman, a valuable citizen, and a most capable engineer; no better epitaph can be written of his life than two words: "Well done."

Mr Wickline was elected an Associate Member of the American Society of Civil Engineers on September 3, 1912, and a Member on July 6, 1920.

ARTHUR JACOB WIDMER, M. ASCE[1]

DIED APRIL 30, 1947

Arthur Jacob Widmer was born in Newark, N. J., on April 1, 1883, of Swiss ancestry. He was the son of Gustavus H. and Mina L. (Luerich) Widmer.

He attended the public school of the small town of Port Richmond, Staten Island, which became the Borough of Richmond in New York, N. Y., where he spent his boyhood. Later he studied at the Westerleigh Collegiate Institute in an adjoining small town on Staten Island. He entered Cornell University in Ithaca, N. Y., in 1900. For two years, partly between college terms and on special leave from the university, he was a mechanic on machine output studies in several important eastern manufacturing plants. During the period from 1904 to 1907 he was engaged in Detroit, Mich., as research designer on adding machine improvements; as designer with the Solvay Process Company on coke ovens, coke briquetting plants, ammonia and soda ash processes; and as designer of the then unfamiliar reinforced concrete construction. Later he was appointed manager of the rib bar department of the Trussed Concrete Steel Company.

In 1907 Mr. Widmer was transferred to St. Louis, Mo., for the purpose of opening an area office and managing the business of selling the rib bar product of the Trussed Concrete Steel Company. During this period of infancy of the reinforced concrete construction industry, it was necessary, not only to sell the reinforcing steel products but to design structures using the rib bar, prove the economy of its use, and supervise the installation of the product. Many times full-size loading tests were performed under his supervision to prove the adequacy of the design using the patented rib bar. During the subsequent seven years, Arthur Widmer acted as consulting engineer on numerous reinforced concrete and steel structures.

In 1914 he established a separate office in St. Louis for the independent practice of mechanical and civil engineering and early in 1917 formed the Widmer Engineering Company of which he served as president until his death. In 1921 he formed and headed Arthur J. Widmer and Associates, Incorporated, an architectural firm. He was one of the very few persons licensed in the State of Missouri to practice both engineering and architecture.

On leave from the Widmer Engineering Company during World War I, he was commissioned a Major and assigned to the Engineering Branch of the Construction Division of the United States Army in various positions, terminating as Chief of the Requirements Branch of the Construction Division. Here, in connection with the large construction program of the Army, he was responsible for appropriation estimates, preparation of data for Congress and other agencies, liaison with the general staff, project esimates, authorizations, and allotments of funds. In the Army service, he demonstrated his ability in organization and administration and in the planning of equipment and personnel for production.

---

[1] Memoir prepared by Elmer H. Oechsle, Pres., Widmer Eng. Co., St. Louis, Mo.

Again on leave in 1940, Arthur Widmer, then a Colonel of Engineers in the Army Reserve, served as a special assistant on organization and procedures to the chief of the new Construction Division which was being developed to carry on the enormous building program of the Army for World War II.

Arthur J. Widmer had been responsibly connected with the design of more than one thousand structures of an extremely varied nature. The construction of a large part of these structures was also carried out under his supervision. His activities embraced innumerable types of civil and mechanical engineering projects, spreading largely throughout the United States and extending abroad as far as China. Many of the works successfully designed by him are outstanding for their size and boldness of conception. Included was the reinforced concrete, twenty-one-story Railway Exchange Building in St. Louis, approximately three hundred feet square, which, when constructed in 1910, involved the largest single usage of reinforced concrete for a building. As a pioneer in reinforced concrete construction, he developed, and assisted and directed others in the development of, many outstanding features of modern building construction. He developed and patented a pre-cast type of tunnel design and a method of construction suitable for inland streams subject to extreme floods and for shifting river bottoms which prevented the use of ordinary tunnel construction practices.

Arthur Widmer obtained more than a score of patents in such varied fields as construction methods and materials, tunnels, and processes relating to fine particles of matter. His familiarity with patents and his knowledge of mechanical devices and processes led to his being called upon for expert testimony in many important patent litigation proceedings. He made a hobby of research in connection with finely divided particles of matter, both microscopic and chemical. He had spent more than five thousand hours in physiochemistry research of this nature and as a result formed and temporarily headed a company to market certain finely processed particles in association with an alkaline chemical compound.

Colonel Widmer was prominent in military activities in the Army Reserve Corps and commanded various engineer reserve regiments. He energetically advocated preparedness; he participated in and led numerous patriotic movements and was also vigorously opposed to the many pacifist and unpreparedness movements which sprang up from time to time. He was an active member of the Reserve Officers Association and the local post of the American Legion.

Arthur J. Widmer was a member of the American Society of Mechanical Engineers, both the Missouri and National Society of Professional Engineers, the Society of American Military Engineers, and the American Concrete Institute. Other organizations of which he was a member included the Engineers' Club of St. Louis, the St. Louis County Chamber of Commerce, the Academy of Science of St. Louis, the Cornell Club of St. Louis, and the Missouri Athletic Club of St. Louis. During the past he held various offices in his clubs and societies and actively served on committee work.

In addition to his professional activities, Arthur Widmer gave generously of his time and energy to local civic affairs. He was energetic in his efficacy for the planning of a large city along new lines—initiating the movement to overcome the barrier in the St. Louis metropolitan area formed by the Mississippi River between the city proper and the localities on the east bank. He maintained that numerous crossings for vehicular traffic would, in effect, overcome the obstacle, and that the harbor of St. Louis would be a tremendous asset with increasing value in the future if no more overhead bridges were built and all future crossings were tunnels.

On November 20, 1906, Arthur J. Widmer was married to Lavina Roberts, daughter of George H. and Margaret (Lindsey) Roberts of Staten Island. In addition to his widow, he is survived by a son, Arthur J. Widmer, Jr., and by five daughters, Harriet Lindsey (Mrs. Bertram R. Kellaway), Mary Elizabeth (Mrs. John Hochreiter), Janet May, Alice Lavina, and Margaret Helen.

No more fitting tribute to Arthur J. Widmer can be expressed than that given by the Rev. Alphonse M. Schwitalla, S.J., in his "Tribute of Affection" as follows:

> "I have sought the phrase that will say in brief what I have found in Arthur Widmer's words and acts as most expressive of his true self. To me, he was a man of 'tempered strength.' His mind was strong because he was clear and sure in his knowledge, both human and technical. His emotions and feelings were strong because he was definite and penetrating in his appreciation of values. His will was strong because he was determined and firm in the pursuit of the objectives he had set before himself to attain. And that strength made him a man of achievement. A builder, a soldier, an organizer, a leader; a guide to others but also a cooperator; a man of stone and steel but also a man of dreams and visions; in all his traits and works there stands out the quality of strength as his characteristic imprint upon all he planned and performed, upon all he valued and loved, upon all he hoped for and ambitioned."

Mr. Widmer was elected a Member of the American Society of Civil Engineers on January 19, 1920.

CLEMENT CLARENCE WILLIAMS, M. ASCE[1]

DIED FEBRUARY 20, 1947

Clement Clarence Williams was born in Bryant, Ill., on February 21, 1882. His mother, Martha Ann (Davis) Williams, was a woman of unusual resourcefulness, managing with poise and dignity her family of nine and the simple home that was maintained on very moderate means. Clement's father, Isaac Greenbury Williams, was the operator of a small mill, and as a youth Clement Williams was interested and able in helping his father repair and maintain the mill equipment.

---

[1] Memoir prepared by Bruce G. Johnston, M. ASCE, assisted by R. K. Laros, Pres., R. K. Laros Silk Co., Bethlehem, Pa., and Mrs. C. C. Williams.

In his early childhood, the family lived on a farm a mile and a half from Banner, Ill., where the district school was located. Written notes of his earliest recollections on the long walks to and from school show a strong love of natural beauty. The old dirt road led part way over rolling hills, then along the bed of a winding creek, where in early spring green willows, wild flowers, and ferns in profusion made every turn of the road a cause for wonderment. In the summer the creek became a swimming hole, and in the winter, he and the children from the neighboring farms tried out their ice skates on its frozen surface.

Clement earned most of the funds to pay his way at the Canton High School and then attended the Southern Iowa Normal School at Bloomfield, Iowa, where he earned all his expenses from odd jobs at rates of from 10 cents to 25 cents per hour. At the normal school, where his brother was an instructor of mathematics, he too showed marked ability in this subject, and after being awarded the degree of Bachelor of Science in Natural Science became a teacher in the county school. His ambition for more practical application of his talents led him, in the fall of 1903, to enter the University of Illinois, at Urbana, where he made an excellent scholastic record. After receiving the degree of Bachelor of Science in Civil Engineering, in 1907, his career for a time became twofold; during the three months of each summer he gained experience as a design engineer, and during the remaining nine months he was a teacher of engineering—initially, in 1907, becoming instructor of civil engineering at the University of Colorado in Boulder.

In his summer work, Mr. Williams began, in 1906, as chainman and rodman for the Delaware, Lackawanna and Western Railroad Company at Scranton, Pa., continuing his railroad experience during successive summers, from 1910 to 1917, as checker, and later designer, for the Chicago (Ill.) office of the Chicago, Milwaukee and St. Paul Railroad Company.

In 1910, at the age of twenty-eight, Mr. Williams was promoted to the post of assistant professor at the University of Colorado, and during the same year he was married to Grace Josephine Black, who died six years later. His summer work for the railroads was a factor that led the University of Kansas, at Lawrence, to offer him, in 1914, a post as professor of railway engineering. In 1919, he was made head of the Civil Engineering Department of the same institution. During World War I he took leave of absence from the University of Kansas to be supervising engineer for the War Department on the construction of explosives plants near Nitro, W. Va.

In 1921, at the age of thirty-nine, he was married to Ora Louella Webb, and in the fall of the following year left the University of Kansas to become professor of civil engineering and head of that department at the University of Illinois. In the fall of 1926 he became dean of the College of Engineering at the State University of Iowa at Iowa City. While there, in 1934, he was honored by election to the presidency of the Society for Promotion of Engineering Education (later the American Society for Engineering Education).

In 1935 Dean Williams was chosen president of Lehigh University, at Bethlehem, Pa. Great educational advances had been made at Lehigh during the ten years prior to 1932. These had come nearly to a standstill during the depression years; stringent economies were necessary to keep the university from operating "in the red." Nevertheless, under the able guidance of President Williams, Lehigh University continued on the progressive course that had been charted. Whereas many other schools were forced to stand still, or lose ground, during the years between 1935 and the advent of World War II, Lehigh increased its undergraduate and graduate enrollment by 37 per cent and 57 per cent, respectively, and the endowment was increased by 40 per cent. New buildings, additions, and improvements costing more than a million dollars were effected during these depression years.

While at Lehigh, President Williams continued his broad interest in engineering education matters. He was active in the Pennsylvania Association of College Presidents and was a member of several commissions which made educational and administrative surveys of other institutions.

President Williams received honorary doctorate degrees from Lafayette College at Easton, Pa.; Northeastern University at Boston, Mass.; Bucknell University at Lewisburg, Pa.; the Hahnemann Medical College at Philadelphia, Pa.; the Case School of Applied Science at Cleveland, Ohio; Muhlenberg College at Allentown, Pa.; Moravian College and Theological Seminary at Bethlehem; and Rutgers University at New Brunswick, N. J.

Dr. and Mrs. Williams created in the President's House, at Lehigh, an atmosphere of warmth and friendliness and soon had a large circle of friends both within the university and in the community, into which Dr. Williams quickly extended his interests. He became an honorary member of the Rotary Club in 1936 and was a regular and interested attendant. His talks to the Rotary were examples of his ability to inject a rich good humor into the most profound subject. He was elected to the Board of Trustees of St. Luke's Hospital, became a director of the Union Bank and Trust Company, and was active in the work of the Chamber of Commerce, Community Chest, the American Red Cross, as well as being on the Executive Committee of the Bach Choir. His counsel and good judgment were extremely valuable in all these services and he gave thoughtful and painstaking attention to every problem presented to him.

Dr. Williams was a devout Christian of irreproachable character and had a high sense of devotion to duty. He was kindly, friendly, possessed of unusual administrative ability, high talent, a penetrating mind, and a well-rounded character. Both he and Mrs. Williams will for many years be affectionately recalled in Bethlehem.

In 1944 he retired from the presidency at Lehigh and moved to Madison, Wis., where he continued in practice as an engineering administrative consultant. At Madison he was a member of the University West End Club which, after his death, prepared a memorial, reading in part as follows:

> "In the death of Dr. Clement Clarence Williams the University West End Club lost one of its distinguished members. He became a member of the organization shortly after he and his family moved to Madison in 1944. A man of sterling character and great personal charm, he possessed the capacity not only of making friends, but of being a loyal friend himself. His sense of humor was keen and he could emphasize a point under discussion with an apt quotation, story, or anecdote. His kindness and tolerance for another's point of view coupled with his own reasoned conclusions made him a character to be loved, admired and respected.
>
> "All those who have known Dr. Williams either for a few years or for many, can attest to an enrichment of life which they have enjoyed because of his warm personality, his breadth of knowledge, his wisdom, his cultured taste, his honesty, and his sincerity."

Dr. Williams was the author of several books on masonry structures and foundations, a book on the engineering career,[2] and many bulletins and articles.

In addition to the organizations previously mentioned, he was a Thirty-Second Degree Mason, a member of Acacia, the Triangle Club, the University Club of Bethlehem, and the Manufacturers' and Bankers' Club of Philadelphia. He was a member of the American Railway Engineering Association, the Pennsylvania Academy of Science, Tau Beta Pi, Sigma Xi, Sigma Tau, the American Association for Advancement of Science, and the Academy of Political Science.

Dr. Williams is survived by his widow and their three children, Ora Louise (Mrs. Charles H. Hoffman), Ellen Webb, and Clement Webb.

Dr. Williams was elected a Junior of the American Society of Civil Engineers on June 1, 1909; an Associate Member on October 1, 1912; and a Member on October 8, 1918.

ALBERT WILLIAM ZESIGER, M. ASCE[1]

DIED JANUARY 9, 1948

Albert William Zesiger, the son of John and Elizabeth (Baumgartner) Zesiger, was born on April 11, 1868, on a farm in Switzer Township, Monroe County, Ohio. The farm was near the Village of Powhatan Point, where he passed his childhood and early manhood.

After receiving his high school education in Powhatan Point, he attended Earlham College in Richmond, Ind., and in 1896 was graduated with the degree of Bachelor of Science from Case School of Applied Science (later the

[2] "Building an Engineering Career," by Clement C. Williams, McGraw-Hill Book Co., Inc., New York, N. Y., 1946.

[1] Memoir prepared by Virgil A. Eberly, Assoc. M. ASCE, with the cooperation of W. A. Stinchcomb and W. E. Blaser, Members, ASCE, Mrs. Zesiger, and Martha Christiansen.

Case Institute of Technology) in Cleveland, Ohio. In 1901 he was awarded the degree of Civil Engineer from Case.

Mr. Zesiger went to Cleveland in 1893. When he retired in 1945, after seventeen years as chief engineer of the Metropolitan Park Board of Cleveland, he went to the home he had established in Oberlin, Ohio.

Shortly after his graduation, Mr. Zesiger became bridge engineer of parks in Cleveland, and for three years, in the mid 1920's, was chief engineer of bridges in the State Highway Department in Columbus, Ohio. In 1925 he was married to Erna Knapp of Columbus.

The record of his employment, from 1896 until his retirement in 1945, is as follows:

1896–1898—instrumentman, draftsman, and designer, in the county surveyor's office in Cleveland;

1898–1901—superintendent on the construction of intercepting sewers in Cleveland;

1901–1902—engineer associated with an architect;

1902–1903—engineer in the mills of the Jones and Laughlin Steel Company;

1903–1908—engineer in charge of bridges for the Department of Parks in Cleveland;

1908–1910—assistant engineer of the Evers Engineering Company in Cleveland;

1910–1912—engineer of construction in charge of checking plans structurally and of reinforced concrete construction for the Department of Buildings in Cleveland;

1912–1921—bridge engineer in charge of the design and construction of the Detroit-Superior Bridge (approximate cost $6,000,000) and the Brooklyn-Brighton Bridge (approximate cost $650,000) in the county surveyor's office in Cleveland;

1922—engineer for Newhall Company, contractors, and assistant engineer in the water works department in Cleveland;

1923–1925—chief engineer of bridges in the State Highway Department at Columbus; and

1925–1945—chief engineer of the Metropolitan Park Board in Cleveland.

Following Mr. Zesiger's retirement in 1945 he served as consultant on the design of several large bridges for the Metropolitan Park Board in Cleveland. He also coached a number of junior engineers.

"Zes" was a keen mathematician. Those who worked in collaboration with him express the same thought—they have never known a better one. He had a keen sense of logic and was able to develop formulas for the solution of difficult problems. Mr. Zesiger developed the first wholly comprehensive pile driving formula; a formula for punching any material or varve; formulas for the holding capacity of anchors; and designs for cantilever retaining walls.

Mr. Zesiger is properly given much credit for the design of the Detroit-Superior Bridge in Cleveland, since there were so many changes made in the structure after 1912 that it was necessary to redesign practically the entire structure after he took charge of the office that year.

One of the first reinforced concrete bridges that Mr. Zesiger designed was a flat slab skew bridge on the Rockefeller Parkway crossing Doan Creek in Cleveland, just to the north of Superior Avenue. In the light of later developments, this would not be considered much of an accomplishment, but in 1905 it was unusual and excited considerable interest, since it was a definite departure from previous practice. The next notable bridge that he designed as park engineer was the Washington Park viaduct in Cleveland, consisting of a series of reinforced concrete arches, carrying Independence Road in Washington Park.

Mr. Zesiger deserves full credit for the design of the Brooklyn-Brighton Bridge in Cleveland. This too was a series of reinforced concrete spans, carrying West Twenty-fifth Street across the Big Creek Valley from what was then the Brooklyn area to the South Brooklyn area.

He designed and superintended a reinforced arch bridge under the Wheeling and Lake Erie Railway at Brookside Park in Cleveland; a reinforced concrete arch at Edgewater Park in Cleveland; a three-hinged reinforced concrete arch at Greenville, Ohio; and many other bridges, foundations, and retaining walls.

One of the unusual structures which Mr. Zesiger designed was a boulder-faced, three-hinged arch of concrete across Big Creek in Brookside Park in Cleveland. At the time this bridge was built it was the flattest three-hinged arch in existence. Shortly thereafter, another three-hinged, boulder-faced, highway bridge was built following his design in Brookside Park across Big Creek. This bridge now carries the traffic into the area where the Bear Dens and Deer Park are located.

"Zes," besides being a man of good judgment, was a good friend to have. He was absolutely unselfish, and could be counted on to help anyone in trouble, regardless of his position. Quoting W. E. Blaser, M. ASCE, who was chief draftsman under Mr. Zesiger, from 1912–1921: "He was one of the best friends I ever had."

Having struggled for his own education, and having made his way unaided through the county school, summer school, Earlham College, and finally Case School, he knew from experience the hardships that make people sympathetic. Once he achieved his goal and was in a position to help others similarly handicapped, he gave most generously of his counsel and his cash to many who came within the scope of his wide acquaintance. Among relatives, he helped numerous nieces and nephews, sisters and brothers, even grandnieces and grandnephews with financial and other problems. An unfailing source of strength and assistance, he never turned away the stranger at his gate without a spiritual and monetary gift. Truly he has left the world richer than he found it.

His ready friendship for children always established a great confidence in them. In particular, he (together with Mrs. Zesiger) assumed charge of a little boy whose father had died.

He was identified with Sigma Xi society, the City Club of Cleveland, and with the Methodist Church. His hobbies were bowling and gunning.

Surviving are his widow; a sister, Mrs. C. V. Blattler of White Lake, S. Dak.; three nephews: W. L. Zesiger, a civil engineer in Lakewood, Ohio, H. A. Zesiger of Fairview Village, Ohio, and Milton Christiansen of Chicago; four nieces: Mrs. A. Helfrich and Mrs. Jack Harris, both of Cleveland, Martha Christiansen of Detroit, Mich., and Mrs. Louis Kruger of Chicago; also numerous nieces and nephews throughout the west.

Mr. Zesiger was elected a Member of the American Society of Civil Engineers on August 31, 1909. He became a Life Member in January, 1939.

ROY RICHARD ZIPPRODT, M. ASCE[1]

Died June 21, 1947

Roy Richard Zipprodt was born in Highland, Ill., in 1890. His parents were Fred A. and Elisa (Combe) Zipprodt. He received his early schooling at the Highland High School where he was valedictorian of his class and in 1915 was graduated from the University of Illinois, in Urbana, with the degree of Bachelor of Science in architectural engineering.

Mr. Zipprodt's first professional engagement was engineer of tests with the Emergency Fleet Corporation in Washington, D. C.; and from 1915 to 1919 he was associated with W. A. Slater,[2] M. ASCE, of Lehigh University (Bethlehem, Pa.), conducting research and comparative tests on different types of concrete floor designs. He did further research at the Bureau of Standards, also in Washington, on the same type of work. From 1920 to 1927 Mr. Zipprodt was engaged in the field of architectural engineering with the firm of Beuttler and Arnold, Architects and Engineers, in Sioux City, Iowa.

During 1928 he accepted an engagement with the Chicago (Ill.) Structural Bureau of the Portland Cement Association, and in 1929 he became the first regional structural engineer in the New York (N. Y.) office of the association, in charge of all structural activities in New York, New Jersey, and New England. In 1936 he was called to Columbia University in New York as associate professor of civil and architectural engineering, remaining there until 1940 when he resigned to work in Washington as principal civil and research engineer, serving with distinction in the Office of the Quartermaster General, United States Army.

At the time of his death Mr. Zipprodt was consulting engineer to the Iron and Steel Institute in New York, and he also was engaged in rewriting a series of textbooks (by George A. Hool, S. B. Kinne, and W. S. Kinne) entitled: "Foundations, Abutments and Footings," "Reinforced Concrete and Masonry Structures," "Structural Members and Connections," "Stresses in Framed

---

[1] Memoir prepared by Stewart S. Neff, M. ASCE.

[2] For memoir, see *Transactions*, ASCE, Vol. 96, 1932, p. 1555.

Structures," "Steel and Timber Structures," and "Movable and Long-Span Steel Bridges."

In his work as consulting engineer for the Iron and Steel Institute, he initiated and gave technical direction to a number of important research projects—notably on footings and on improved types of reinforcing bars. He exerted wise leadership in encouraging and sponsoring research of a thorough and fundamental nature.

He is probably best known for his long service as secretary of committee No. 318 of the American Concrete Institute. By his inspiration, his sound technical knowledge, and his careful and accurate editing of all committee reports, he contributed largely in this capacity to the "Standard Building Code Requirements for Reinforced Concrete," which has had nationwide influence on design and construction practice in reinforced concrete buildings.

Mr. Zipprodt was respected and admired by all who knew him for his honesty, integrity, and thoroughness. He had a kindly and unassuming personality and an unlimited capacity for work. He accepted responsibilities willingly, carring them out with remarkable energy and zest.

He is survived by his widow, the former Edna Bradley to whom he was married in 1916, and by a son, Elliott.

Mr. Zipprodt was elected a Member of the American Society of Civil Engineers on February 15, 1937.

Associate Members

ERNEST SAMUEL ALDERMAN, Assoc. M. ASCE[1]

DIED JANUARY 9, 1947

Ernest Samuel Alderman was born at Grass Valley, Calif., on June 30, 1886. He obtained the degree of Bachelor of Science in Civil Engineering in 1911 from the University of California in Berkeley, where he was a member of the Alpha Kappa fraternity.

His chosen profession was engineering, like that of his father, Samuel J. Alderman, who was a civil and mining engineer in Grass Valley. As a boy in his "teens" he assisted his father during vacations and served as transitman on surveys in Nevada and Sierra counties in California. During the summers of his college vacations he was transitman in general mining surveys in California and after graduation he went into private practice as engineer and surveyor on miscellaneous surveys and on design of water supply systems, one of the first being for the small resort townsite on Lake Tahoe, California.

After a year of practice Mr. Alderman found that highway work offered many opportunities and he accepted an appointment with the United States Office of Public Roads and Rural Engineering. Sixteen months were spent in studies of field and laboratory methods; and then as a junior highway engineer he worked on surveys, plans, and construction of various types of post roads and drainage structures. He progressed rapidly and during 1915 and 1916 made investigations of bituminous treatment of local materials in Palm Beach County, Florida. During World War I he served in the United States Army as engineer officer in charge of highway work at Camp Travis in Texas.

---

[1] Memoir prepared by Leo L. Laine, Assoc. M. ASCE.

From 1918 to 1920 he represented the Bureau of Public Roads in Oklahoma and during 1921–1922 he accepted the position of chief engineer for the state highway department. Perhaps his greatest contribution to society as an engineer came at this time when he was instrumental in establishing the federal aid system in Oklahoma on a sound basis and in drafting state highway specifications in conformity with government standards.

With this work completed he went into private practice as a contractor dealing mainly in drainage structures. His interest in state affairs continued and during 1931 to 1935 he served on the water resources board for the State of Oklahoma. After this time he was again in the service of the highway department and worked on research analysis until a sudden heart attack ended his career.

Mr. Alderman was a pioneer highway engineer and a man of high principles and integrity. He was noted for his dependability and accuracy and was held in high esteem by his associates. Although his work was his hobby, he still found time for the activities of the First Presbyterian Church, the Oklahoma Society of Professional Engineers, and other organizations.

He is survived by his widow; four daughters, Patsy, Sally, Mrs. R. O. Bell (Houston, Tex.), and Mrs. W. A. Doty, Jr. (Bartlesville, Okla.); and a son, Ernest Alderman, Jr. A brother, E. T. Alderman, of Portola, Calif., and two sisters, Mrs. Ethel Read and Mrs. Marguerite Bell—both of Los Angeles—also survive.

Mr. Alderman was elected a Junior of the American Society of Civil Engineers on October 3, 1911, and an Associate Member on January 15, 1917.

ROBERT MORRISON ANDREW, Assoc. M. ASCE[1]

DIED NOVEMBER 27, 1945

Robert Morrison Andrew was born at Columbia, Tenn., on Nevember 7, 1907. He was the son of John Morrison and Sally (Jones) Andrew. During his early boyhood his parents moved to St. Petersburg, Fla., where he was graduated from high school in 1928.

---

[1] Memoir prepared by J. T. Hallett, M. ASCE.

While regularly pursuing his high school education, he showed an intense interest in engineering as a result of holding minor positions with various engineering firms during this time, and serving as transitman for the City of St. Petersburg on street and sewer construction. In September, 1929, Mr. Andrew entered Purdue University in West Lafayette, Ind., from which he was graduated in June, 1933, with the degree of Bachelor of Science in Civil Engineering.

From January to September, 1931, he served as office assistant with the state highway commission of Indiana, and on completing his college training in June, 1933, he returned to serve as a project engineer until September, 1942. During this service as a project engineer he was in responsible charge of several highway projects, which embraced phases of construction that included both rural and municipal work. In October, 1942, Mr. Andrew entered the employ of Shumaker Brothers of Indianapolis, Ind., as a promotional engineer for ready-mixed concrete, and he was employed by this firm until his death, after an illness of about one year.

Mr. Andrew was well liked among his associates, within and without the engineering field, and he was an upright member of any community in which he lived. He will be remembered by all with whom he came in contact for his high standards of ethics and morals.

Mr. Andrew was married to Margaret Inman of Plainfield, Ind., on December 13, 1929. He is survived by his widow; a daughter, Roberta Jane; and two sisters, Viola (Mrs. C. M. Garney) of Columbia, and Margaret (Mrs. Jack Cole) of Chicago, Ill.

He was a licensed professional engineer and land surveyor in the State of Indiana. He held memberships in Tau Beta Pi and Chi Epsilon fraternities, and also an associate membership in the Society of Sigma Xi.

Mr. Andrew was elected a Junior of the American Society of Civil Engineers on October 30, 1933, and an Associate Member on August 16, 1937.

MURRAY CHASE AYERS, Assoc. M. ASCE[1]

DIED NOVEMBER 24, 1947

Murray Chase Ayers, the son of Henry and Ellen (Chase) Ayers, was born in Hartsgrove, Ashtabula County, Ohio, on December 19, 1883. After secondary school he attended the Case School of Applied Science (Cleveland, Ohio) and later received the degree of Bachelor of Arts from Stanford University (Stanford University, Calif.) in 1912.

Mr. Ayers' first engineering position was with the Wailuku Sugar Company in Wailuku, Maui, Hawaii, where he surveyed and mapped land, in addition to designing and supervising construction of irrigation systems and railways for the sugar plantations. After spending four years in the Hawaiian Islands he returned to the United States and worked as resident engineer for the California Division of Highways in the Sacramento office and then became inspector of construction for the Pacific Electric Railway Company in Los Angeles (Calif.).

---

[1] Memoir prepared by Howard O. Borrowdale, Dept. of Building and Safety, County of Los Angeles, Los Angeles, Calif.

Turning to structural design in 1922, Mr. Ayers worked in the architectural offices of Ross Montgomery, Edwin Bergstrom, John Austin, M. ASCE, and C. R. Johnson in Los Angeles, and as structural engineer for B. D. Kronnick (construction) Company. Notable among the buildings on which Mr. Ayers did design work are the Los Angeles General Hospital and the Carmelite Mission in Alhambra, Calif.; the Calvary Mausoleum, the Shrine Auditorium, sections of the Los Angeles County Museum, the Southern California Athletic Club, St. Vincent's Hospital, and the Guaranty Building —all in Los Angeles; also, the Los Angeles Chamber of Commerce Building, the Los Angeles Patriotic Hall, Hollywood Bowl, Sylvania Convent, Loyola Retreat, and the enlargement of St. Vibiana's Cathedral. Outside Los Angeles he did engineering work for St. Clare's School (Oxnard, Calif.), St. Andrew's Church, and the Pasadena Municipal Auditorium (Pasadena, Calif.), the high school auditorium (Redlands, Calif.), and the restoration of the Franciscan Mission (Santa Barbara, Calif.).

With the organization of the Los Angeles County Department of Building and Safety in 1933 Mr. Ayers became the senior structural engineer, holding the position until his death. His duties in the building department were both technical and administrative. During his more than fourteen years of service in the department, all structural plans for buildings erected in the unincorporated area of the county were processed and checked under his supervision.

His knowledge, experience, and integrity did much to gain for this department its reputation for soundness and efficiency. The respect and friendship which Mr. Ayers enjoyed among his colleagues may be taken for granted; a greater tribute to his abilities and personality is evident in the number of his friends in the Los Angeles area.

For many years Mr. Ayers made his home in Alhambra, near Los Angeles, where he was active in fraternal and civic work. He was a member of the Alhambra Lodge of the F. and A. M. and the Granada Lodge of the Order of the Eastern Star, and belonged to the Presbyterian Church of Alhambra.

In 1917 Mr. Ayers was married to Elsie L. Whittemore of Alhambra. He is survived by his widow and by two sons, Alden Ayers, a petroleum engineer, and Donald Ayers, a graduate student in the classical language and literature department at Princeton University (Princeton, N. J.).

Mr. Ayers was elected an Associate Member of the American Society of Civil Engineers on May 15, 1917.

THOMAS GEORGE GORDON BECK, Assoc. M. ASCE[1]

DIED JANUARY 6, 1948

Thomas George Gordon Beck was born at Palmerston South, Otago, New Zealand, on August 2, 1901. His parents were Thomas Smith and Roslyn (Noy) Beck. He completed his secondary school education at Otago Boys' High School there.

In 1919 he joined the New Zealand Public Works Department, working for two years in the North Auckland District, from which he was transferred to Arthur's Pass, where he acted as assistant engineer in charge of the electrification of Otira tunnel for three years. After completing his engineering course at Canterbury University at Christchurch he was transferred to the Dunedin District in 1925 where his work gave promise of the great heights which he was to attain.

Awarded a Commonwealth Fund Service Scholarship in 1931, he spent two years abroad—in the United States—studying irrigation, drainage, and river control. On his return he commenced investigations and preliminary surveys on irrigation in Canterbury. Under the direction of J. Wood, engineer-in-chief, he prepared a complete report and his recommendations were approved and adopted by the New Zealand Government. Work was soon under way with the Redcliff project in Canterbury to irrigate 5,000 acres and shortly after the Levels scheme also in Canterbury was undertaken to irrigate 12,000 acres of farming lands hitherto too dry for intensive utilization.

Simultaneously, comprehensive investigations were organized by Mr. Beck on the subjects of rainfall, soil moisture, runoff, evaporation, humidity, wind velocity, river flow, and response to irrigation, with the result that the need for irrigation became well defined in Mid-Canterbury. Work was then commenced on the Ashburton-Lyndhurst scheme and the Rangitata diversion race. On the latter project, Mr. Beck pioneered the use of a modern earth-moving plant (bulldozers, carryalls, and so on), and Public Works Department workshops were erected at Temuka to service this plant, which comprised 70% of all such equipment in New Zealand. The construction of the 42 miles of diversion race involved the excavation of 5,000,000 cubic yards of material.

At a later stage Mr. Beck conceived the idea of using the 1,000 cubic feet per second of water in the diversion race for electric power generation when it was not needed for irrigation. A power station generating 25,000 kilowatts was installed to help supply peak loads, and thus assure maximum use of this great flow of water. The workshops, established to service mechanical equipment, were later used to fabricate equipment and installations for the irrigation plan and Tekapo hydroelectric scheme, thus saving the New Zealand Government many thousands of pounds in the cost of repair and construction work.

During the active stages of development of the diversion race in 1937, the biggest rural water supply project in New Zealand was undertaken—the Downlands water supply scheme—which proved a boon to farmers over a large area of good land. While construction work proceeded on the diversion race, the Mayfield-Hinds irrigation plan was commenced and rapid progress made. The envisaged development in Mid-Canterbury will irrigate 420,000 acres distributed over five separate schemes, 30,000 acres of which will draw on the Rangitata diversion race.

---

[1] Memoir prepared by Harry L. Hume, M. ASCE.

In 1938, at Tekapo, Mr. Beck pioneered the shield method of tunnel construction and supervised the design and construction of the first shield to be used in New Zealand. Mr. Beck became district engineer at Christchurch in 1940 and, in addition to irrigation responsibilities, shouldered those of war construction. In 1942 he was transferred to Wellington to assist in the defense program as second assistant engineer-in-chief. Later he became assistant engineer-in-chief and finally engineer-in-chief, prior to taking over his last position as deputy commissioner of works in the Ministry of Works in 1946.

During his sojourn in the head office Mr. Beck was an active member, and chairman for a period, of the Soil Conservation and Rivers Control Council. To these duties he gave enthusiasm and zeal in his characteristic way, leaving an indelible impression in yet another field of progress. During this period he was closely associated with the late A. P. Grant, engineer to the council.

Mr. Beck had a brilliant career and won meteoric promotion by a rare combination of sheer brilliance and ability, coupled with a dynamic personality and resourceful nature. His imagination and perspicacity were brought to bear with forceful artistry on New Zealand engineering problems—particularly with irrigation in Mid-Canterbury. His loss to the department and to New Zealand is not only untimely but of the first magnitude.

His has been a proud record of achievement as one of the master architects of New Zealand's destiny, and it is an inspiration to his colleagues; as a man capable of molding the greater future of New Zealand, his loss will be keenly felt by the New Zealand Government and by all with whom he came in contact.

On February 11, 1931, Mr. Beck was married to Francis Ayson, who survives him. Four children, Pamela, Alistair, Margery, and Elizabeth also survive.

Mr. Beck was elected an Associate Member of the American Society of Civil Engineers on August 15, 1932.

ROYALL DOUGLAS BRADBURY, Assoc. M. ASCE[1]

Died March 21, 1947

Royall Douglas Bradbury was born in Jefferson City, Mo., on October 4, 1883. He attended the University of Missouri at Columbia, and the Massachusetts Institute of Technology, then in Boston, receiving the degree of Bachelor of Science in Civil Engineering from the latter school.

---

[1] Memoir prepared by C. D. Curtiss and C. N. Conner, Members, ASCE, and A. R. Rankin, Assoc. M. ASCE.

Following his graduation in 1906, he returned to the Massachusetts Institute of Technology as an instructor in civil engineering, teaching structural theory and bridge design until 1913. The clarity and preciseness of his teaching and his ability to simplify a complicated problem so that it could be readily understood were so much appreciated by his students that he won their lifelong respect and friendship. His friendly, helpful, and earnest manner demonstrated the fact that he was a born teacher. Mr. Bradbury was one of the first to introduce the theories being developed in Germany on continuous structures in the classroom. During this period, he also engaged in outside engineering consultation for the Boston Elevated Railways and the Clinton Wire Cloth Company (Boston), as well as others. In 1913 he gave up teaching to devote full time to a consulting practice in Boston.

In 1916 he became manager of the structural products department of the Clinton Wire Cloth Company and for a time was general sales manager of the company. In 1923 this company merged with others to form the Wickwire Spencer Steel Company, and Mr. Bradbury was made manager of the structural products department in Buffalo, N. Y. During this period he was very active in the design of reinforced concrete structures, and prepared a loose-leaf manual on the use of wire mesh reinforcing in such structures. In 1925 Mr. Bradbury took the position of contract manager with the Aberthaw Company of Boston and during the next five years was engaged in contract work on many types of construction.

Mr. Bradbury was selected as engineer-director of the Wire Reinforcement Institute in 1930, a position he held until 1945. It was in this position that he will be best remembered by his engineering associates, for he became recognized as a national (and even international) authority on the design of reinforced concrete pavements. In 1938 he published a treatise which was widely used as a textbook in many engineering colleges and as a reference book in the libraries of practicing engineers.[2] He was frequently called upon by state highway departments for assistance in recommending and preparing standards in pavement design. At his death he was chairman of the committee on rigid pavement design of the Highway Research Board of the National Research Council.

Although probably best known for his work in the highway field, Mr. Bradbury continued his interest in building construction until his death. For more than seventeen years he was a member of the building code committee of the American Concrete Institute, and was chairman of two subcommittees of this group which prepared standards for detailing buildings. He was active in technical committee work for the American Society for Testing Materials and the American Road Builders' Association.

As special assignment engineer, Mr. Bradbury joined the staff of the Public Roads Administration in January, 1946, and was actively engaged in work on the theory of design for reinforced concrete pavements at his death. Participation in pavement design standardization by the American Association of State Highway Officials was an important aspect of his work.

---

[2] "Reinforced Concrete Pavements," by Royall D. Bradbury, Wire Reinforcement Inst., Washington, D. C., 1938.

Because of his prior teaching experience and his many years of public relations work, Mr. Bradbury was selected to arrange study courses and field inspection tours for the many foreign highway engineers coming to the United States to study and to observe modern highway design and construction methods. His technical ability and interest in people made an indelible impression on a group of twenty-two engineers from India in 1946, for whom he had arranged a comprehensive course of instruction. He was in the midst of planning for a second group of engineers from India, when he died of a sudden heart attack.

Mr. Bradbury was married to Agatha C. Carney of Boston, on June 14, 1916. He is survived by his widow; a son, John D. Bradbury (Major, United States Marine Corps); a daughter, Martha (Mrs. Long D. Chambliss); a granddaughter, Diana D. Bradbury; and his mother, Mrs. Mattie C. Bradbury (Jefferson City, Mo.).

In his younger days Mr. Bradbury was a member of the Boston Athletic Club and the Wollaston (Mass.) Golf Club, where, at one time, he took golf lessons from Walter Hagen. However, as he grew older he retired from these activities to devote more time to his family, since he was basically a family man. His work was always his hobby, and he found relaxation in the complicated mathematical calculations of pavement design.

Mr. Bradbury was elected an Associate Member of the American Society of Civil Engineers on April 2, 1912. He became a Life Member in Jaunary 1947.

HARRY CUSTER DIESEM, Assoc. M. ASCE[1]

DIED JANUARY 5, 1948

Harry Custer Diesem, the son of Louis Israel and Margaret (Cook) Diesem, was born on July 11, 1877, in Galion, Ohio. He attended the public schools in Galion and was graduated from the University of Kansas at Lawrence with the degree of Bachelor of Arts in 1899.

Mr. Diesem, through choice or circumstance, entered the field of civil engineering and soon after graduation was employed as a deputy county surveyor of Finney County, Kansas, until 1903, at which time he became county surveyor. He occupied this post until the spring of 1905 when he was employed as office engineer of the Standard Beet Sugar Company on an irrigation project in Culbertson, Nebr.

During the academic year of 1905–1906, Mr. Diesem attended the graduate school of the University of Nebraska in Lincoln, and in 1906–1907 he was employed by the Tri-State Land Company on irrigation work at Scottsbluff, Nebr. In the latter part of 1907, as an employee of J. G. White and Company, he was in Denver, Colo., and in June, 1908, was transferred to Richfield, Idaho. The excellent background of professional knowledge and experience which he had gained on these irrigation projects resulted in Mr. Diesem's employment by the United States Department of Agriculture on irrigation investigations in the semi-arid states.

---

[1] Memoir prepared by George H. Hudson, M. ASCE.

In May, 1918, Mr. Diesem answered the call to the colors and was commissioned in the Corps of Engineers, United States Army. Captain Diesem served as commanding officer of the engineer depot at Fort Leavenworth, Kans., until his release from service in October, 1919. He retained a reserve commission and made the affairs of the organized reserve one of his most important hobbies. In 1937 he was graduated from the Command and General Staff School at Fort Leavenworth. He earned promotions through all intermediate grades and attained the grade of Colonel in the Corps of Engineers Reserve prior to his retirement in 1941 because of age.

After his release from the Army in 1919, Mr. Diesem was employed as an engineer-appraiser by the Federal Land Bank at Wichita, Kans. He remained with that office, utilizing his knowledge of hydraulics and land development in evaluating drainage projects until 1929. At that time he was transferred to the Federal Land Bank in New Orleans, La., remaining with that agency until his retirement at the age of seventy in 1947.

Mr. Diesem was an active member of the Presbyterian faith. He retained membership in the Society of American Military Engineers.

On September 22, 1909, Mr. Diesem was married to Bessie Louise Paine of Topeka, Kans. He is survived by his widow and two daughters, Margaret (Mrs. Estill Roberts) and Dorathy (Mrs. R. T. DeLouche, Jr.).

Mr. Diesem was elected an Associate Member of the American Society of Civil Engineers on March 5, 1912. He became a Life Member in January, 1947.

JAMES DOUGAN, Assoc. M. ASCE[1]

DIED DECEMBER 16, 1946

James Dougan, the son of Felix and Margaret (Leslie) Dougan, was born in New York, N. Y., on August 8, 1874. He had one sister, Margaret.

Mr. Dougan was educated in the public schools of New York; then he attended the Cooper Union Institute at night while working for Clinton and Russell, Architects, in the daytime. Mr. Dougan was graduated from Cooper Union in 1901, with the degree of Bachelor of Science; and in 1902 he received the degree of Civil Engineer from the same institution.

---

[1] Memoir prepared by T. Kennard Thomson, M. ASCE, and William Young, Pres., William Young Co., New York, N. Y.

His association with Clinton and Russell lasted from 1895 to 1939. He was first a draftsman, then an assistant engineer, and finally, in 1919, chief engineer, a position which he held until his retirement, due to heart trouble, in 1939. As assistant engineer and then chief engineer for that firm, he designed, specified, and directed work on foundations, structural design, construction details, heating, ventilation, and plumbing for the buildings which Clinton and Russell erected.

Some of the buildings in New York of which he supervised construction include: The Rhinelander printing buildings; the Mutual Life Insurance Company and the Atlantic Mutual Insurance Company buildings; the Broad Exchange Building, the Apthorp, or Astor, apartment; and the Hotel Astor and its additions (1909). In 1903 and 1904 he undertook construction of the Seventy-First Regiment Armory, the Mutual Assurance Society Building in Richmond, Va. (its addition in 1909), and the International Bank. Other outstanding buildings in lower Manhattan constructed under his supervision were: The United States Express Building, the American Exchange National Bank, the Hudson Terminal buildings, and the Whitehall Building. From 1911 to 1913 he was engaged on the same type of work on the Life Insurance Company Building of Richmond (its addition in 1923) and the First National Bank of Richmond. In 1914 he was engaged on the building at 1337 Broadway in New York, and several years later on the Colonial Bank of San Juan (Puerto Rico).

Other examples of Mr. Dougan's work are: The New Bedford Hotel (New Bedford, Mass.), the Trust Company of Jersey City (N. J.), the State and City Bank of Richmond, the New Amsterdam Casualty Company Building (New York), 60 Wall Street Tower Building (New York), the Elks Memorial Building (Chicago, Ill.), and the Elks Home (New Bedford, Mass.).

At one time Mr. Dougan was special engineer for the Department of the Interior in Washington, D. C., as chief engineer for Clinton and Russell, on heating, ventilating, and so on. During World War I, Mr. Dougan also did much work for the government.

He was a member of the F. and A. M. (Thirty-Second Degree), and Past Grand Patron of the Order of Eastern Star of New Jersey.

From acquaintance of almost half a century, since Mr. Dougan's work on the Mutual Life Building, the writers have a keen realization of his engineering ability and of the fact of his eligibility for full membership in the Society for most of that time. They are indebted to his daughter, Mrs. J. Edward Schierloh, for much information as to details of his engagements.

Everything that he did was well and cheerfully carried out. He was absolutely reliable, a true friend, and a citizen of the highest caliber in every respect.

He was married on June 25, 1902, to Mrs. George Moore Wilmot (a widow with a daughter, Minna) at Haddonfield, N. J. They moved to Hackensack, N. J., where a daughter, Agnes, was born on August 15, 1903. He is survived by his widow; two daughters, Minna (Mrs. L. H. Ackerman) and Agnes (Mrs. J. Edward Schierloh); four grandsons, Robert, Donald, and William Ackerman, and James E. Schierloh; two granddaughters, Katherine and Elizabeth Ackerman; two great-grandchildren, Leslie and Allan Ackerman; and a brother, Peter Dougan.

Mr. Dougan was elected a Junior of the American Society of Civil Engineers on March 5, 1901, and an Associate Member on March 2, 1904.

DOUGLASS HEWITT FERRY, Assoc. M. ASCE[1]

DIED NOVEMBER 25, 1947

Douglass Hewitt Ferry was born at Elkhart, Ind., on March 29, 1886. He was the son of John Howard and Clara (Smith) Ferry.

His elementary education was received in the schools of San Diego, Calif., where his parents moved when he was only a few months old. Part of his boyhood was spent on several ranches which his father owned and operated in San Diego County. It was at that time that he learned how to take care of himself and his horse on trips into the back country and also how to do the many tasks connected with operating a ranch. This experience proved to be most useful to him in his work as an engineer in unsettled country.

Later, the family moved to Chicago and Lake Forest in Illinois, the home of his grandparents. He attended Armour Academy (Chicago), from which he was graduated in 1903.

Following his graduation, Mr. Ferry spent a year in California at one of the aforementioned ranches assisting in the management of three thousand acres of fruit and cattle land. He became an expert horseman and learned all phases of caring for cattle.

Mr. Ferry used to say that when he was a small boy he chanced to pass an office in a building in San Diego and saw on the door the words, "Civil Engineer." He liked the looks of the title and determined then and there to become an engineer. When he started his college course at Stanford University (Stanford University, Calif.) in the fall of 1904 it was, therefore, as a civil engineering student that he enrolled. He took an active part in campus activities, especially as a charter member of Hammer and Coffin, the Journalistic Society, and as a contributing artist and, finally, as editor of *Chaparral,* the Stanford humorous publication. In 1907 he was art editor of *The Quad,* the Stanford yearbook, and also art editor of *Sequoia,* the literary magazine published at that time by the English Club, of which he was a member.

While attending Stanford he worked during the summer vacations on various engineering jobs, surveying and assisting in mapping and field work in Siskiyou and San Diego counties.

Immediately following his graduation in May, 1909, Mr. Ferry left for the Yukon, to join the engineering force of the Yukon Gold Company, a Guggenheim corporation which at that time was operating nine gold dredges in the Klondike Basin as well as numerous hydraulic mines. Mr. Ferry worked on mapping and drafting in the offices of this company and was given the opportunity to make an extensive research of the gold-saving devices used on the dredges and to design new and improved equipment. In March, 1912, he was made superintendent of the thawing department, in full charge of nine camps and four hundred men engaged in thawing the frozen ground ahead of the dredges. Part of his work was the locating and delivering of thirty thousand cords of wood to the steam boilers ahead of the dredges.

---

[1] Memoir prepared by Leon B. Reynolds, M. ASCE.

In the fall of 1914, Mr. Ferry brought his wife and son, John, to the United States for a three-month vacation, intending to return to Canada in the spring. He decided to remain, however, and spent the following year in San Diego. In the spring of 1916 he renewed his association with the Yukon Gold Company and was placed in charge of prospecting crews working in Trinity County in California. He continued in this type of work until the spring of 1917 when he supervised the building of a dredge on the American River, near Auburn, Calif. After operating the dredge for a year, he was sent to Murray, Idaho, to take charge of the operation of a dredge on Pritchard Creek. He remained there as manager for eight years.

After the Murray operation was finished, the dredge was sent to the Malay States, where the Yukon Gold Company was inaugurating an extensive tin mining operation. Mr. Ferry was offered the management of the project but preferred to remain in the United States, so as not to be separated from his family.

For two years he conducted examinations for a small syndicate composed of former Yukon Gold Company officials, since the company had concluded all its mining operations in the United States. In the spring of 1927 Mr. Ferry started an examination of ground on Foots Creek, in Jackson County in southern Oregon, later building and operating a dredge there for this same syndicate. In 1935 the dredge was torn down, rebuilt, and moved to Grave Creek in Josephine County, about forty miles away. There operation continued with Mr. Ferry as manager until the fall of 1940.

By that time Mr. Ferry had developed a property in Idaho, near Boise, where the Oregon dredge was moved during the winter of 1940–1941. Operations were started in the spring of 1941, at Twin Springs, Idaho, the property being known as Boise King Placers. The dredge continued to operate until forced to close by World War II.

After traveling in California for some time, Mr. Ferry retired and settled down as consulting engineer at San Jose, Calif. His health had not been good for some time and he devoted himself largely to his garden and orchard. His death occurred in his sleep, from a heart attack, on November 25, 1947.

Mr. Ferry was known as a man who was hard to work for because he exacted a high type of excellence from his men, but also as a man who was absolutely just. His men responded by giving him such respect and loyalty that some of them had worked for him from ten to twenty-five years and refused to work for anyone else.

He was a man of the highest personal integrity, giving his entire thought and concern to his work, denying himself recreations and friendships ordinarily enjoyed by men in his position. He was devoted to his family and took them with him whenever it was possible to do so. Another consistent loyalty was his alma mater, Stanford University.

Mr. Ferry's main hobby was horticulture, in which he excelled as a grower of fine fruit and flowers. A talented artist, he never had time for much work in that field. As a writer he was prolific and witty, and one friend told him that he should have followed that profession exclusively. Many of his friends thought that a good doctor was also lost to the world when he became an engineer.

Mr. Ferry's natural aptitude for mathematics, his thoroughness, and quick grasp of detail, as well as his ability to handle men and large-scale operations, made him a successful engineer. His training in civil engineering was invaluable to him in surveying and mapping; in building roads, dams, and bridges; and in other problems connected with opening and operating mining properties. The opportunity afforded him in the Yukon to enter the mining field, as well as the field of civil engineering, enlarged his scope of operations and gave him opportunities for advancement far ahead of most men of his years. He became an authority on prospecting for gold and estimating the values of gold-bearing properties, and his advice and opinions were highly considered. His ability to handle current problems and his foresight in anticipating and preparing for future ones enabled him to make a signal success in the operating field as well.

On August 5, 1911, in Dawson, Yukon Territory, Canada, he was married to Eudora Bundy, a Stanford classmate. He is survived by his widow; a son, John; and twin daughters, Elizabeth F. Morris and Frances F. Perske.

Mr. Ferry was elected an Associate Member of the American Society of Civil Engineers on March 2, 1915.

ALEXANDER SYLVESTER FORSTER, Assoc. M. ASCE[1]

DIED JANUARY 25, 1947

Alexander Sylvester Forster, the eldest son of Alexander Edward Forster and Laura (Brown) Forster, was born in Toledo, Ohio, on June 10, 1879.

He was educated in the Toledo public schools and was graduated from Toledo Central High School. He studied engineering under a private tutor during his employment in the field of engineering.

In June, 1898, he was employed in the Toledo city engineers' office, being clerk, inspector, draftsman, and assistant engineer, successively. In March, 1901, Mr. Forster entered the employ of the American Bridge Company in the

---

[1] Memoir prepared by George A. Taylor, M. ASCE.

Toledo plant, where his employment continued until October, 1915. Here, he obtained a broad experience in structural engineering, having been frequently sent to other plants of this company to assist in planning various structures on important engineering works.

He accepted a position in October, 1915, in the engineering department of the Toledo Bridge and Crane Company, as estimator and chief draftsman, later becoming superintendent of the plant. His employment continued there until the end of 1919.

In January, 1920, Mr. Forster was employed by the DeVore Company of Toledo, an engineering firm specializing in the design of industrial plants, such as glass manufacturing, paper mills, foundries, and power plants.

He became a partner in the architectural and engineering firm of Rheinfrank and Forster in May, 1924. This association continued until January, 1926, when he organized an engineering firm which became the partnership of Forster, Wernert, and Taylor, in 1928, specializing in structural engineering and factory design. He was active in this business until his death.

Mr. Forster had a wide acquaintance, and was an active member in many organizations. He was an Elder in the Collingwood Presbyterian Church, a member of the Kiwanis Club, serving as chairman of various committees, and as director of the club for three terms. He was a member of Sylvania Country Club, the Masonic Order, and the National and Ohio Societies of Registered Professional Engineers.

In addition, Mr. Forster was interested in civic affairs, being a member of the Toledo Port Commission and the Toledo Chamber of Commerce and was on the committee appointed by the city manager to revise the Toledo City Building Code. With the adoption of the code in 1946, he was made chairman of the Board of Appeals, whose duties were to interpret the provisions of the code.

In 1903 Mr. Forster was married to Ruth Jean Campbell; they had two children, a son, John, of Toledo, and a daughter, Jean, of New York, N. Y. He is survived by his widow; two children; two grandchildren; two brothers, Frank H. and Erle H.; and a sister, Eva Fern (Mrs. Merle Planck).

Mr. Forster was elected an Associate Member of the American Society of Civil Engineers on May 31, 1916.

MAGNUS LAWRENCE HYDLE, Assoc. M. ASCE[1]

DIED JANUARY 29, 1947

Magnus Lawrence Hydle, the son of Lars Magnus Hydle and Kathrine (Hakestad) Hydle, was born at Ulvik, Hardanger, Norway, on September 19, 1883. After receiving his elementary education in Ulvik, he attended Trondheim (Norway) Institute of Technology, being graduated with the degree of

---

[1] Memoir prepared by Fred D. Pyle, M. ASCE.

Civil Engineer in 1905. He then attended Christiania Institute at Oslo, Norway, majoring in design of indeterminate structures.

After a short period on the design of the Empire State Building in New York, N. Y., he went with the Northern Pacific Railway Company in 1906. He progressed through the various steps from draftsman at Saint Paul, Minn., to resident engineer on construction in the State of Washington. He then returned to Saint Paul as inventory engineer from 1915 to 1917. From May, 1917, to August, 1919, he was with the Oregon State Highway Department at Salem, Ore., as office engineer, efficiency engineer, and bridge designer, except for a leave of absence from September, 1917, to January, 1918, when he served as a First Lieutenant in the Engineer Corps of the United States Army.

With the exception of six months when he was with the Southern Pacific Railroad Company at Los Angeles, Calif., as head draftsman and field engineer, Mr. Hydle was employed from 1919 to 1923 by the California State Highway Department at Sacramento, Calif., as designer and resident engineer on bridge construction. The following year he was with the Pan American Petroleum Company at Los Angeles, in charge of harbor development, and at the Lorain, Ohio, plant of United States Steel Corporation, supervising the manufacture of 150 miles of heavy oil pipe for the Elk Hills project. From November, 1924, to October, 1929, Mr. Hydle served on various work, generally in the employ of consulting engineers on design of irrigation projects, storm drains, subdivisions, and highway bridges.

From October, 1929, to January, 1942, he was with the California Division of Highways on designs, estimates, and reports. From January, 1942, to October, 1945, he became structural engineer for the Consolidated Aircraft Corporation at San Diego, Calif., on design of foundations and of concrete, steel, and wooden buildings, also making critical reviews of plant as to safety and adequacy. From October 15, 1945, until his death, Mr. Hydle was with the Harbor Department of the City of San Diego on structural design.

On September 29, 1919, he was married to Alice Rosalyee Bahr at San Francisco. He is survived by his widow; two daughters, Mildred (Mrs. Edward Getz) and Jacqueline (Mrs. Howard C. Guy); three brothers, Olaf, Lars, and Odmund Hydle; and a sister, Eva Standley.

Mr. Hydle was elected an Associate Member of the American Society of Civil Engineers on May 22, 1944.

ROY WRENSHAW JABLONSKY, Assoc. M. ASCE[1]

DIED JUNE 13, 1947

In writing the biography of a man of accomplishment it is interesting to note his background, as contributing to the character and ideals of the man himself.

---

[1] Memoir prepared by Raymond E. Julius, Asst. Highway Engr., Clayton, Mo.

Roy Jablonsky was born on May 24, 1891, in St. Louis County, Missouri. The home of his parents was located on the eastern side of Kienlen Avenue at its intersection with what was then called Hamburger Avenue (later changed to St. Louis Avenue). His father, August Jablonsky, was born in Germany and his mother, Priscilla (Saunders) Jablonsky, was born in England. Both his parents immigrated to America at an early age. August Jablonsky at the time of his son's birth was engaged in the florist business. Roy Jablonsky, however, at no time evinced any interest in or desire for this line of work.

He attended the Wellston public schools and when he had finished his grade school studies, he entered a business school to study bookkeeping and stenography. On the completion of his commercial course he secured employment in a bond brokerage house which position he retained until accepting employment with a friend of his father, William Elbring, county surveyor and highway engineer of St. Louis County. In this employment he soon realized a particular ambition to study engineering and to undertake an engineering career. Thus began a life devoted to the study of professional engineering, and it may be said that he continued as a student of that profession until his death. For the most part his study of engineering was informal and somewhat unorthodox. Being an insatiable reader was of immeasurable aid to him in the methods he pursued in the study of his profession.

After procuring a working knowledge of algebra, geometry, and trigonometry, he secured books by eminent authors on the technical aspects of the various branches of the civil engineering profession. In stating that he pursued his studies in an unorthodox manner, particular reference is made to the fact that he became proficient in the design of reinforced concrete structures before he undertook the design of structural steel. Thus it was that in his own way he proceeded relentlessly to master the various branches of civil engineering required in the design and construction of county highways and bridges.

While studying engineering he was enabled through his employment with the county highway engineer to give practical application to theory, which was, indeed, an ideal arrangemtent. As quickly as his ability permitted he advanced in his work; in November, 1911, he became instrumentman in a survey party and in April, 1914, he was promoted to chief of the survey party.

A little more than two years later, in September, 1916, Mr. Jablonsky was made assistant county highway engineer, a position he held until July, 1919, when he was appointed by the county court as a special engineer of St. Louis County, as well as engineer in charge of construction on Missouri highway project S 18.39. From September, 1920, until April, 1921, during the construction of federal aid highways under the Centennial Road Law of Missouri, Mr. Jablonsky was engineer in charge of project No. 79.

On the completion of this project he engaged in the construction business until his appointment in February, 1924, by Arthur M. Hyde (who was then governor of Missouri), as county surveyor and ex officio highway engineer of St. Louis County to complete the unexpired term of William Elbring who had resigned. At the elections held in 1924 and 1928 Mr. Jablonsky was elected and re-elected county surveyor and ex officio highway engineer, remaining in that office until January 1, 1933. From that date until January 1, 1941, he engaged in private engineering business, specializing in street and sewer design for subdivision development.

From the time of his appointment by former Governor Hyde until the relinquishment of this office on January 1, 1933, Mr. Jablonsky supervised the expenditure of the funds derived from $3,000,000 and $10,000,000 road bond issues. It was his responsibility to design and construct a system of modern and convenient highways in St. Louis County. His acomplishments during this period brought him nationwide acclaim and they will remain as lasting momuments to his ability.

It was during this period that his forthright character manifested itself. When he assured himself that he was right, neither political expediency nor personal gain could effect a compromise—a most unusual characteristic in one holding a political office. His honesty, integrity, and ability could not be denied even by his political opponents. Many times intimate friends would complain that their friendship never influenced him in the least in attempting to secure official favors. That he planned wisely and that he directed efficiently is attested by the fact that the engineering costs in all the projects undertaken in the expenditure of $13,000,000 did not exceed five per cent.

During 1928 a cash refund from the State of Missouri to the County of St. Louis was authorized by the legislature, for roads taken over by the state. This money, under the provisions of the law, was required to be expended in the establishment of other roads by the county. The sums thereby derived were sizable and sufficiently so to inspire Mr. Jablonsky to plan a north and south highway through the center of St. Louis County with a right-of-way width of 100 feet. At the time rights of way 100 feet wide were unheard of in this area and the establishment of such a highway was bitterly opposed, not only by property owners and taxpayers, but by county officials as well. His keen foresight, however, revealed to him that this artery had potentialities and would in the not distant future become a very important and heavily traveled highway. Therefore, notwithstanding objection and criticism, he refused to compromise, and in his characteristic forthright manner he pressed his point until the county court finally acquiesed. This highway became a major artery just as he had predicted, and the state highway commission, which now controls it, has praised him publicly for his vision and foresight.

Later he envisioned a need for another major highway running southwestwardly through the southern half of St. Louis County. Not having the authority nor the funds to carry out this project, he proceeded to sell his idea to the Missouri State Highway Commission. Again he met opposition; he refused, however, to compromise, and undaunted, he promoted his idea with greater vigor. Finally, the state highway commission conceded the point and established and constructed the road which is now route No. 66

running southwestwardly from the City of St. Louis. He has often been acclaimed for his persistence in promoting this project which anyone traveling westwardly from St. Louis knows is an important and convenient traffic artery. The establishment of this project also served another purpose, that of developing real estate along its entire length. On January 1, 1941, Mr. Jablonsky again became county surveyor and ex officio highway engineer of St. Louis County and was re-elected to that office for a four-year term beginning on January 1, 1945.

During World War II governmental regulations restricted the use of materials almost entirely to maintenance and repair, permitting very little for construction and reconstruction. While this was an expedient most revolting to Mr. Jablonsky, he nevertheless subordinated his feelings and submitted in full measure. During those dark days traffic had to be accommodated and without hesitation he cooperated to that end. Many war industries were located within the County of St. Louis and every plant without a single exception was adequately served despite the difficulty in securing materials and labor for maintenance of highways.

As testimony to his loyalty it is only necessary to mention the fact that he organized and actively participated in the Office of Civilian Defense in St. Louis County. It can be said without fear of contradiction that he put forth more effort and spent more of his own time toward maintaining the Office of Civilian Defense than any other member of that organization in this county. He served as secretary from its inception until its dissolution after the war.

What might be considered the greatest tribute to his ability was his appointment on September 21, 1945, by the late Thomas H. MacDonald, Hon. M. ASCE, Commissioner of Public Roads of the Public Roads Administration, as a member of the Board of Highway Consultants. The board consisted of eleven engineers from various parts of the United States who met with the commissioner of public roads to discuss the various features of the secondary federal aid highway program. On January 11 and 12, 1946, he was called to Washington, D. C., to attend a meeting of this board. That he impressed the members of the board is evidenced by the number of letters which he received seeking information and counsel on the various phases of the secondary road program.

During November, 1946, Mr. Jablonsky was invited to lecture on secondary highways in several midwestern states but after reviewing the agenda he realized that the lecture tour could not be undertaken without interfering with his work as county highway engineer. His inordinate devotion to the office to which he was elected by the people of St. Louis County is best illustrated in a letter to Mr. MacDonald tendering his resignation from the board of consultants. It reads as follows:

> "On November 18th, 1946, Mr. Fuller of your Division Office called on me and outlined my agenda as highway consultant for the coming months. The conferences and discussions I am sure would be very instructive and conducive of sincere cooperation amongst the various agencies, but I have

> concluded because of certain circumstances that I should not undertake the assignment.
>
> "Since the adoption of new laws my functions as Highway Engineer have been considerably enlarged and this factor, coupled with my limited technical personnel, requires me to devote all of my time to the official duties of the office. At this juncture I might add that attending the hearing would be one thing and thoroughly studying all matters involved in preparation for the meetings would be another, and for neither of which could I devote the necessary time.
>
> "That I should terminate my appointment as highway consultant I am sure you will agree, thereby leaving a vacancy to be filled by someone who is in a position to devote the necessary time to this important office.
>
> "Please be assured that I have enjoyed working with your Department, limited as my work was, and I regret very much that I find it necessary to discontinue that work."

The foregoing letter also bespeaks of Mr. Jablonsky's sincerity in the conduct of official matters.

He is survived by his widow, Frieda (Wagner) Jablonsky, to whom he was married on August 21, 1912, at the Emmanuel Evangelical Lutheran church in St. Louis County, and by three children, August W., Roy D., and Betty Jane.

His passing has been a distinct loss, not only to his family, who revered him greatly, but to all the people of St. Louis County whose welfare was his guiding star. No one can gainsay that he was devoted to the people of St. Louis County and that his limitless efforts in their behalf contributed to his untimely death.

Mr. Jablonsky was elected an Associate Member of the American Society of Civil Engineers on June 6, 1921.

ROLAND WINTHROP LEFAVOUR, Assoc. M. ASCE[1]

DIED JULY 15, 1947

Roland Winthrop Lefavour was born in Beverly, Mass., on July 7, 1890. His parents were Howard Richard and Rebecca Ober (Perry) Lefavour. Among his relatives and forebears were ship captains, soldiers and sailors in the War for Independence and in the Civil War, town officials, and college presidents.

He attended school in Beverly, and continued his education in art school and under tutors, for a time making a serious study of music. Upon taking a position with a firm of landscape architects he discovered his vocation—surveying, mapping, drawing, and allied subjects.

From 1909 to 1911 Mr. Lefavour was assistant city engineer of Beverly. In 1918 he was engaged by Tufts College in Medford, Mass., as an instructor in surveying, and in 1922 was made assistant professor of civil engineering, a post which he held at his death.

---

[1] Memoir prepared by Frederic N. Weaver, M. ASCE.

He was a member of the American Society for Engineering Education, the Society of American Military Engineers, the American Association for the Advancement of Science, and was affiliated with the Odd Fellows and the National Grange. For years he belonged to the Society of the Sons of the American Revolution.

Professor Lefavour's life did not fall into any set pattern—in fact, it was an unusual combination of the practical and the artistic. As an avocation he painted in oils and water colors, and excelled in etchings. He was unusually competent in his own field and was an excellent teacher, a genial friend, and an educated and cultured gentleman.

He is survived by two brothers, Howard L. Lefavour of Northboro, Mass., and W. Russell Lefavour of Beverly.

Professor Lefavour was elected an Associate Member of the American Society of Civil Engineers on August 4, 1924.

PAUL WRIGHT LONGSDORF, Assoc. M. ASCE[1]

DIED AUGUST 28, 1946

Paul Wright Longsdorf was born on October 6, 1882, in Floradale, Adams County, Pa. He was the son of Charles S. and Elizabeth (Wright) Longsdorf.

His early education was obtained in the public schools of Floradale and in the private schools conducted by the Society of Friends. Later, he attended George School in Newtown, Pa., and was graduated in 1902. Subsequently, he entered Pennsylvania State College at State College, where he studied civil engineering for two years.

After leaving college Mr. Longsdorf was employed by the Pennsylvania Railroad Company. This engagement lasted from April, 1905, to June, 1908, when he was employed in making surveys for a low-grade freight line from Morrisville, N. J., to Newark, N. J.; he made property and construction surveys and was also masonry inspector in charge of the construction train on elevated track work.

From 1908 to 1915 Mr. Longsdorf was occupied primarily in real estate development and in landscaping private estates. During this period he was engaged by M. R. Yerkes in Bryn Mawr, Pa. (from June to November, 1908); the Schuylkill Stone Company in Monocacy, Pa. (from January to March, 1909); Thomas Meehan and Sons in Philadelphia, Pa. (from March, 1909, to February, 1910, and from September, 1910, to June, 1913); and C. C. Worthington in Shawnee-on-Delaware, Monroe County, Pa. (from February to September, 1910).

---

[1] Memoir prepared by George B. Mebus, M. ASCE.

In May, 1915, he was appointed township engineer of Cheltenham Township, Montgomery County, Pa., a position he held until June, 1923. When Mr. Longsdorf was township engineer rapid development took place in the township due to the unusual influx of residents from Philadelphia. The township initiated a very comprehensive road and bridge construction program, and its present excellent highway system is the result of Mr. Longsdorf's foresight as a planner and his ability as an organizer.

In June, 1923, he formed a partnership with George Meyers Patterson to engage in construction work, consisting primarily of grading and road and sewer construction. During the seven years of this partnership Mr. Longsdorf handled the construction of the majority of many excellent suburban land subdivisions, in addition to doing a great quantity of municipal construction. This partnership was terminated in 1930. He continued in the construction business after 1930, having organized the firm of Paul W. Longsdorf, Incorporated. He remained active in this business until his death.

Mr. Longsdorf completed the following works: The Oak Lane Manor, Carl Metz, Getler and Helwig, and Joshua M. Holmes developments; several projects at Lehigh University (Bethlehem, Pa.), including Richards Dormitory, Eugene Grace Hall, Drinker House (another dormitory), with all grading, walks, and drives, in addition to the new track and athletic field for the Department of Athletics; Sunset Memorial Park with new roads; two estates, one for James Elliott in Pottstown, Pa., and another for Archibal Johnston in Bethlehem; Jeanes Hospital in Philadelphia; the Thomas Williams School for the Cheltenham Township School Board; and playgrounds for Girard College in Philadelphia.

He was always a sincere citizen and a good neighbor. He was very active in a multitude of civic and historical organizations, and was a very generous person, who contributed to many worthy enterprises, almost always anonymously. Membership in the following organizations is indicative of his many interests: The Pennsylvania Horticultural Society, the Historical Society of Pennsylvania, the Philadelphia Zoological Society, the Pennsylvania Alpine Club, the American Road Builders Association, the American Public Works Association, the Society of American Military Engineers, the Engineers and the Union League clubs of Philadelphia, and the Old York Road Country Club and the Rotary Club of Jenkintown, Pa.

On October 28, 1909, he was married to Annie Michener at Huntingdon Valley, Pa. He is survived by his widow; a daughter, Alice E. (Mrs. J. Linden Heacock, Jr.); and a son, Charles M. Longsdorf.

Mr. Longsdorf was elected an Associate Member of the American Society of Civil Engineers on April 18, 1927.

BURTON LOWTHER, Assoc. M. ASCE[1]

DIED SEPTEMBER 7, 1945

Burton Lowther was born on June 15, 1874, at Saugerties, N. Y. He was the son of James Lowther, a native of Northern Ireland, and Eliza (Allen) Lowther, a native of Devonshire, England. He received his engineering education at Rensselaer Polytechnic Institute in Troy, N. Y.

He began his professional career in 1900 as instrumentman and second assistant engineer in railway and mill construction, with the T. A. Edison Cement Company in Stewartsville, N. J., and then proceeded to other professional assignments. From 1900 to 1901 he made field drawings in the office of the resident bridge engineer of the New York Central Railway Company, becoming an instrumentman in 1901 and 1902 with the American Railways Company of Philadelphia, Pa., on survey and construction of the Chicago and Joliet Electric Railway, and an engineer inspector of masonry and bridge construction. In the resident engineer's office at Dayton, Ohio, he was engaged on the improvement of railway properties, and later was made assistant resident engineer in entire charge of reconstruction and strengthening of city bridges, in addition to survey and computation for city trackwork and pile driving.

The next year he was first assistant resident engineer with the Western Ohio Electric Railway, in the building of 20 miles of track, taking charge on the resignation of the resident engineer soon after work was begun. From 1903 to 1904 as draftsman with the Minneapolis (Minn.) Steel and Machinery Company, he detailed steelwork for bridges and buildings.

In the spring of 1904 he surveyed 20 miles of electric railway in Jackson and Cass counties in Missouri; also, he became mechanical engineer for the Prouty-Pierce Gasoline Locomotive Company in Kansas City, Kans. After this Mr. Lowther was engineer of tests and materials for the Bell Telephone Company in Kansas City, Mo., in charge of acceptance of material, electrolytic surveys in Missouri and Kansas, and design of special apparatus in telephone construction.

In 1907, as resident construction engineer with the Freeborn Engineering and Construction Company in Kansas City (Mo.), Mr. Lowther supervised the building of a 2,000-barrel Portland cement plant at Independence, Mo., for the Kansas City (Mo.) Portland Cement Company. The same year he became vice-president of the Moechel and Lowther Engineering Company, engineers, chemists, and metallurgists in Kansas City (Mo.), engaging in consulting work in mining for cement companies, with personal direction of physical tests in the laboratory, and having entire charge of the civil engineering work. He also made the design for developing the gold district in Phonolite, Nye County, Nev.

---

[1] Memoir prepared by Dwight D. Gross and Robert Follansbee, Members, ASCE, and John McGowan, Assoc. M. ASCE.

As construction engineer (from 1908 to 1914) for the Kansas City (Mo.) Municipal Water Works, Mr. Lowther had charge of the construction of a 45,000,000-gallon reservoir, as well as the repair and remodeling of another reservoir; the installation of steam driven pumps of a total capacity of 80,000,000 gallons per day with boilers and general powerhouse construction; and the building of a $250,000 river improvement project on the Missouri River to protect the city water supply.

From 1914 to 1915 Mr. Lowther was chief engineer of the Kansas City Municipal Water Works by civil service appointment, having entire charge of this municipal utility valued at more than $12,000,000. Three years later he became superintendent, as well, of the same organization, with full executive authority in conducting the affairs of this utility under the board of fire and water commissioners.

He was chief engineer and general superintendent of the Denver (Colo.) Municipal Water Works from 1918 to 1926. In August, 1918, he was employed as engineer by the Denver Union Water Company (the Denver water plant being privately owned at that time), and on November 1, 1918, when the city acquired the water plant, Mr. Lowther was engaged as chief engineer and general superintendent. He at once recommended extensive improvements to the plant and had charge of the planning and installation of improvements valued at $10,000,000.

In 1926 Mr. Lowther set up his own office as consulting hydraulic and sanitary engineer in Denver, specializing in design and construction of water works and sewage disposal plants, continuing until 1945. Some of his more notable engagements as consulting engineer included: The Water System for Boulder City, Nev., at the time of construction of the Hoover Dam; the construction of the arms plant at Denver; the water and sewage plants for the cities of Colorado Springs and Montrose in Colorado; the water works systems of Johnstown, Longmont, Louisville, Craig, Walsenburg, and Oak Creek in Colorado; and the sewage disposal systems of Brighton, Colo.

Before studying engineering Mr. Lowther studied medicine, including pathology, physiology, and water-borne diseases, and he also took a special laboratory course in bacteriology. During his career of water works engineering this training was of great value to him. He was a member of the American Water Works Association and the American Public Health Association, and he served as collaborator in the preparation of the material for the *Water Works Practice Manual.* He was a pioneer in the use of chlorine in water treatment, and in reinforced concrete pressure pipe with expansion joints. In addition to his other activities he belonged to the F. and A. M.

Mr. Lowther was an outstanding engineer in the fields of water works and sanitation. He was a gifted conversationalist and a man with the courage of his convictions. He made many friends, but he would not compromise his opinions in order to make friends.

On January 5, 1924, he was married to Dr. Kay R. LaCroix. He is survived by his widow, and by two daughters by a previous marriage, Mrs.

Elizabeth Campbell of Washington, D. C., and Mrs. Lillian Porter of California.

Mr. Lowther was elected an Associate Member of the American Society of Civil Engineers on October 7, 1908.

JOHN JOSEPH McGINLEY, Assoc. M. ASCE[1]

DIED DECEMBER 9, 1940

John Joseph McGinley, the son of James and Mary Elizabeth (Brennan) McGinley, was born in New York, N. Y., on March 2, 1889.

After completing his preparatory education in the New York City schools, Mr. McGinley attended the College of the City of New York for four years and was graduated in 1909 with the degree of Bachelor of Science in Mechanical Engineering. Later, he did graduate work in the School of Civil Engineering at Columbia University in New York, and, after completing his studies in three years, he was awarded the degree of Civil Engineer in 1912.

Mr. McGinley's initial professional training was received in his native city, where for two years, from 1912 to 1913, he was associated with major highway and bridge construction projects, including the Hell Gate Bridge. In 1914 he joined the engineering staff of the New York State Public Service Commission and until the advent of World War I supervised engineering work in the field on the extensive subway construction program then under way in New York.

Shortly after the outbreak of World War I, Mr. McGinley enlisted in the air service of the United States Army. After completing the courses at the Officers Training School at Kelly Field in San Antonio, Tex., and the School of Military Aeronautics at the Georgia School of Technology in Atlanta, he received a Second Lieutenant's commission in the Air Service. He served consecutive assignments with the Headquarters Staff at Hazelhurst Field in Mineola, N. Y.; the 361st and the 1,107th Aero-Squadrons in Winchester, England; and the Headquarters Staff of the Air Service in London, England. In June, 1919, he was honorably discharged.

After a three-year service with the engineering division of the Texas Company in a supervisory capacity, Mr. McGinley, in 1922, became attached to the Department of Plant and Structures, later the Department of Public Works of the City of New York, and for eighteen years, until his death in 1940, served in the Bridge Division as an assistant engineer. During this period he was associated with the construction and maintenance of all bridges over navigable waters in the metropolitan area of New York and came to be recognized as an authority on bridgework, particularly the movable bridge type.

---

[1] Memoir prepared by James I. Rooney, M. ASCE.

Mr. McGinley was known as a man of high principles, sound judgment, and fine character—truly, a cultured gentleman, respected by his associates, and loved by his friends.

On October 8, 1934, Mr. McGinley was married to Cecilia A. Coyle of Huntsville, Ala., who survives him.

He was a registered professional engineer in the State of New York, and a member of the Newman Club of Columbia University and Post No. 1,222 of the American Legion in New York.

Mr. McGinley was elected an Associate Member of the American Society of Civil Engineers on September 10, 1923.

WILLIAM CANON MULDROW, Assoc. M. ASCE[1]

DIED JANUARY 14, 1947

William Canon Muldrow, the son of Simon O. and Annie L. Muldrow, was born at Paducah, Ky., on August 31, 1882. He was educated at the Mississippi Agricultural and Mechanical College at Starkville, which he attended from September, 1899, until March, 1903, majoring in agriculture.

Mr. Muldrow (Bill, to his many friends) had practiced engineering since 1903, when he started work as rodman with a field party of the Bureau of Reclamation at Phoenix, Ariz. In 1904 he transferred within the Bureau to the State of Washington where he continued in engineering work with advancing responsibilities and where he was engaged on locally financed irrigation projects, and in private practice in the Pasco, Yakima, and Okanogan districts in Washington until 1918.

In March, 1918, he was employed by the Inter-Ocean Barge and Transport Company of Seattle, Wash., as chief engineer, in full charge of design and construction of two five hundred-ton concrete barges, the first of their kind to be constructed in the United States. At last report, as of about 1945, they were still in active service and in excellent condition. Because of a lack of precedent and information on this type of construction, it was necessary to devise methods for the accurate placement of the reinforcing steel and for the settlement of the concrete around the steel to meet the rigid requirements of inspection and safety, all of which were satisfactorily solved. This work was terminated in 1918, at the end of World War I.

From 1920 to 1941 Mr. Muldrow served as engineer-manager and secretary of the Lake Chelan Reclamation District and the Columbia and Sunnyside irrigation districts in Washington. His studies while in the latter position furnished the basis and initial impetus for the passage of the National Repayment Act of 1939. These studies contributed much to the knowledge and practice of irrigation project maintenance and water use.

---

[1] Memoir prepared by Mark L. Nelson, M. ASCE.

In 1941 he was employed by the Corps of Engineers, United States Army, on the construction of military facilities in Alaska and the Aleutians, where he earned a citation from the War Department for his work during World War II. Since 1943, he was employed by the Portland District of the Corps of Engineers on flowage appraisals and as specialist on irrigation and water use studies for multiple-purpose project planning. He died on January 14, 1947, at Midland, Tex., where he was visiting with relatives while on annual leave from the Engineer Corps.

Mr. Muldrow was a registered professional engineer in the State of Washington and a member of the following organizations: The Washington State Reclamation Association, the Oregon Professional Engineering Employees Association, the Benton Lodge, No. 277 of the F. and A. M., and the Scottish Rite of Kennewick, Wash.

He was married at Yakima, Wash., on February 3, 1906, to Magdalene Caroline Hearle, who died at Portland, Ore., on August 11, 1945. He is survived by a sister, Annie Lida (Mrs. John Perkins) of Midland, and three nephews, Maxwell L. Larson, Ronald E. Larson, and Eugene H. Larson, all of Portland.

Mr. Muldrow was elected an Associate Member of the American Society of Civil Engineers on September 12, 1921.

LEMUEL BYNUM OGILVIE, Assoc. M. ASCE[1]

Died December 4, 1946

Lemuel Bynum Ogilvie was born in Crutchfield, Ky., on September 3, 1901. He was the son of Leslie Eugene and Ethelyn (Farrel) Ogilvie. At an early age he moved with his family to the Panhandle district of Texas and Oklahoma.

His education was informal. After attending high school in this district, he turned his attention to the rapidly developing oil industry and to its possibilities for engineering and construction. His first job in September, 1917, at the age of sixteen, was with the Texas Company, in Houston, Tex., in the Refinery Engineering Department, where he was employed as tracer in the drafting room and, later, as rodman in a field survey party. From this time, until the end of his life, Mr. Ogilvie was identified with the southwest and its oil production activity.

In October, 1920, Mr. Ogilvie left the Texas Company and took a position with the Humble Oil and Refining Company in Houston in the Production Engineering Department. He started as draftsman, then worked as transitman on land surveys and field locations, and later became chief of party. He spent three years with the Humble Oil and Refining Company.

For the next three years he held various jobs as draftsman, instrumentman, or chief of party. He was employed by J. M. Moskowitz, Surveyor, of Houston; the American Petroleum Company in Houston; the City of Corpus Christi, Tex.; and the Pure Oil Company in Mexia, Tex.; in addition to engaging in private engineering work in Fort Worth and Dallas, Tex.

---

[1] Memoir prepared by David R. Williams, Williams Brothers' Co., Engineers-Contractors, Tulsa, Okla.

Mr. Ogilvie returned to Houston in 1926 to take a position with the Harris County Engineering Department, in whose employ he remained for the next ten years. During this time he worked as chief of party on highway, bridge, and grade separation locations. He was county engineer on the Harris County Drainage Report of 1930—a $33,000,000 program. As office engineer of the county's bond program for highways and bridges, he did considerable design on drainage structures and was in charge of preparation of estimates.

From 1936 to 1938, Mr. Ogilvie was superintendent on highway and bridge construction for Parker Brothers and Company, Incorporated, in Houston. In January, 1938, he accepted the position of assistant chief engineer with the Mené Grande Oil Company, Compania Anonima (a subsidiary of the Gulf Oil Corporation), in Venezuela and became chief engineer in February, 1940. While employed by the Mené Grande Oil Company, Mr. Ogilvie was actively in charge of design and construction of docks, terminals, roads, bridges, pipe lines, and terminal structures—together with water, sewer, electric, and gas systems serving two large terminals. The first major oil pipe line in Venezuela was completed under his supervision in 1939.

In September, 1942, he requested, and was granted, a leave of absence from the company for the duration of World War II. It was during the early part of 1942 that submarine warfare in the Caribbean Sea was at its most critical period. Too young for World War I, Mr. Ogilvie now became fully occupied in construction projects which were a part of the over-all strategy for the prosecution of World War II. He worked for the Bechtel-Price-Callahan Company in Edmonton, Alberta, Canada, as principal engineer in charge of all planning and scheduling for the Canol Project. His work was completed on April 17, 1943, at which time Mr. Ogilvie resigned and returned to the United States as superintendent of construction for the Williams Brothers' Corporation on a water line for the United States Navy from Homestead to Key West, Fla., and later on for the Tennessee Gas Transmission line.

In 1944 he went to the Canal Zone, still in the employ of Williams Brothers' Corporation, as chief engineer on the construction of transisthmian Navy fuel lines, linking the Atlantic and Pacific terminals, complete with terminal facilities, loading racks, supplementary water plants, and pumping stations necessary to operate these pipe lines. The outstanding ability and devotion to duty displayed by Mr. Ogilvie, together with his unceasing hard work, contributed substantially to the success of these projects.

In September, 1945, Mr. Ogilvie returned to Venezuela for the Williams Brothers' Corporation. All of 1945 and half of 1946 he spent in eastern Venezuela on the construction of roads. From July, 1946, until his death he was in Maracaibo as chief engineer in charge of all Williams Brothers' activities in western Venezuela.

Mr. Ogilvie had filled all the junior grades in his profession and was devoting his later years to projects demanding mature and seasoned judgment. Possessed of imagination, quick sympathies, professional integrity, rare broad-gaged vision, he put to good use these qualities which are so essential in Americans representing our country abroad.

He is survived by his wife and two children, a daughter and a son, by his first marriage, and two small daughters by his second marriage.

Mr. Ogilvie was elected an Associate Member of the American Society of Civil Engineers on October 19, 1942.

ARTHUR GEORGE READY, Assoc. M. ASCE[1]

Died August 14, 1947

Arthur George Ready, the son of George A. and Katherine (Brennan) Ready, was born in Albany, N. Y., on December 28, 1895. His preliminary education was received at St. John's Preparatory School in Brooklyn, N. Y.

For his professional studies he enrolled at St. John's College in Brooklyn, N. Y., and after completing a four-year course was graduated in 1917 with the degree of Bachelor of Science in Civil Engineering.

Meanwhile, he had spent his summers to good advantage in obtaining engineering training; during 1915 he was timekeeper for the Tremper Construction Company in Brooklyn, and during 1916 he worked as transitman on a government project in Newport News, Va., for Westinghouse, Church, Kerr and Company. After graduation Mr. Ready continued with this latter association and immediately was appointed assistant engineer in the civil engineering department, engaged in office and field work at the embarkation station where he had charge of septic tank construction. When he completed one year of this work, he joined the United States Navy and served for a year.

A civilian once again, Mr. Ready was engaged from May, 1919, to December, 1920, by his previous employer, Westinghouse, Church, Kerr and Company —this time as field engineer on industrial construction in and near New York, N. Y. There followed a short employment with Henry R. Kent and Company of Rutherford, N. J., for whom he served as field engineer on a power plant at Lock Haven, Pa.

Mr. Ready's next employer was Walter E. Truesdell, a consulting engineer in New York City. While working for Mr. Truesdell he spent a short period on surveys and designs for paper mill improvements and then a year as resident engineer in Pearl River, N. Y., on construction of a high school and factory. For a time in 1921 he was engaged by George L. Watson, M. ASCE, consulting engineer, as estimator on the design of a sewerage system for Clifton, N. J.

---

[1] Memoir prepared by R. G. Macdonald, Secy.-Treas., Technical Assn. of the Pulp and Paper Industry, New York, N. Y.

Commencing in January, 1923, Mr. Ready began an association with the late George F. Hardy, M. ASCE, consulting engineer, which continued, with the exception of short interruptions, for many years and which developed his career as a construction and operations engineer in the paper industry. First employed as draftsman, he was soon promoted to positions of greater importance, such as assistant resident engineer and resident engineer in charge of pulp and paper mill construction. This work took him first to Moss Point, Miss., in 1924; then to Everett, Wash., for a year with the Everett Pulp and Paper Company; and again to the south, where he spent a number of years in Monroe, La., in connection with the plant of the Brown Paper Mill Company.

During this time Mr. Ready was in responsible charge of not only the construction of buildings, but also the process and power equipment. His duties, in addition, included design work on a hydroelectric station. This engagement was interrupted at the end of 1932 by the depression.

For a few months in 1933, Mr. Ready was superintendent with Beckerle and Wright, engineers and contractors of Pearl River, N. Y., being responsible for the construction of a residence, a garage, and a studio at New City, N. Y. From August, 1934, to July, 1935, he was employed by the Robert Gair Company in Piermont, N. Y. This engagement was a return to his interest in the paper manufacturing industry, and comprised the engineering charge of layout and installation of paper mill machinery.

Mr. Ready again resumed work with the George F. Hardy organization, this time for five and a half years. He supervised the construction of the mills of the Union Bag and Paper Corporation in Savannah, Ga. On completion of this undertaking he was transferred in 1938 to Lufkin, Tex., where he was similarly engaged for the Southland Paper Mills—an important development in the industry in which southern pine was first used in manufacturing newsprint.

His familiarity with the construction of paper mills led naturally to his being charged with the operation of such enterprises. On completion of the work at Lufkin, he was sent to St. Marys, Ga., where he made his home for the rest of his life. After starting construction of a new mill, he was induced to take charge of its operation as manager on behalf of the St. Marys Kraft Corporation, the construction of which plant he had handled for that company and Mr. Hardy.

Mr. Ready continued in this work until 1943, at which time he entered the employment of Rayonier, Incorporated, in its engineering department. Toward the end of 1944, he resumed his work on paper manufacture, when he accepted a position with Cia Industrial de Atenquique, Société Anonyme of Guadalajara, Jalisco, Mexico. The work included selection and purchase of equipment for a kraft pulp and paper mill as well as the hiring and training of personnel for operating the new mill. Shortly before his death, he became consulting engineer for the National Container Corporation in Jacksonville, Fla., in March, 1947. His death occurred in a Savannah hospital, to which he had been transferred from his home in St. Marys.

His long experience qualified him as an expert in paper manufacture in the southern states. Many years of work made Mr. Ready familiar with all the phases of the industry in the varied geographic fields. He was a member of the Technical Association of the Pulp and Paper Industry. He also belonged to the Knights of Columbus and St. Marys Catholic Church.

Surviving are his widow who, before their marriage in May 28, 1927, was Florence Berg; a sister, Mrs. Harry Patton, of Brooklyn; and two uncles, James Ready, of New York, and Frank Ready, of Hackensack, N. J.

Mr. Ready was elected a Junior of the American Society of Civil Engineers on July 6, 1920, and an Associate Member on March 5, 1928.

JOHN GEORGE SCHMIDT, Assoc. M. ASCE[1]

Died April 11, 1945

John George Schmidt was born in 1885 in Logansport, Ind. His education consisted in part of a correspondence course in mechanical engineering, courses in drafting at the Logansport Young Men's Christian Association, and a mathematics course at the University of Cincinnati (Cincinnati, Ohio), in addition to studies at night school.

Mr. Schmidt began his engineering career as draftsman in the shops of the Pennsylvania Railroad Company at Logansport. From 1907 until 1910 he was city engineer for Logansport, where he was engaged in designing and constructing sewerage systems, street improvements, and other general municipal projects.

He joined the Chicago Great Western Railroad Company in January, 1910, as draftsman, and in that same year was appointed city engineer of Oelwein, Iowa, building sewerage extensions and an addition to a water works plant, as well as laying pavements. In addition, he was elected surveyor of Fayette County, Iowa, in charge of large (100,000-yard) pavement projects. His time was equally divided between the work on the railroad and the latter positions.

In November, 1911, Mr. Schmidt went to Jacksonville, Fla., and, as principal assistant engineer, was in charge of topographical survey and sewer design. He supervised the investigation and redesign of sewage plants in that city, making topographical surveys and maps. Following this position, Mr. Schmidt went to Cincinnati in May, 1913, where he became assistant engineer in the sewerage department, improving some of the sewage facilities and designing many others. From January to March, 1914, he became a junior engineer with the United States Engineering Department, Corps of Army Engineers, on the design of steel dump scows and other steel construction during his stay there.

In March, 1914, Mr. Schmidt became chief engineer of the Department of Public Service in the city of Norwood, Ohio, a position which he held until 1919, except for a period during World War I when he was an inspector in the Department of Naval Ordnance. From 1919 until 1943 he spent his time in private practice, specializing in subdivision work, including architectural, street, sewer, and survey projects.

---

[1] Memoir prepared by Fred R. McMinn and Hunter W. Hanly, Members, ASCE.

Recovering from a serious illness in 1943, Mr. Schmidt was appointed, for a second time, city engineer of Norwood, a position he held until his death. He had charge of street paving, a water works plant and water mains, an electric light plant, and sewerage and garbage disposal, as well as other municipal projects. He was making a topographical survey of the city to eliminate railroad grade crossings by constructing undergrade crossings, in addition to his other work, when recurrence of his earlier illness brought an end to his career.

He is survived by his widow, Signe Nelson Schmidt, of Norwood.

Mr. Schmidt was elected an Associate Member of the American Society of Civil Engineers on September 12, 1916.

EDWARD SIMEON SKILLIN, Assoc. M. ASCE[1]

DIED JULY 1, 1947

Edward Simeon Skillin was born in 1866 in Hempstead, Long Island, N. Y. His parents were Edward Skillin and Mrs. Georgiana Dallas (Hewlett) Skinner. He was educated in private schools in Orange, N. J., entering New York University in New York, N. Y., as a sophomore in 1884. He was graduated in 1887 with the degree of Bachelor of Science in Civil Engineering.

Shortly after leaving college, Mr. Skillin started his business career as inspector for a water supply line, working under the direction of Charles B. Brush,[2] M. ASCE. In 1888 he joined the engineering staff of the New York Telephone Company, as assistant engineer, working on the underground electric conduit system installed by that company in New York. Three years later, in 1891, he joined Post and McCord, structural steel contractors, as draftsman and later became a contracting engineer for that company. In 1900 he joined the Snead and Company Iron Works, structural and ornamental iron and steel contractors.

Mr. Skillin was employed by this company as contracting engineer until 1902, when he left to join the Snare and Triest Company, contracting engineers, in New York, serving first as a contracting engineer; in 1906 he was elected a vice-president of that company, retaining this office until his death. During the forty-six years in which he was connected with the Snare and Triest Company (the name of the company being changed in 1921 to Frederick Snare Corporation), he was actively engaged in the supervision of the numerous contracts which the company carried out in the United States, the West Indies, and South America.

---

[1] Memoir prepared by A. W. Buttenheim, Pres., Frederick Snare Corp., New York, N. Y.

[2] For memoir, see *Transactions*, ASCE, Vol. LXXXIV, 1921, p. 818.

Since his principal activity was securing new business, he traveled extensively for the company and was very active and helpful in solving the problems involved in carrying out contracts after they had been awarded. Although he was stationed on various occasions in the Havana (Cuba) office of the corporation, his principal duties were in connection with work in the New York and Philadelphia (Pa.) areas.

Mr. Skillin actively assisted his company in carrying out important construction contracts for the United States Army and the United States Navy during World War I. They included the Chickamauga (Georgia) Cantonments, the Raritan (N. J.) Arsenal, and the Quartermaster Terminal in Philadelphia. During World War II, the company with which he was associated built the Caven Point Terminal, in Jersey City, N. J., for the Engineer Corps, U. S. Army; the naval bases at Guantánamo (Cuba), Jamaica, and the Bahamas; also a new breakwater, marine railways, and graving docks in the Canal Zone.

His active interest in the construction industry did not prevent his taking a keen interest in his home town, Glen Ridge, N. J., where he was a member of the Borough Council from 1911 to 1914, and active in other civic work. During World War I, he was a member of the Home Guard. He made many trips to Europe and spent a number of summers in Nova Scotia. He greatly enjoyed golf and fishing. His kindly and sympathetic nature brought him a host of friends, many of whom were members of the Society.

Mr. Skillin was an Episcopalian, and a regular attendant at Christ Church in Glen Ridge. He was a patron and member of the Montclair (N. J.) Art Museum. Greatly interested in welfare work, he was a regular contributor to the Bonnie Brae Farm for Boys in Millington, N. J.

Two of Mr. Skillin's ancestors were Sir Henry Skilings, Lord High Sheriff of Glasgow in the seventeenth century, and Simeon Skillin of Philadelphia, who carved the first figurehead on "Old Ironsides," the *U.S.S. Constitution*. He was an active member of the Sons of the American Revolution, the Pilgrims of the United States, and the Society of Colonial Wars. In addition, he was a member of the Pan-American Society, the Commerce and Industry Association of New York, Incorporated, and the Peruvian-American Chamber of Commerce, of which he was a director. For many years he was treasurer of the Engineers' Club of New York. He was also a member of the Railroad-Machinery Club, the University Club, and the Glen Ridge Country Club.

On May 6, 1903, Mr. Skillin was married to Geraldine Fearons, who died in 1914. He is survived by two children, a daughter, Elizabeth (Mrs. James D. Andrew), and a son, Edward S. Skillin, Jr.

Two of his associates, with whom he was actively engaged in business, Frederick Snare, Affiliate, ASCE, and Wolfgang Triest,[3] M. ASCE, both died within ten months of the date of Mr. Skillin's death. He will be greatly missed by the friends and business associates who survive him.

Mr. Skillin was elected an Associate Member of the American Society of Civil Engineers on December 1, 1908.

---

[3] For memoir, see *Transactions*, ASCE, Vol. 112, 1947, p. 1538.

JEROME BRANCH STOCKING, Assoc. M. ASCE[1]

DIED JULY 9, 1947

Jerome Branch Stocking, one of the seven children of Myron T. and Elizabeth (Thompson) Stocking, was born on November 4, 1873, at Lisbon, N. Y.

He attended the rural school in Lisbon and then spent three years as a student at Ogdensburg Free Academy (Ogdensburg, N. Y.); he was graduated from the academy and entered Amherst College (Amherst, Mass.), where he was a student for two years. To earn money to further his education he then spent several terms as a rural school teacher in New York State, commuting on horseback from his home. One such teaching position was in Amagansett, Long Island, N. Y.

Deciding to change his course of study, he entered the law college at the University of Michigan, in Ann Arbor, from which he was graduated in 1899 with the degree of Bachelor of Law. While at the university the Spanish-American War was declared, and he enlisted, serving from April 26 to September 28, 1898. At Amherst he joined the Delta Kappa Epsilon fraternity.

On being graduated he went to Albany, N. Y., where he passed the state bar examinations and subsequently established a law office in Buffalo, N. Y. There, while practicing law, he was stricken with a severe illness, diagnosed by the attending physicians as pleurisy. Fearful that this would develop into tuberculosis his physicians recommended that he go west and follow some kind of outdoor activity.

Accordingly, in 1904 he went to Dalhart, Tex., where his brother, Forest B. Stocking, was employed. After some months his health improved and, becoming restless, he went to Colorado in 1905. In Colorado Mr. Stocking learned that some railroad survey parties were being organized and he secured a position as chainman on such a party and was employed from June to September, 1905, by the Great Northern Railroad Company and the Northern Pacific Railroad Company. From September, 1905, to November, 1907, he worked for the Oregon Short Line Railroad Company (O.S.L.R.R.), part of the Union Pacific Railroad Company system, successively, as head chainman, rodman, topographer, leveler, and transitman. During this period he was engaged on the survey of a proposed railroad from Huntington, Ore., to Lewiston, Idaho, through the famous Hell's Canyon of Snake River. He also worked on the survey and construction of the Rupert to Bliss cutoff in Idaho for the O.S.L.R.R.

From November, 1907, to April, 1909, he was field assistant and chief of party with the United States Reclamation Service on the Boise-Payette project in Idaho, in charge of the design and construction of the canal system in a division of about 18,000 acres. He was engineer with the Conrad (Mont.) Land and Water Company on canal surveys from April to July, 1909.

---

[1] **Memoir prepared by Lynn Crandall, M. ASCE.**

From that date until 1916 Mr. Stocking was employed on the Salmon River irrigation project at Hollister, Idaho—first, as division engineer and, later, as assistant chief engineer. From September, 1916, to April, 1917, he was engineer (Carey Act) in the office of the Idaho state engineer. From 1917 until his death he was watermaster and engineer for the North Side Canal Company of Jerome, Idaho, on a 170,000-acre irrigation project in Jerome and Gooding counties in Idaho. He died while observing the effect of a prairie grass fire on the telephone line of the North Side Canal Company on Sugar Loaf Butte (east of Jerome).

"J. B.," as he was known to hundreds of friends, never married. His life was characterized by unremitting and steadfast industry and attention to the details of his job. As a young man he earned his way through college and paid all the expenses of his education.

R. J. Newell, M. ASCE, director, Region No. 1, United States Bureau of Reclamation, writes, as follows, concerning Mr. Stocking's early years in Idaho:

> "My close acquaintance with Mr. Stocking began with the construction of the Salmon Dam southwest of Twin Falls. This dam of considerable size was located over 30 miles from a railhead and the connecting road through the sagebrush was almost entirely unimproved. On this account, the hauling of a large volume of construction materials and supplies (principally cement) to the dam proved to be an important feature of the construction job. It was done by traction engines and trailer wagons and a large number of freight teams.
>
> "Mr. Stocking was in charge of the hauling during 1910 and 1911. He worked tremendously, hiring and organizing the crew, and galloping back and forth on a saddle horse, to hurry the loading at one end and the unloading at the other and assist with breakdowns along the road. There was rarely any delay at the dam on account of shortage of material while Stocking was on the job."

As watermaster for thirty years with the North Side Canal Company at Jerome he lived in the canal company office building. There he had a battery of telephones beside his desk and bed, keeping constant watch over the water levels in every section of the thousand miles of canals and laterals embraced within that project.

Mr. Stocking lived much to himself, finding his pleasure in the successful accomplishment of his daily work. He seldom talked about his personal affairs, and friends and associates of many years never heard him mention his early experiences, except in reply to specific questions. Trained in a rigorous school where long hours of hard work—beginning not later than 7 a.m. each day—were the accepted procedure, he had scant sympathy with such modern innovations as forty-hour weeks, time and a half for overtime, and so on.

His only consideration was to get the job done well, as economically and as quickly as possible. A few days before his death he remarked to a fellow worker that he took more pride in his membership in the Society that in anything he possessed.

He is survived by two sisters, Venila S. (Mrs. L. C. Heptonstall) and Emma L. Stocking, and by one brother, Forest B. Stocking.

Mr. Stocking was elected an Associate Member of the American Society of Civil Engineers on January 2, 1912.

ROBERT RAYMOND TWAY, Assoc. M. ASCE[1]

DIED AUGUST 21, 1946

Robert Raymond Tway, the son of Harry and Clara (Cartlich) Tway, was born in London, Ohio, on September 4, 1888. He attended the public schools in Springfield, Mo., and after completing two years of work at the School of Mines at Rolla, Mo., he moved to Oklahoma where he attended the Oklahoma State School of Mines at Wilburton, from which he received the degree of Bachelor of Science in Civil and Mining Engineering in 1912.

With three years of practical experience as city engineer for Wilburton and county engineer for Latimer County, Oklahoma, he returned to educational work to serve as instructor in mining engineering in the extension department of the State School of Mines at Henryetta, Okla., while continuing some private practice in engineering. In 1917 he began a five-year period as county engineer for Okmulgee County, Oklahoma, where he supervised the expenditure of $500,000 annually. In 1922–1923 Mr. Tway served as project engineer on federal aid project No. 53 in Okmulgee County, which was a million dollar undertaking

After six months in 1924 as division engineer for the State Highway Department, he entered the contracting field in which he prospered for twenty-two years before succumbing to a heart attack while on vacation in Buena Vista, Colo. His work consisted largely of bridge and drainage structures. His projects included: An underpass at Dalhart, Tex.; an overpass at El Reno and Cushing in Oklahoma; a bridge over the Trinity River north of Dallas, Tex.; and two bridges over the Arkansas River near Fort Smith, Ark. Mr. Tway was ever alert to new methods and was responsible for developing a patented pneumatic tamping roller.

He was a man of high principles and integrity. He has been described as one of the best contractors that Oklahoma has had and was noted for his sense of fair play and honest dealing. In addition to his activities in the Oklahoma Society of Professional Engineers, he belonged to the Chamber of Commerce, and was a Shriner, a Rotarian, and Thirty-Second Degree Mason. He was also active in the First Christian Church.

In Wilburton, on July 30, 1913, he was married to Lora Collier. He is survived by his widow; two daughters, Betty Gene Tway of Oklahoma City,

---

[1] Memoir prepared by Leo L. Laine, Assoc. M. ASCE.

Okla., and Mrs. John Charles Herndon of Salmon City, Idaho; and a son, Jack C. Tway. A son, Robert, Jr., has since passed away.

Mr. Tway was elected an Associate Member of the American Society of Civil Engineers on November 26, 1923.

BENJAMIN WEISS, Assoc. M. ASCE[1]

Died December 30, 1946

Benjamin Weiss, the son of Abraham and Lotte (Gruenwald) Weiss, was born on May 14, 1886, in Russia. He studied engineering at Cooper Union in New York, N. Y., receiving the degree of Bachelor of Science in 1909 and the postgraduate degree of Civil Engineer in 1921.

After several years as draftsman with the New York Telephone Company, as a result of a competitive civil service examination, Benjamin Weiss was appointed to the Queens Borough Topographic Bureau in 1907. For forty years he served on the civil service engineering staff of the City of New York—for almost all his professional career in the office of the President of the Borough of Queens, one of the five semiautonomous governmental subdivisions of the Greater City.

Successively, he held positions of increasing responsibility, finally serving on the staff of the Consulting Engineer to the Borough President and as engineering representative on the Queens Board of Local Improvements. This board initiates or approves all borough projects that are paid for entirely or in part by assessments on property to be benefited. The board's opinion also has considerable influence on city-wide improvements and private enterprises in so far as they affect the interests of the Borough of Queens—the population of which increased from less than 500,000 to more than 1,500,000 during the decades covered by Mr. Weiss' service.

One of his collateral activities was to supply radio publicity about the present needs and future requirements of Queens Borough for the benefit of the local taxpayers and to further Borough developments. Among the outstanding projects of national importance which he publicized were the site of the New York World's Fair, the temporary home for the United Nations activities, La Guardia Field, and Idlewild Airport. Of local importance was publicity on the transition of Queens from farm and suburban communities into an integrated urban unit involving street openings, highway paving, parkway developments, and provisions for building some of the largest sewers in the city—in all of which Mr. Weiss had some part.

On May 12, 1932, in New York, he was married to Lillian Fleischman. Mr. and Mrs. Weiss lived in the Jamaica Estates section of Queens where he indulged in music and painting as spare time hobbies.

---

[1] Memoir prepared by Alfred Brahdy, M. ASCE.

Mr. Weiss was a director of the Municipal Engineers of the City of New York and had been chairman of the Lecture and Publication Committee and editor of the quarterly, *Municipal Engineers Journal.* He was a licensed professional engineer and land surveyor in the State of New York.

Mr. Weiss was elected an Associate Member of the American Society of Civil Engineers on August 27, 1928.

Juniors

WILLIAM GEORGE CLARK, Jun. ASCE[1]

Died July 11, 1946

William George Clark was born on December 22, 1858, on the ancestral estate of his parents near Wattsburg, Erie County, Pa. He was the eldest of the six children born to Lorenzo Dow and Jane (Mitchell) Clark and was the last of the family to die.

Mr. Clark attended school in Wattsburg until 1875, and high school in Ann Arbor, Mich., for two years. In 1879 he entered the University of Michigan, also in Ann Arbor, from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1884, having been absent from college one year. He was a member of Delta Upsilon fraternity.

During the period from August, 1884, to June, 1887, Mr. Clark served, successively, as instructor in mathematics and chemistry, assistant professor of civil engineering, and acting professor of civil engineering at the Missouri School of Mines and Metallurgy at Rolla. From 1887 until 1892, he was first assistant city engineer of Toledo, Ohio, and for the following three years he was junior member of the firm of Wickenden and Clark, engineers, in Toledo. In 1895, he was elected city civil engineer of Toledo, remaining until 1897, when he became chief engineer for the American Sanitary Engineering Company of Detroit, Mich., holding that position until 1900. Mr. Clark engaged in private practice as a consulting engineer in Toledo from 1900 until his death—specializing in water supply, water purification, water softening, sewers, sewage disposal, and hydraulic developments.

He acquired recognition as one of the leading sanitary engineers in the Middle West. In addition to the many plant designs done exclusively by his office, he was frequently consulted, and collaborated with others, on water works improvements. Since the turn of the twentieth century, he made, or assisted in making, reports on a number of water supplies, including those at Toledo, Elyria, and Piqua, in Ohio; Decatur, Ill.; Rocky Ford, Colo.; and others. His firm built, rebuilt, or enlarged water purification and softening plants in Toledo, Sandusky, Port Clinton, Fremont, Napoleon, Lima, Barberton, and Piqua, in Ohio and in Flat Rock, Dearborn Ford Plant, Flint, and Alpena, in Michigan—as well as those in Decatur and Rocky Ford.

---

[1] Memoir prepared by William Clark Jones, Div. Engr., Water Dept., City of Toledo, Toledo, Ohio, and Owen E. Clark, Div. Engr. of Constr., Water Dept., City of Toledo, Toledo, Ohio.

Mr. Clark was one of the pioneers of rapid-sand filtration working along in the early days with George W. Fuller[2] and J. W. Ellms, Members, ASCE. He was designing engineer on some of the earliest plants of this type, notably the old Maumee River Works in the City of Toledo, which was first placed in operation on February 12, 1910. (This plant was abandoned and superseded by the Lake Erie Plant in 1942.)

He also did much of the early work in the development of technique and plant design for lime-soda softening. He worked closely with Charles P. Hoover of Columbus, Ohio, in this pioneering activity. Early softening plants of his design, in Piqua and Fremont, are still in successful operation.

Besides being an old and active member of the American Water Works Association, Mr. Clark was a member of the National Society of Professional Engineers and the Ohio Society of Professional Engineers. In his later years, Mr. Clark took pride in the distinction of being the oldest Junior in the Society, having acquired that membership prior to the adoption of age limitation rules. He never transferred his Society membership from Junior to Associate Member.

On December 21, 1886, at Plainfield, N. J., Mr. Clark was united in marriage to Annie Beasley, a Virginian of unusual cultural attainment and gracious personality, who died in Toledo in June, 1906. In June, 1914, Mr. Clark was married to Mrs. Arrilla Richter who died in 1943.

Mr. Clark's work was his hobby and absorbing interest. His ideals were high and he gave unswerving loyalty to what he believed to be right. He possessed a fine personality and no day was so crowded with work that there was not time for a story or a joke. He was an omnivorous reader. His extensive library bore ample testimony to the fact. Many of his technical books and periodicals will continue to serve in the Toledo Public Library and the library of the University of Toledo.

Since he had long been a member of the Masonic Order in which he had received the Thirty-Second Degree of the Scottish Rite, his funeral was conducted under the auspices of this order. He also belonged to the Toledo Chamber of Commerce and the Exchange Club of Toledo.

During the lifetime of the first Mrs. Clark, both Mr. and Mrs. Clark were active charter members of the Collingwood Presbyterian Church, but in later years Mr. Clark's religious connection was with the Baptist Church. No citizen was ever more interested in and loyal to the city of his chosen residence and occupation than William G. Clark was to Toledo and it is certain the word was graven in his heart.

Mr. Clark was elected a Junior of the American Society of Civil Engineers on April 4, 1888.

---

[2] For memoir, see *Transactions*, ASCE, Vol. 100, 1935, p. 1653.

LUDLOW VANDERBURG CLARK DEICHLER, Jun. ASCE[1]

DIED JUNE 27, 1945

Ludlow Vanderburg Clark Deichler was born on September 9, 1909, in Philadelphia, Pa., the son of L. Waller Deichler and Bessie L. (Clark) Deichler. Many years of usefulness were ahead of him when he was killed on June 27, 1945, on Okinawa. Seldom has a young man gone so far in his duties and so far in his rank in the United States Navy Civil Engineer Corps Reserve, at so early an age.

Before he entered college, Mr. Deichler spent more than two years in practical engineering work. For more than a year (1928–1929), he was job engineer with the Frank Stewart Construction Company in Philadelphia, on apartment house construction. The following year, August, 1929, to September, 1930, he was employed as draftsman for the United Engineers and Constructors, Incorporated, in Philadelphia, in connection with the electrification system of the Pennsylvania Railroad.

His activities are a matter of record, unusually complete—in the Navy Department; in the registrar's office at Georgia School of Technology in Atlanta; and in the office of its National Alumni Association's secretary in Atlanta. Abstracts from those records are given as furnished by the offices mentioned, and a few are selected and given herein from among the commendatory letters sent to the Board of Examiners for the Civil Engineer Corps of the United States Navy in 1936.

His scholastic and athletic activities are shown in the following letter from the registrar:

> "Mr. Deichler was admitted to the Georgia School of Technology on September 17, 1930. He was awarded the degree of Bachelor of Science in Civil Engineering on June 4, 1934, 'with honor'; on June 8, 1936, the degree of Master of Science in Civil Engineering; and on June 3, 1940, the Professional Degree of Civil Engineer.
>
> "As an undergraduate he was a member of the honor societies of Phi Kappa Phi, Tau Beta Pi, Phi Eta Sigma, and Scabbard and Blade. His name appeared upon the Honor Roll during the four years as an undergraduate. He received the president's Gold 'T' for scholastic excellence in his junior year. He was also a member of the Bulldog Club, Civil Crew, A.S.C.E., and Yellow Jacket Club, and the social fraternity of Phi Gamma Delta. He participated in football during his freshman year, and track during his sophomore year, was a member of the Rifle Team during his four years as an undergraduate, and was a Captain in the Reserve Officer's Training Corps."

Commencing in the fall of 1937, he was active on a number of construction projects as superintendent or engineer. For a few months he was in the employ of the Tellepsen Construction Company in Houston, Tex., on construction at the Baytown Refinery of the Humble Oil and Refining Company. The following year (1938) he was with the Standard Oil Company of California in San Francisco, designing steel and concrete refinery structures. For the first eight months of 1939, he worked with E. B. Badger and Sons in Boston, Mass., erecting cracking plants for high-octane gasoline.

---

[1] Memoir prepared by L. F. Bellinger, M. ASCE, and Carl W. Porter, Capt. (C.E.C.), U. S. N.

His early years and subprofessional work are covered in the following letter from H. R. Jeward, Superintendent of Irwin and Leighton, Contractors, of Philadelphia. The period covered by the letter is from 1921 to 1936.

"Philadelphia, 24th, August, 1936

"Dear Captain Allen:

> "Relative to your letter of the 21st instant, please be advised that I have known the applicant for the past fifteen years, and can honestly state that his character is of the best. He graduated from the Georgia School of Technology two years ago, an honour man, in the Engineering Class.
>
> "On several occasions he has been employed as an instrumentman, and superintendent of construction, on work of which I was the General Sup't.
>
> "At all times I found him to be reliable, and painstaking to a high degree. His work always gave entire satisfaction, to all with whom he came in contact.
>
> "I am certain that if he passes the examinations, he will if appointed uphold the traditions of the service."

His work for and with a contractor, from about 1932 to 1936, his carrying on the work of that contractor as manager before and after said contractor's decease, and a high opinion of his character and business ability, are given in this letter by his mother-in-law, Mrs. Allan Artley:

"September 1, 1936

"Dear Capt. Allen:

> "I am very pleased to give you the following information concerning Mr. Clark Deichler as requested by yourself in your letter of Aug. 21st.
>
> "My only way of judging his engineering ability would be to accept the very high opinion that I know my husband, the late Mr. Allan Artley, had of him.
>
> "Clark Deichler first worked for Mr. Artley while he was in school at Ga. Tech. He designed concrete and did some estimating in a part time position during the school year, and in summer worked both in the office and superintended work outside.
>
> "After his graduation from Ga. Tech. Clark accepted a position with Montgomery Ward & Co.
>
> "I can remember Mr. Artley's keen disappointment at losing Clark, but he was unable to compete with northern wages.
>
> "However, at Mr. Artley's repeated invitation, Clark returned to Atlanta several years ago, and joined the firm.
>
> "During the latter months of my husband's life, Mr. Artley sufficiently trusted Clark with partial control of his business, and just before his death the boy was put in complete charge.
>
> "Since Mr. Artley's death, Clark has handled all of my affairs and taken care of a large part of the business of the estate."

It is of interest to note that for the examination for the Civil Engineer Corps United States Navy, there were 850 applicants, and only about a dozen passed the examination. Mr. Deichler did well enough to receive an invitation with others near the top, to join the Civil Engineer Corps Reserve as Lieutenant (jg) (C.E.C.), U.S.N.R., which offer was accepted on July 8, 1938. He went on active duty on October 2, 1939.

His service duties are summarized in the following official record:

> "Subj.: Comdr. L. V. C. Deichler, (CEC), USNR—Abstract of Record of.
>
> 1. Comdr. Deichler was appointed Lt (jg), (CEC), USNR, rank from 3 June 1938, which appointment was accepted on 8 July 1938.
> 2. He went on active duty 2 October 1939 and since that date has had the following duties which are listed chronologically:
>   - (a) From 2 October 1939 to March 1941—Assistant Public Works Officer, Navy Yard, Boston; Resident Officer in Charge of Construction, Naval Air Station, Squantum; Naval Hospital, Chelsea; Naval Ammunition Depot, Hingham, Mass.
>   - (b) April, 1941—in the Bureau of Yards and Docks War Plans Section.
>   - (c) May, 1941 to January, 1942—Public Works Office, Naval Operating Base, Norfolk, additional duty Fifth Naval District.
>   - (d) February, 1942—Duty in the Bureau of Yards and Docks with temporary additional duty under Officer in Charge of Construction, Naval Air Station, Quonset Point, R. I.
>   - (e) March, 1942 to October, 1942—Naval Construction Training Command, Camp Allen, Va., as Ordnance Officer and Assistant Training Officer.
>   - (f) November, 1942—Naval Construction Training Command, Camp Peary as Ordnance Officer.
>   - (g) 30 November 1942—Assigned as Officer in Charge of 36th Naval Construction Battalion; sailed overseas in January, 1943, and returned September 18, 1944. He was detached from the 36th Construction Battalion 22 November 1944.
>   - (h) December, 1944 and January 1945—at Camp Parks.
>   - (i) 24 January 1945—was assigned as Officer in Charge of 42nd Naval Construction Regiment; sailed overseas in February 1945. Was killed 27 June 1945 on Okinawa.
> 3. (a) He was promoted to Lt. Comdr. by spot promotion 12 March 1943; was given an out-of-line promotion to Lt. Comdr. on 1 May 1943.
>   - (b) He was spot promoted to Comdr. on 1 September 1943 and promoted to Comdr. on 1 February 1944."

His advancement from Lieutenant (jg) to Commander in about three years indicates the strenuousness of his Sea Bee duties and the appreciation of his superior officers. His record, both in civilian and in service activity, would indicate that his was a strong character. He was notable for his clearness in speech, boldness in conception of ideas, independence in arriving at conclusions, and forcefulness in seeing that orders were carried out.

His outstanding capacity was recognized while he was still in college. At Georgia "Tech" he was president of the Student Chapter of the Society, and received the competitive prize granted by the Georgia Section for the best special thesis. He was quite a regular attendant at the monthly meetings of the section while he was in Atlanta.

Besides his family, Commander Deichler leaves his numerous college classmates and friends, all with deeply respectful regrets that he is not permitted to carry on into old age his engineering energies and his creative capabilities.

He was married on June 29, 1934 to Miss Emogene Artley, in Atlanta. Surviving him are the following near relatives:

Next of kin:	Mrs. Emogene Artley Deichler (wife), San Francisco, California.
Children:	Emogene Clark Deichler (daughter), born 12 February 1935. Ludlow Vandenburg Clark Deichler, II (son), born 2 October 1937.
Parents:	L. Waller Deichler (father), Philadelphia, Mrs. Bessie L. (Clark) Deichler (mother).

Commander Deichler was elected a Junior of the American Society of Civil Engineers on October 29, 1934, and an Associate Member on July 9, 1945, before the Society was advised of his death on June 27, 1945.

HUGH JOSEPH NOONAN, Jun. ASCE[1]

Died December 13, 1944

Hugh Joseph Noonan, the son of John J. and Margaret (O'Brien) Noonan, was born in Peabody, Mass., on October 24, 1919.

Mr. Noonan received his early schooling at St. John's grade school and St. Mary's high school. He attended Northeastern University in Boston, Mass., for five years, being graduated with the degree of Bachelor of Science in Civil Engineering.

In June, 1942, Mr. Noonan enlisted in the United States Army Air Corps, and was called to active duty in October, 1942. He was assigned, as an aviation cadet, to the Army Air Corps Technical Training Command at Chanute Field, Ill. Upon completion of his training, in January, 1943, he was commissioned a Second Lieutenant, and assigned to the Army Air Corps Engineering Division as an aircraft engineering officer.

In June, 1944, Lieutenant Noonan was ordered to the Pacific Theater of Operations where he valiantly performed the duties demanded of an Air Corps engineering officer. He was fatally injured while ably directing maintenance on an aircraft, and later died on December 13, 1944. He is buried somewhere on the Island of Leyte, in the Philippines.

Lieutenant Noonan was an engineer of great promise with ambition for success in the field of his chosen profession; above all he had an ardent desire to serve the United States to the fullest of his ability.

---

[1] Memoir prepared by F. J. Lariviere, Jun. ASCE.

In addition to his parents, Lieutenant Noonan is survived by one sister, Mrs. Joseph Deneen, and two brothers, John and William.

Lieutenant Noonan was elected a Junior of the American Society of Civil Engineers on October 19, 1942.

BERNARD WICK SHRUBB, Jun. ASCE[1]

DIED JULY 13, 1947

Bernard Wick Shrubb, the son of Bernard Zietz Shrubb and Elsie (Wick) Shrubb, was born in Brooklyn, N. Y., on March 16, 1921. A year later the family moved near to Freehold, N. J., where Mr. Shrubb attended a little two-room country school; he had the same teacher until he entered the Freehold High School from which he was graduated in 1937. While in school he won many prizes in 4H Club competition.

He was only sixteen years old when he went to Tuscaloosa, Ala., to attend the University of Alabama. He earned a good part of his tuition during vacations, but was forced to miss one year because of insufficient finances. After he received the degree of Bachelor of Science in Civil Engineering in 1943, he went to work for the Douglas Aircraft Company at Santa Monica, Calif.

There Mr. Shrubb did layout and design work on the hydraulic systems of the C–54 and C–74 type airplanes. His work at this time was valuable in building a vitally important air transport service.

In July, 1944, he received his commission as Ensign in the United States Naval Reserve and attended the indoctrination schools at Tucson, Ariz., and Hollywood, Fla. After receiving his amphibious training at Little Creek, Va., he went to Pearl Harbor, Hawaii, on the Landing Ship Medium (L.S.M.) 298, as executive officer. Returning to Astoria, Ore., he assisted in decomissioning the L.S.M. 298 and preparing her for the "Moth Ball Fleet."

Promoted to the rank of Lieutenant (jg), he was sent to Green Cove Springs, Fla., to do the same type of work with the L.S.M. 108 and L.S.M. 109. He was commanding officer of the latter ship.

After Mr. Shrubb had returned to inactive status in December, 1946, he secured a position as junior engineer with the Real Estate Department of the American Express Company in New York, N. Y. He was to have been advanced to a higher position in this company the following September.

He was elected chaplain of the Veterans of Foreign Wars Post in Freehold. Since he loved to sing, he became a member of the choir of the Ardena Baptist Church, which he attended nearly all his life—whenever at home. He was a member of the church from his early school days.

Mr. Shrubb died in an automobile accident of a fractured skull; he was killed instantly. The cause of the accident was never determined. He will be remembered for his kindness, for his sense of humor, and for his marked determination in all undertakings. Everyone he met became a friend—because he himself was friendly. His interests were many—among them was his love of sports. His detailed records of the major league baseball teams (also college football) showed that he was a worthy statistician. The engineering profession has lost an engineer; his associates have lost a friend; but all have benefited from having known him.

---

[1] **Memoir prepared by Harold Rozelle, formerly Stress Analyst at Douglas Aircraft Co., Santa Monica, Calif.**

He was married to Jane Gulledge of Tuscaloosa, on July 31, 1942. A son, Richard Gordon Shrubb, survives.

Mr. Shrubb was elected a Junior of the American Society of Civil Engineers on October 18, 1943.

DEAN EDWIN SWIFT, Jun. ASCE[1]

Died January 7, 1946

Dean Edwin Swift, the son of Edwin Dean and Bessie (Minor) Swift, was born in Blackburn, Mo., on December 1, 1911. In 1921, his family moved to Olathe, Kans., where he attended high school, being graduated in 1930 with an outstanding scholastic and athletic record .

In 1930 he entered the College of Emporia in Emporia, Kans., but a year later transferred to Kansas State College at Manhattan. At "K-State" he distinguished himself as a student and earned an enviable record as an athlete. His extracurricular activities included the Sigma Tau fraternity, the Acacia society fraternity, and the glee club, as well as football and wrestling. He was also president of the Student Chapter of ASCE, and held the rank of Lieutenant Colonel in the Reserve Officers Training Corps (R.O.T.C.). As a result of being selected the "Outstanding R.O.T.C. Student in the Seventh Corps Area," he was awarded a trip to Washington, D. C., where he received the Pershing Gold Medal for Military Merit. He was graduated with honors in 1935, with the degree of Bachelor of Science in Civil Engineering.

Following graduation he was engaged for a short time in highway and dam construction in Kansas, and on February 12, 1937, entered the United States Army as a Second Lieutenant in the Corps of Engineers. After a two-year assignment with the Second Engineers at Fort Logan, Colo., he entered Massachusetts Institute of Technology at Cambridge, and in 1940 received the degree of Master of Science in Civil Engineering.

From 1940 to 1944, he held various assignments, and, while in command of an armored engineer battalion at Camp Chaffee in Arkansas, he received the Legion of Merit award,

> "* * * for exceptionally meritorious conduct in the performance of outstanding service in organizing and supervising rescue work in connection with the all-time high water flood of the Arkansas River, 11 May to 27 May 1943, in which his efforts and professional knowledge saved many lives and

---

[1] Memoir prepared by C. L. Erb, Jr., and I. P. Hanson, Assoc. Members, ASCE.

> much property. He planned and directed the construction of two pontoon bridges over dangerous flood waters in order to provide support for temporary water mains to carry water into Fort Smith, Arkansas, when that city's water supply was completely cut off. By his zeal and energy, Colonel Swift efficiently controlled his partially trained battalion in these efforts, thereby displaying high professional and leadership qualities."

In March, 1944, Dean Swift, then a Lieutenant Colonel, went overseas to command the Forty-Eighth Combat Engineers and with this unit was in the battle for Cassino in Italy. His unit built the twin bridges across the Rapido River and roads through the mountains to Rome, and later took part in the invasion of southern France. In January, 1945, he assumed command of the 1,175th Engineer Combat Group and with that unit built several major bridges across the Rhine at Ludwigshafen, Mannheim, and at Heidelberg.

He was commissioned a full Colonel in May, 1945, and in June sailed directly for the Pacific theater of operations. In the Philippines he was in command of a port construction and repair group, engaged in the construction of gasoline storage and pumping facilities for Clark Field and in reconstruction of dock facilities at Manila.

On December 28, 1945, while in the Philippine Islands, Colonel Swift was stricken with poliomyelitis and died on January 7, 1946. He is buried in the United States Armed Forces Cemetery in Manila.

In addition to the Legion of Merit award, he received the Purple Heart and the Bronze Star. From the French Government, he received the Croix de Guerre with Palm "for exceptional war services rendered in the course of operations for the liberation of France."

He was married to Rita Brown at Manhattan, Kans., on June 6, 1936. He is survived by his widow; three daughters, Marilee, Carol, and Deanna; his parents, Mr. and Mrs. Edwin Swift; and two brothers, Harry and Philip.

Colonel Swift was elected a Junior of the American Society of Civil Engineers on October 14, 1935.

WILLIAM FRASER TOMPKINS, JR., Jun. ASCE[1]

DIED MARCH 13, 1945

William Fraser Tompkins, Jr., was born in Washington, D. C., on December 28, 1919. He was the son of an Army engineer, William F. Tompkins, then a Major, stationed at Fort Humphreys (later Fort Belvoir), Virginia. His mother was Elizabeth Hamilton, daughter of Mr. and Mrs. George E. Hamilton of Washington. On the paternal side of his family in Virginia, and on the maternal side in Maryland, he had many ancestors who, since early colonial days, had distinguished themselves in the service of their country. This background, combined with an intense loyalty for every person and every organization with whom he was associated, was the cause of his development into a young American citizen growing to manhood with the highest ideals of patriotism and devotion to duty.

---

[1] Memoir prepared by William F. Tompkins, M. ASCE.

Because of the constant moves of his Army father he was obliged to attend many different schools in boyhood. His principal education, prior to college, was received in the Bethesda-Chevy Chase High School at Bethesda, Md., from which he was graduated with distinction in 1936. Since his father had been ordered to New Orleans, La., he entered Tulane University there in the fall of 1936, taking the course in civil engineering. Although he was then but sixteen years old, he was unusually well developed, both physically and mentally, and for several years had determined to become an engineer. He was graduated with honors from Tulane in June, 1940, receiving the degree of Bachelor of Science in Civil Engineering. While at Tulane, Mr. Tompkins was elected to the honorary engineering society, Tau Beta Pi; he was a member of the Phi Kappa Sigma fraternity and of the boxing and baseball squads during his college years. His principal hobby, however, was hunting, and, as a natural corollary, he collected guns of all types. During summer vacations he worked with surveying parties; to illustrate his natural inclination for engineering, he always spent much of his spare time reading any engineering articles, technical magazines, or books he could lay his hands upon.

After graduation, Mr. Tompkins entered the office of the chief engineer of the Southern Pacific Lines at Houston, Tex., and almost immediately thereafter he enlisted in the 111th Engineers, a regiment of the 36th Division of the Texas National Guard. When the National Guard was called to duty in September, 1940, the 111th Engineers, with the 36th Division, were sent for training to Camp Bowie in Brownwood, Tex. He remained with the 111th Engineers for more than a year and was promoted from a Private to a Corporal; he was then commissioned a Second Lieutenant, and later promoted to First Lieutenant.

Early in 1942 he was ordered to Washington (D. C.) for duty with the Operations Division of the War Department General Staff. His work was connected with that of the logistics group, and one of his principal tasks was to allot ammunition to the entire United States Army. This was a most difficult and trying assignment, requiring not only an intimate knowledge of the subject, but much patience and tact, for ammunition was then in very short supply. His success is shown by his promotion first to Captain, and then to Major, and by his being awarded the Legion of Merit. He was Commissioned a Major when only twenty-two years old and certainly one of the youngest Majors of the Corps of Engineers—and, at that time, very possibly the youngest.

Like most young officers Major Tompkins was not satisfied with desk duty and his repeated requests (almost demands) to be assigned to a combat unit finally led to a transfer to Camp Breckinridge, Kentucky, in the spring of 1943, for training with an engineer combat group scheduled for assignment overseas. He accompanied this group to England in December, but subsequently was transferred to the 181st Engineers, a heavy pontoon battalion. As executive officer of this unit, he landed in Normandy shortly after "D"

Day and, on the drive to Paris, assisted in the construction of the first heavy pontoon bridge constructed in France over the Seine River.

On December 21, 1944, he was relieved from duty with the 181st Engineers and assigned to another heavy pontoon battalion, the 552d Engineers, as commanding officer. He remained with this unit to the end; with it Major Tompkins participated in the erection of the first heavy pontoon bridge constructed in Belgium, over the Meuse River, and, some time thereafter, of the first bridge of a similar type over the Rhine River. This was the bridge constructed from Kripp to Linz in Germany, some ten miles south of the famous Remagen Bridge; it was completed on March 11, 1945.

On March 13, at approximately 3:30 p.m., he was standing in an anchor barge just upstream of the bridge, when a German plane flew over and bombed the bridge; a bomb fragment struck him and pierced his helmet, causing his death. Major Tompkins was buried in the Henri Chappelle Cemetery near Aachen, Germany. The bridge was named after him, and the history of the 552d Engineers was dedicated to Major Tompkins with a full page photograph of him as the frontispiece. After the fixed bridge at Remagen collapsed, this pontoon bridge proved to be a vital necessity. More than 57,000 vehicles crossed this bridge while it was under the maintenance of the 552d Engineers. He received the Silver Star posthumously, the citation reading:

> "For gallantry in action. From 10 March 1945 to 13 March 1945, at ***. [The location was then secret information.] Major Tompkins, a Battalion Commander, displayed fearless and unflinching devotion to duty, planned and supervised the technical phase of the difficult construction of the first heavy ponton bridge over the treacherous Rhine River. Unmindful of his personal safety, he repeatedly exposed himself to aerial bombardment and constant enemy-observed shellfire to direct many technical details on the bridge construction. He so imbued and inspired his men by his gallant actions and extraordinary leadership that successful and timely completion of a hazardous project was achieved. Major Tompkins was mortally wounded while engaged in this vital task."

A person's character can best be judged by what his companions think of him. A few short excerpts are given from the many letters received after his death. The army engineer, First Army, wrote that he had seen him early that fatal afternoon, very happy in a job well done, and anxious to get on to the next one. The corps engineer, Seventh Corps, wrote that he was a fine battalion commander and that he did an outstanding job on this bridge, and, according to all present, more than anyone else; also, that at the time of the bombing he was checking the guy lines to make sure that the bridge was secure. His successor in command of the 552d Engineers wrote:

> "Major Tompkins was held in the highest esteem by all members of his command. He was a splendid leader, much admired by all his subordinates and was an outstanding personality. Those of us who have had the good fortune to serve under him feel that we have learned much and benefitted greatly by our associations with him. His loss will be deeply felt by his many friends."

The commanding officer of the 181st Engineers, the unit with which he served in Normandy, wrote:

"His passing was a great shock to us and has been keenly felt by everyone in the unit. His association with this organization will never be forgotten, for he was a friend and an inspiration to all, and to me personally, one of the finest officers I have ever been associated with."

His former professor of civil engineering at Tulane University wrote that he was an "original thinker," of one of the few he had ever taught; and the vice-president (formerly the chief engineer) of the Southern Pacific Lines at Houston wrote to the effect that, although Major Tompkins had been with the railroad but a short time before the war, he had won their regard and that they regretted he was not returning to fill the place which had been reserved for him.

Major Tompkins was married on December 6, 1941, the day before Pearl Harbor, to Evelyn Knopp, daughter of Dr. and Mrs. Thomas B. Knopp of Hondo, Tex., whom he met when stationed at Brownwood. He is survived by his widow and by two sons, William F. Tompkins, III, and Thomas K. Tompkins. He is also survived by his parents, Maj.-Gen. and Mrs. William F. Tompkins of Richmond, and by a brother, Christopher Tompkins, of New Orleans. Another brother, George Hamilton Tompkins, a night pursuit flyer, U. S. Army Air Forces, was killed in Normandy.

Major Tompkins was elected a Junior of the American Society of Civil Engineers on October 9, 1940.

JOHN MERLIN WILSON, Jun. ASCE[1]

DIED MAY 4, 1945

John Merlin Wilson, the son of John and Lorena (Woltzen) Wilson, was born in Guthrie Center, Iowa, on July 22, 1920. John, the eldest of three sons, spent his early life in Guthrie Center and Guthrie County. He attended Guthrie Center High School, from which he was gaduated in 1937. In 1937 he won a First in American history and a Second in economics in the Iowa Brain Derby. He entered Iowa State College at Ames, in 1938, being graduated in June, 1942, with the degree of Bachelor of Science in Civil Engineering. Immediately after graduation he started work for North American Aviation, Incorporated, of Kansas as an engineering trainee. Later he became an analyst in the production control department.

On November 16, 1942, Mr. Wilson joined the United States Marine Corps, shortly thereafter receiving a commission as Second Lieutenant. From November, 1942, until April, 1943, Leiutenant Wilson received his military training at Camp Le Jeune, New River, N. C., and Camp Pendleton, Oceanside, Calif. In February, 1942, he was promoted to First Lieutenant, and six weeks later he embarked for the South Pacific. He participated in the battle of Peleliu and, when not in combat, his duties at various times included operating a saw mill, building roads, and other engineering jobs.

---

[1] Memoir prepared by Keith R. Jeffers, Lt. (j.g.), U. S. Naval Reserve, Torrance, Calif.

He died while helping his platoon repulse a Japanese landing in the battle of Okinawa. A baseball diamond, named Wilson Field, has been constructed on Okinawa as a memorial to Lieutenant Wilson. He was awarded the Bronze Star and citation, posthumously, for meritorious achievement in action during the battle on Okinawa.

Lieutenant Wilson was sincere and diligent in all his work. These traits won the admiration of his superiors and associates; they also won him many friends. He was always interested in sports—his two favorites being hunting and fishing.

He is survived by his parents and two brothers, Robert and Thomas.

Lieutenant Wilson was elected a Junior of the American Society of Civil Engineers on October 19, 1942.

Affiliates

FREDERICK SNARE, Affiliate, ASCE[1]

DIED SEPTEMBER 22, 1946

Frederick Snare was born in Huntingdon, Pa., on December 4, 1862, the son of Edmund and Andria M. (Ziegler) Snare. His father was a physician. He was educated in private and public schools.

In 1879, he started his business career with the Huntingdon Car Works, after which he was employed by James G. Lindsey and Company, iron and steel commission merchants. From 1884 to 1899, he was with the Pencoyd Iron Works, during which time he became its vice-president. This experience, prior to the forming of his own construction company, admirably fitted him for the prominent part he was to take in later years in bridge building as the Pencoyd Iron Works, later incorporated in the American Bridge Company, was one of the leading rolling mills and fabricators of steel bridges.

On January 1, 1900, Frederick Snare, in association with W. G. Triest,[2] M. ASCE, organized an engineering and construction corporation known as Snare and Triest, Incorporated. The name of the corporation was later changed to the Snare and Triest Company, and finally to the Frederick Snare Corporation. Mr. Snare was president of the corporation until 1927, when he became the chairman of its board of directors. Under his leadership, foundations for some of the outstanding bridges in the New York (N. Y.) district were built by his corporation, and numerous other complete bridges including foundations were constructed. The Bronx-Whitestone Bridge across the East River; the Rip Van Winkle Bridge across the Hudson River; and the Outer Bridge and Goethals Bridge connecting Staten Island with New Jersey are examples of the type of work successfully carried out.

---

[1] Memoir prepared by A. W. Buttenheim, Pres., Frederick Snare Corp., New York, N. Y.

[2] For memoir, see *Transactions*, ASCE, Vol. 112, 1947, p. 1538.

In 1902 Mr. Snare went to Cuba to supervise some pier work under a contract awarded to his company by Gen. Leonard Wood, who was then in charge of construction work for the Cuban government. This started a career of port, bridge, and other heavy construction work in Latin American countries, which was later to include Colombia, Chile, Ecuador, Peru, Puerto Rico, Venezuela, and many other countries in Central America and the West Indies. Such well-known steamship terminals as the United Fruit Company and the Ward Line in Havana (Cuba), and the North Coast Railway piers at Nuevitas, Cuba, as well as the ports of Callao and Matarani in Peru; Cartagena, Colombia; and Cruz Grande, Chile, are a few of the many ports which were constructed under Mr. Snare's supervision. In many cases the contracts included design as well as construction.

During World War I, while his company was carrying out important construction contracts for the United States government, Mr. Snare, with the rank of Colonel, went to France to head some of the important activities of the Red Cross. During World War II, because of his wide experience his corporation had in construction work in the West Indies, his organization was selected to build the many new facilities that were needed at the United States Naval Base at Guantánamo, Cuba. His corporation did similar work in Panama, Jamaica, and Great Exuma Island in the Bahamas, and also handled all the field work in connection with the nickel oxide plant, adjacent to Levisa Bay on the north coast of Cuba. Additional war work included the design and building of the plant for storage and loading of bauxite which was constructed at Trinidad, and many other contracts for the United States Army and Navy.

One of the outstanding accomplishments of Frederick Snare was the service he rendered the cause for better understanding between the citizens of Latin America and the citizens of the United States. He spent many years in Cuba, and was twice decorated by the Cuban government for his many contributions to the social and economic life of that country. At the time of Mr. Snare's death, Grau San Martin, President of Cuba, gave public recognition that Frederick Snare was the outstanding representative of the foreign colony in Cuba, and cited the many services he had rendered to the Cuban people.

An ardent golfer, Mr. Snare organized the Havana Country Culb in 1911, and was its president from that time until his death. By organizing this beautiful club, which was the first golf club in Cuba and which is patronized by leading Cubans and by Americans who visit Havana, a common meeting ground was made available. This probably contributed more than any other single factor toward better understanding between the citizens of these two countries.

Mr. Snare's interest in golf gave him other opportunities to help international relations. He assisted in the founding of the Canadian Seniors' Golf Association and he was instrumental in the organization of the Great Britain Seniors Golfers' Society. As captain of the team of the United States Senior Golf Association, he frequently visited England and Canada, accompanied by a delegation of Americans who met and played with the leading citizens of these two countries. While Mr. Snare was president, the United States Seniors Golf Association also entertained many prominent British and Canadian golfers, when their seniors' associations were visiting United States.

Wherever Mr. Snare's construction activities brought him into contact with the citizens of Latin America, he did much to aid inter-American relations. An example of this was the important part he played in the organization of the Anglo-American Hospital in Havana. This hospital is used extensively by Cubans as well as by Americans, and has been very successful in serving the purpose for which it was organized.

Among the many clubs of which he was a member were the Engineers Club, the Metropolitan Club, the Union League Club, and India House, all of New York City.

On December 13, 1883, Mr. Snare was married to Ellen N. Brown at Huntingdon, Pa. They had four children. He is survived by two daughters, Elsie Lawrence (Mrs. Hugh Peters) and Helen Jeannette (Mrs. Frederic A. Stanwood).

It is interesting that his death on September 22, 1946, occurred within a few hours of, and at the same age as, that of his old friend and former associate, Mr. Triest.

Mr. Snare was elected an Affiliate of the American Society of Civil Engineers on October 6, 1903.

MAXIMILIAN TOCH, Affiliate, ASCE[1]

DIED MAY 28, 1946

Maximilian Toch, a learned man in many fields—chemistry, law, and art—was born in New York, N. Y., on July 17, 1864. His parents were Moses and Caroline (Levy) Toch.

In 1882 he completed a special course in chemistry at New York University in New York City, and in 1886 he received the degree of Bachelor of Legal Law from this university. Later he did graduate work in chemistry and engineering in New York City at Columbia University, and at the College of the City of New York. Mr. Toch lectured on organic chemistry at Columbia University in 1905 and 1906 and was the municipal lecturer on paint at the College of the City of New York during 1909. From 1919 to 1924, he was adjunct professor of industrial chemistry at Cooper Union, also in New York City.

Many of Mr. Toch's important contributions to paint technology were associated with his work for the United States government. In World War I, he developed the Toch camouflage system for the entire eastern seaboard. In addition to inventing the battleship-gray paint formula for the United States Navy, he perfected the cement filler used in the Panama Canal (1904 to 1914) as well as the integral waterproofing incorporated in the construction of numerous United States Navy dry docks. Mr. Toch was largely responsible for the introduction of China wood oil in the United States. His interest in the defense problems of the United States was shown by his long membership in the Army Ordnance Association and the Society of American Military Engineers. Mr. Toch was also a frequent adviser to fellow chemists and engineers—Leo Baekeland once remarked that he never would have perfected Bakelite if it had not been for the help and encouragement of Maximilian Toch.

---

[1] Memoir prepared by the late Lawrence H. Singer, Esq., New York, N. Y.

Mr. Toch's major activity throughout his life was in the field of chemistry and chemical engineering. For many years he was president and chief chemist of Toch Brothers, Incorporated, of Staten Island, N. Y. He served as chairman of the board of the Standard Varnish Works and was a past-president and an honorary member of both the Chemists' Club of New York and the American Institute of Chemists.

In 1924, he was appointed an honorary professor of chemical engineering and industrial chemistry at the University of Peking and lectured at the National Institute of Technology, both in Peking, China. During this same year he was awarded the degree of Doctor of Science by the University of Peking.

Among the several books, which Maximilian Toch wrote in connection with chemical engineering and industrial chemistry, were "The Chemistry and Technology of Paint" and "The Protection and Decoration of Concrete."

Dr. Toch carried a camera almost everywhere, and he became recognized as one of the world's leading photographers. His prints were exhibited in countless international shows, and he was constantly collecting medals and prizes for lens work. He was a fellow of the Royal Photographic Society of London, England, and of the Photographic Society of America; a past-president of the Camera Club of New York; and treasurer of the Oval Table, a leading camera group in the United States.

Allied with his work in photography was his deep interest in the world of art. For many years Dr. Toch held the position of professor of artistic painting at the National Academy of Design. In 1931 he provoked an international storm by charging, at a meeting of the New York Microscopical Society, that only one of the approximately thirty Rembrandts at the Metropolitan Museum of Art in New York City was genuine. He was the author of several book on art, including "Materials for Permanent Painting," "How to Paint Permanent Pictures," and "Paint, Painting, and Restoration." His last article pertaining to art, completed shortly before his death, was entitled "Hell-Bent for Art."

In addition to the many organizations already listed, Dr. Toch was a fellow of the American Association for the Advancement of Science, the New York Microscopical Society, and the Chemical Society of London. He was a member of the American Association of Arts and Sciences, the American Chemical Society, the American Institute of Chemical Engineers, and the Society of Chemical Industry in London.

Willam Howard Taft, when President of the United States, appointed Dr. Toch to the Second International Congress of Chemists.

On the social side, Dr. Toch was a member of the Cosmos Club of Washington, D. C., and the Bungalow Island Club of Portland, Ont., Canada. Also, among his wide range of interests was his active membership in the Society of American Magicians. A great sportsman, he rode horseback almost daily until he was eighty. He was an expert with a rifle and a lifetime devotee of fishing.

Mr. Toch was a warmhearted individual with a genial, vivacious personality outstanding in his professional attainments, and diligent in the pursuit of his hobbies. He will long be remembered with affection by all his friends and acquaintances.

On October 14, 1891, he was married to Hermine E. Levy. He is survived by his widow and four daughters, Elaine (Mrs. M. Pinco), Constance (Mrs. Arthur D. Robson), Alma (Mrs. Morris Lober), and Maxine (Mrs. Richard Frakenfelder).

Dr. Toch was elected an Affiliate of the American Society of Civil Engineers on September 1, 1903.

DERR, ORVILLE VOSBURY
Memoir of, 1445.

DEVELIN, RICHARD GRIFFITH
Memoir of, 1447.

DEWELL, HENRY D.
"Tests of Timber Structures from Golden Gate International Exposition," by Committee of the San Francisco (Calif.) Section, ASCE, on Timber Test Program, 1123.

DIESEM, HARRY CUSTER
Memoir of, 1587.

DIETZ, ALBERT G. H.
"Thin-Shelled Domes Loaded Eccentrically," 293.

DOHN, CHARLES W.
Mill bents, 1114.

DONNELL, L. H.
Cylindrical shells, 709.

DOUGAN, JAMES
Memoir of, 1588.

DOUGHERTY, R. E.
"The Society's Future and Its Economic Limitations," Annual Presidential Address, 1391.

DOUMA, J. H.
Saint Anthony Falls stilling basin, 545.

DRESSER, ELBERT HERMON
Memoir of, 1449.

DRUCKER, D. C.
Inelastic bending, 248.

DUNNELLS, CLIFFORD GEORGE
Memoir of, 1450.

ELAM, W. E.
Cutoffs, 16.

ELDER, R. A.
"Friction Coefficients in a Large Tunnel," 1027.

EREMIN, A. A.
Frame analysis, 634.

EWALD, ROBERT F.
Saint Anthony Falls stilling basin, 550.

FADUM, RALPH E.
Soils classification, 931.

FELD, JACOB
Soil slopes, 164.
Soils classification, 946.
Subsidence, 399.
Tunneling geology, 1332.
Underground conduits, 347.

FERGUSON, PHIL M.
Frame analysis, 644.

FERRY, DOUGLASS HEWITT
Memoir of, 1590.

FIESENHEISER, E. I.
Mill bents, 1100.

FISHER, RALPH L.
Transition curve, 884.

FITTERER, JOHN CONRAD
Memoir of, 1452.

FLORIS, A.
Beam deflections, 465.
Frame analysis, 625.
Mill bents, 1112.
Simultaneous equations, 1377.

FLUHR, THOMAS W.
Tunneling geology, 1334.

FORBES, HYDE
Subsidence, 400.
Tunneling geology, 1336.

FORSTER, ALEXANDER SYLVESTER
Memoir of, 1592.

FOSTER, WILLIAM S.
Sands and gravels, 206.

FOX, CHARLES KIRBY
Irrigable lands, 570.

FOX, PORTLAND P.
Tennessee Valley, 137.
Tunneling geology, 1335.

FRAENKEL, STEPHEN J.
Frame analysis, 643.

FRENCH, JAMES BENTON
Memoir of, 1453.

FREUDENTHAL, ALFRED M.
"Reflections on Standard Specifications for Structural Design," 269.

FURBER, PIERCE POWERS
Memoir of, 1457.

GAIN, E. J. A.
Airport drainage, 817.

GARFINKEL, HARRY
Frame analysis, 667.

GAVETT, WESTON
Tunnel coefficients, 1047.

GAYLORD, EDWIN H.
Frame analysis, 660.

GIBSON, JAMES EDWIN
Memoir of, 1458.

GILLULY, JAMES
Subsidence, 397.

GLOSSOP, R.
Soils classification, 966.

GLYNN, D. F.
Soils classification, 964.

GODFREY, EDWARD
Memoir of, 1461.

GOTTSCHALK, OTTO
Influence lines, 779.

GOULD, JOHN J.
"Tests of Timber Structures from Golden Gate International Exposition," by Committee of the San Francisco (Calif.) Section, ASCE, on Timber Test Program, 1123.

GRANT, U. S.
Subsidence, 397.

GRAVES, ARTHUR R.
Mill bents, 1107.

GRAVES, EUGENE A.
Cutoffs, 24.

GRAY, WALTER J.
Mill bents, 1102.

GREGORY, ALFRED COOKMAN
Memoir of, 1462.

GRUNER, HEINRICH EDUARD
Memoir of, 1464.

HAILE, ELMER R., JR.
Transition curve, 889.

HAINE, J. A.
Soils classification, 941.

HALL, C. L.
Cutoffs, 17.

HALL, JULIUS REED
Memoir of, 1466.

HALL, LESLIE STANDISH
Memoir of, 1468.

HAMMILL, HAROLD B.
"Tests of Timber Structures from Golden Gate International Exposition," by Committee of the San Francisco (Calif.) Section, ASCE, on Timber Test Program, 1123.

HANRAHAN, FRANK J.
Timber tests, 1248.

HANSEN, HOWARD J.
Timber tests, 1240.

HARLOW, EUGENE H.
"Subsidence of the Terminal Island-Long Beach Area, California," 375.

HARRIS, BORDEN BAKER
Memoir of, 1470.

HARRIS, FREDERIC R.
"Subsidence of the Terminal Island-Long Beach Area, California," 375.

HARVEY, HERBRAND
Memoir of, 1472.

HAYBROOK, STEPHEN H.
Tunnel coefficients, 1063.

HAYES, JOHN M.
Design specifications, 289.

HAYS, JAMES B.
Sands and gravels, 206.

HEMPLE, H. W.
Triangulation net, 863.

HENRY, PHILIP WALTER
Memoir of, 1475.

HICKERSON, T. F.
Simultaneous equations, 1375.

HICKOX, G. H.
"Friction Coefficients in a Large Tunnel," 1027.

HICKS, W. I.
Airport drainage, 813.

HILF, J. W.
Soils classification, 941.

HINDS, JULIAN
Tunnel coefficients, 1059.

HIRASHIMA, K. B.
Soil slopes, 169.

HOGUE, CHESTER JAMES
Memoir of, 1480.

HORNE, MICHAEL R.
Inelastic bending, 250.

HORONJEFF, ROBERT
Pavements of airfields, 440.

HOUGH, B. K., JR.
Soils classification, 985.

HRENNIKOFF, ALEXANDER
"Theory of Inelastic Bending with Reference to Limit Design," 213.

HSU, SHIH-CHANG
"Beam Deflections by Second and Third Moments," 445.

HYDLE, MAGNUS LAWRENCE
Memoir of, 1593.

IRWIN, W. H.
Tunneling geology, 1345.

IZZARD, CARL F.
Airport drainage, 825.

JABLONSKY, ROY WRENSHAW
Memoir of, 1594.

JACKSON, MELVIN W.
Timber tests, 1243.

JANES, ROBERT L.
Frame analysis, 643.

JENS, STIFEL W.
"Drainage of Airport Surfaces—Some Basic Design Considerations," 785.

JOHNSON, ARTHUR F.
Irrigable lands, 567.

JONES, HENRY MACY
Memoir of, 1481.

KAVANAGH, THOMAS C.
Frame analysis, 623.

KAYS, MARION REED
Memoir of, 1483.
KAZMANN, RAPHAEL G.
"River Infiltration As a Source of Ground Water Supply," 404.
KEAYS, R. H.
Tunneling geology, 1329.
KEENE, PHILIP
Drain wells, 747.
KELLEY, E. F.
Underground conduits, 364.
KELLEY, JOSEPH GRANT
Memoir of, 1487.
KELLOGG, F. H.
"Investigation of Drainage Rates Affecting Stability of Earth Dams," 1261.
KEMP, JOHN EDWARD
Memoir of, 1488.
KENNISON, KARL R.
Tunnel coefficients, 1053.
KING, TAO
Frame analysis, 626.
KITTREDGE, GEORGE WATSON
Memoir of, 1403.
KJELLMAN, WALTER
Drain wells, 748.
LAMBE, T. W.
Drainage rates, 1294.
LANE, E. W.
Soils classification, 984.
LANE, KENNETH S.
Drain wells, 743.
Soils classification, 949.
LATHAM, GEORGE R.
Reservoir gates, 1015.
LAURENCE, ROBERT A.
Tennessee Valley, 124.
LAUSHEY, LOUIS M.
Saint Anthony Falls stilling basin, 539.
LEA, RICHARD SMITH
Memoir of, 1491.

LEA, WILLIAM SCHURMAN
Memoir of, 1493.
LEE, GEORGE ALLEN
Memoir of, 1495.
LEEMING, JOHN JOSEPH
"The General Principles of Highway Transition Curve Design," 868.
LEFAVOUR, ROLAND WINTHROP
Memoir of, 1598.
LEWIS, M. R.
Irrigable lands, 571.
LING, DANIEL S.
"Analysis of Stepped-Column Mill Bents," 1077.
LOBO, CARLOS
Memoir of, 1496.
LOCKWOOD, JAMES BUTTON CLYDE
Memoir of, 1497.
LONGSDORF, PAUL WRIGHT
Memoir of, 1599.
LOWTHER, BURTON
Memoir of, 1601.
LUIGGI, LUIGI
Memoir of, 1406.
MacCULLOCH, CHARLES HARVEY
Memoir of, 1499.
MACHIS, ALFRED
"Experimental Observations on Grouting Sands and Gravels," 181.
MACKINTOSH, CHARLES
Timber tests, 1244.
MAGNESS, HOWARD N.
Irrigable lands, 576.
MAINS, ROBERT M.
Column behavior, 73.
MANEY, GEORGE ALFRED
Memoir of, 1500.
MARSHALL, O. C. J.
"Least Squares Adjustment of Triangulation Net Between Geodetic Stations," 837.
MARSTON, ANSON
Cutoffs, 22.
Underground conduits, 351.

MATTHES, GERARD H.
"Mississippi River Cutoffs," 1.

MAXWELL, WAYNE DICKSON
Memoir of, 1504.

MAYO, ROBERT S.
Tunneling geology, 1325.

McCLURE, THOMAS MERO
Memoir of, 1505.

McCORMICK, FRANK J.
Beam deflections, 469.

McCORMICK, ROBERT LEE
Memoir of, 1508.

McDONALD, WILLIAM NAYLOR
Memoir of, 1509.

McGINLEY, JOHN JOSEPH
Memoir of, 1603.

McKEEN, BENJAMIN
Memoir of, 1511.

McNEW, JOHN THOMAS LAMAR
Memoir of, 1512.

MENSCH, L. J.
Frame analysis, 614.
Mill bents, 1103.

MERRITT, FREDERICK S.
Frame analysis, 616.
Simultaneous equations, 1378.

MEYER, CARL F.
Transition curve, 881.

MILLER, RUDOLPH PHILIP
Memoir of, 1517.

MIXER, CHARLES ADAM
Memoir of, 1524.

MONEYMAKER, BERLEN C.
Tennessee Valley, 120.
Tunneling geology, 1322.

MOORE, R. L.
Cylindrical shells, 713.

MOORMAN, ROBERT B. B.
Beam deflections, 466.
Frame analysis, 635.

MORRISON, I. F.
Simultaneous equations, 1379.

MULDROW, W. C.
"Forecasting Productivity of Irrigable Lands," 562.
Memoir of, 1604.

MURPHY, GLENN
Cylindrical shells, 707.

NACE, ROBERT REGNAULT
Memoir of, 1526.

NEY, C. H.
Triangulation net, 856.

NICKELL, F. A.
Tunneling geology, 1326.

NIEDERHOFF, A. E.
Reservoir gates, 1017.

NISHKIAN, LEON H.
"Tests of Timber Structures from Golden Gate International Exposition," by Committee of the San Francisco (Calif.) Section, ASCE, on Timber Test Program, 1123.

NOBLE, CHARLES M.
Transition curve, 893.

NOBLE, WILL H.
Irrigable lands, 568.

NOONAN, HUGH JOSEPH
Memoir of, 1621.

NOVICK, SIDNEY
Timber tests, 1246.

NOWELL, J. C.
Tennessee Valley, 128.

OESTERBLOM, I.
Design specifications, 288.
Frame analysis, 621.

OGILVIE, LEMUEL BYNUM
Memoir of, 1605.

PARRY, CHARLES EDWARD
Memoir of, 1527.

PARSHALL, R. L.
Irrigable lands, 575.

PARTRIDGE, JOHN F.
Tennessee Valley, 130.

PAULS, ARTHUR L.
"Cleaning and Grouting of Limestone Foundations, Tennessee Valley Authority (symposium): Fort Loudoun Dam," 82.

PEABODY, DEAN, JR.
"Thin-Shelled Domes Loaded Eccentrically," 293.

PETERKA, A. J.
"Friction Coefficients in a Large Tunnel," 1027.
Saint Anthony Falls stilling basin, 534.

PETERSON, DEAN F., JR.
"Influence Lines for Continuous Structures by Geometrical Computation," 755.

PHARR, HARRY N.
Cutoffs, 20.
Memoir of, 1529.

POPOV, E. P.
Inelastic bending, 258.

PORTER, HENRY CYRUS
Memoir of, 1533.

PRATT, WALTER M.
Timber tests, 1251.

PUGH, De WITT PAWLING
Memoir of, 1535.

PULIDO y MORALES, RENÉ S.
Soils classification, 960.

RAMIREZ, REINALDO
Memoir of, 1536.

RATHBUN, J. CHARLES
"Continuous Frame Analysis by Elastic Support Action," 577.

READY, ARTHUR GEORGE
Memoir of, 1607.

REEVES, A. B.
Tunneling geology, 1345.

RHOADES, ROGER
Tunneling geology, 1345.

RIEGEL, ROSS M.
Drainage rates, 1293.

RIGHTS, THEODORE B.
Reservoir gates, 1012.

ROBBINS, ALLAN APPLETON
Memoir of, 1537.

ROBINSON, ERNEST L.
Column behavior, 76.

ROOS, SIGMUND
Simultaneous equations, 1381.

ROUSE, HUNTER
Tunnel coefficients, 1049.

ROWE, R. ROBINSON
Column behavior, 71.

ROWLAND, WILLIAM JOSEPH
Memoir of, 1539.

RYAN, WALTER J.
Timber tests, 1250.

RYDER, FREDERICK L.
"A Rational Explanation of Column Behavior," 40.

SAWYER, JOSHUA STEWART
Memoir of, 1540.

SCHMIDT, JOHN GEORGE
Memoir of, 1609.

SEERY, FRANCIS JOSEPH
Memoir of, 1541.

SHAFER, GEORGE E.
Underground conduits, 354.

SHANNON, W. L.
Drainage rates, 1302.

SHRUBB, BERNARD WICK
Memoir of, 1622.

SIEMS, VALENTINE BERNARD
Memoir of, 1543.

SIESEL, SIDNEY MONTEFIORE
Memoir of, 1544.

SIMMONS, LANSING G.
Triangulation net, 865.

SIRRINE, JOSEPH EMORY
Memoir of, 1546.

SKEMPTON, A. W.
Soils classification, 966.

SKILLIN, EDWARD SIMEON
Memoir of, 1610.

SMITH, FREDERICK J.
Sands and gravels, 208.

SMITH, LEONARD SEWALL
Memoir of, 1548.

SNARE, FREDERICK
Memoir of, 1628.

SNOW, JESSE BAKER
Memoir of, 1550.

SOLLID, ERIK
Mill bents, 1108.

SOWERS, GEORGE F.
Soils classification, 959.

SPANGLER, M. G.
Soils classification, 978.
"Underground Conduits—An Appraisal of Modern Research," 316.

SPAULDING, RALPH E.
Influence lines, 772.
Mill bents, 1099.

SPEERT, JULIUS L.
Triangulation net, 855.

STALEY, HOWARD R.
"Thin-Shelled Domes Loaded Eccentrically," 293.

STANDER, ISAAC JOSHUA
Memoir of, 1555.

STANFORD, HOMER REED
Memoir of, 1557.

STEIN, MANUEL
Cylindrical shells, 706.

STERN, E. G.
Timber tests, 1242.

STEWART, RALPH W.
Frame analysis, 645.
Influence lines, 772.

STOCKING, JEROME BRANCH
Memoir of, 1612.

STRATTON, JAMES H.
Soils classification, 933.

STURM, R. G.
"Stability of Thin Cylindrical Shells in Torsion," 681.

SWIFT, DEAN EDWIN
Memoir of, 1623.

TAN, EK-KHOO
"Stability of Soil Slopes," 139.

TAPLEY, G. S.
Tunnel coefficients, 1064.

TAYLOR, T. F.
"Cleaning and Grouting of Limestone Foundations, Tennessee Valley Authority (symposium): Douglas Dam," 102.

TOCH, MAXIMILIAN
Memoir of, 1630.

TOMPKINS, WILLIAM FRASER, JR.
Memoir of, 1624.

TREMPER, BAILEY
Underground conduits, 365.

TSCHEBOTARIOFF, GREGORY P.
Soil slopes, 163.

TWAY, ROBERT RAYMOND
Memoir of, 1614.

VALLERGA, BERNARD A.
Inelastic bending, 261.

VAN ALSTYNE, HENRY ARTHUR
Memoir of, 1559.

VAN LOO, H. W.
Irrigable lands, 568.

VAN VLECK, ALBION NOYES
Memoir of, 1563.

VARGAS, MILTON
Soils classification, 970.

VOGEL, H. D.
Cutoffs, 18.

VOSS, WALTER C.
"Thin-Shelled Domes Loaded Eccentrically," 293.

WAHLSTROM, ERNEST E.
"Application of Geology to Tunneling Problems," 1310.

WANG, CHI-TEH
Column behavior, 74.

WARD, JAMES B.
Tennessee Valley, 126.

WARD, WILLIAM BERNARD
Memoir of, 1566.

WEGNER, WILLIAM GODFREY
Memoir of, 1567.

WEINER, BERNARD L.
"Variation of Coefficients of Simultaneous Linear Equations," 1349.

WEISS, BENJAMIN
Memoir of, 1615.

WELTY, WILLIAM R.
Transition curve, 888.

WESTERGAARD, H. M.
"New Formulas for Stresses in Concrete Pavements of Airfields," 425.

WICKLINE, GEORGE GROVER
Memoir of, 1568.

WIDMER, ARTHUR JACOB
Memoir of, 1571.

WILLIAMS, CLEMENT CLARENCE
Memoir of, 1573.

WILLIAMS, E. J., JR.
Cutoffs, 24.

WILLIAMS, H. M.
Airport drainage, 810.

WILSON, JOHN MERLIN
Memoir of, 1627.

WING, S. P.
Tunnel coefficients, 1066.

WINTER, GEORGE
Column behavior, 71.
Inelastic bending, 248.

YAO, YI-MAI
Influence lines, 776.

YOUNGQUIST, C. V.
River infiltration, 421.

ZESIGER, ALBERT WILLIAM
Memoir of, 1576.

ZIPPRODT, ROY RICHARD
Memoir of, 1579.
